where D is the bulk distribution coefficient of the solid assemblage of minerals, which is calculated from the sum of the individual mineral distribution coefficients weighted by their modal abundance in the rock:

$$D = \sum X_M D_M \quad (7)$$

where D_M is the distribution coefficient for mineral “M” and X_M is the modal abundance of that mineral in the solid rock. For a typical fertile mantle peridotite composed of 60 % olivine, 20 % clinopyroxene, 10 % orthopyroxene, and 10 % garnet, the bulk D for Sm is 0.2 and for Nd is 0.093. Estimates of fertile mantle Sm and Nd concentrations are 0.406 and 1.25 ppm, respectively (McDonough and Sun 1995). Using equation 6, a 1 % melt of the mantle will have 1.92 ppm Sm and 12.2 ppm Nd for a $^{147}\text{Sm}/^{144}\text{Nd} = 0.095$. At 20 % melting, the melt will have 1.12 ppm Sm and 4.55 ppm Nd for a $^{147}\text{Sm}/^{144}\text{Nd} = 0.149$. Partial melting of the mantle thus will produce magmas with a fairly small range in Sm/Nd ratio that is always lower than the Sm/Nd ratio of the source rock. In contrast, because so much more Nd than Sm is partitioned into the melt during melting, the residue can develop quite high Sm/Nd ratios. In the 20 % melting case described above, the $^{147}\text{Sm}/^{144}\text{Nd}$ of the residue is 0.323. The fractionation of Sm from Nd during partial melting is the basis for perhaps the most significant use of Sm–Nd dating where variations in $^{143}\text{Nd}/^{144}\text{Nd}$ of igneous rocks are used to infer the time when their mantle source regions experienced some fractionation event that caused their composition to deviate from an estimate of the fertile mantle (see ► [Sm–Nd Model Ages](#)).

The examples above illustrate one of the weaknesses of the Sm–Nd dating system, the combination of small parent–daughter fractionation and the long half-life of ^{147}Sm conspire to create very limited variation in $^{143}\text{Nd}/^{144}\text{Nd}$. With typical modern measurement uncertainties of 0.1 % on Sm/Nd ratio and 20 ppm for $^{143}\text{Nd}/^{144}\text{Nd}$ ratio, the igneous rock data modeled above produce an isochron with an age uncertainty of ± 13 Ma. For the $^{146}\text{Sm}/^{142}\text{Nd}$ system, where typical measurement precisions on $^{142}\text{Nd}/^{144}\text{Nd}$ are ± 5 ppm, the data above provide an age precise to ± 2 Ma. These age precisions are roughly an order of magnitude larger than the most precise ages currently being obtained with U–Pb in zircon (Schoene et al. 2006; Amelin 2008). Where Sm–Nd becomes important as a dating tool, however, is that not all rocks contain minerals with high enough U–Pb ratios to make them amenable for U–Pb dating. Examples include some types of meteorites, particularly those from Mars, most lunar rocks, and terrestrial Mg-rich rocks such as komatiites, basalts, layered mafic intrusions, and peridotites. In addition, garnet’s unique ability to strongly concentrate Sm over Nd, with $^{147}\text{Sm}/^{144}\text{Nd}$ ratios up to over 4 (Pollington and Baxter 2011), has turned garnet into a particularly useful mineral for Sm–Nd geochronology (see entry on ► [Sm–Nd, Metamorphic Rocks](#)).

The high isotope ratio precisions needed to provide useful chronological precisions were the primary factor that delayed the development of the Sm–Nd system as a geochronological tool. The first inroads into the use of Sm–Nd dating were two papers from the group at the University of Tokyo who reported ^{147}Sm – ^{143}Nd data for an eclogite inclusion in the Roberts Victor kimberlite of

South Africa (Notsu et al. 1973b) and both ^{147}Sm – ^{143}Nd and ^{146}Sm – ^{142}Nd data for the Juvinas eucritic meteorite (Notsu et al. 1973a). In both cases, the Nd isotopic composition for all phases measured was unresolved within the uncertainties of ~0.1–0.2 % (Fig. 2), but the work showed the potential of Sm–Nd dating if isotope ratio precisions could be improved. In 1975, Lugmair et al. (1975b) used ^{147}Sm – ^{143}Nd with Nd isotope ratio precisions of 80 ppm to determine an age of 3.70 ± 0.07 Ga for lunar mare basalt 75075. Perhaps more important, this work also started the use of the Nd model age approach to understand the time of chemical differentiation in the source region of a volcanic rock. Lugmair et al. (1975a) then attempted to find evidence of ^{146}Sm decay in the Juvinas meteorite (Fig. 2), but even with precision on $^{142}\text{Nd}/^{144}\text{Nd}$ improved to 60 ppm, they could not resolve variability in $^{142}\text{Nd}/^{144}\text{Nd}$ in the mineral separates. Convincing evidence for live ^{146}Sm in the early solar nebula had to wait until Lugmair and Marti (1977) improved the $^{142}\text{Nd}/^{144}\text{Nd}$ precision to 20 ppm and resolved variability in $^{142}\text{Nd}/^{144}\text{Nd}$ in mineral separates from the Angra dos Reis meteorite. With these precision improvements, the use, and diversity of uses, of the Sm–Nd dating system grew rapidly (DePaolo and Wasserburg 1976b; Lugmair et al. 1976; O’Nions et al. 1979; Allègre and Othman 1980; DePaolo 1980; Allègre et al. 1983; DePaolo 1988).

Sm–Nd Dating

While U–Pb dating of zircon (see ► [Zircon](#)) has reached a level of sophistication and precision in age determination for rocks that contain zircon that cannot be bettered by other dating systems, the Sm–Nd system has proven particularly useful for age dating of zircon-free rocks, which includes the majority of extraterrestrial rocks (see ► [Sm–Nd, Meteorites](#)) and Mg-rich rocks including basalts, komatiites, and peridotites. Sm–Nd dating has also been applied to date altered/metamorphosed rocks due to its greater stability through these processes compared to, for example, Rb–Sr and K–Ar dating (see ► [Sm–Nd Metamorphic Rocks](#)).

The Sm–Nd system has been heavily used in lunar geochronology because most lunar rocks do not contain zircon, and the Moon is highly depleted in volatile elements with the result that many lunar rocks have too low a concentration of volatile Rb to be amenable to precise Rb–Sr dating and such low concentrations of volatile Pb as to be extremely sensitive to contamination, thereby making U–Pb chronological measurements an analytical challenge. The first high-precision Sm–Nd age was determined on a lunar basalt (Lugmair et al. 1975b). An excellent summary of the application of Sm–Nd to understanding the history of lunar volcanism is given by Nyquist and Shih (1992). Sm–Nd chronology has been particularly important in defining the age range of the lunar highlands crust as most of the highlands crust consists of rocks highly dominated by plagioclase with variable amounts of pyroxene and/or olivine as their main mineral constituents. An example of a recent application of ^{146}Sm , ^{147}Sm – ^{142}Nd , and ^{143}Nd dating of what is perhaps the oldest lunar rock is found in Borg et al. (2011). For much the same reasons, Sm–Nd has been an essential dating tool for the Martian samples delivered to Earth as meteorites of the SNC – shergottite, nakhlite, and chassignite clan (Nyquist et al. 2001).

Another area where Sm–Nd dating has made a major contribution is in determining the timing of high-grade metamorphic events. This is enabled largely because of the extreme fractionation of Sm and Nd typical of garnet. For this reason, eclogites, the high-pressure form of basalt that is composed of pyroxene and garnet, are a common target for Sm–Nd dating (Mork et al. 1988; Chavagnac and Jahn 1996). As with all minerals, Sm and Nd diffuse through garnet at high temperature, but the diffusion is slow enough that garnet begins to faithfully maintain its record of Sm decay at temperatures below about 600 °C (Mezger et al. 1992), allowing garnet to serve as

Fig. 3 Sm–Nd isochron diagram illustrating the potential and pitfall of whole rock isochrons. In this model, a magma is created by melting the mantle at 2.7 Ga. A portion of this magma undergoes crystal fractionation to create a series of compositionally distinct rocks with different Sm–Nd ratios, but, initially, the same $^{143}\text{Nd}/^{144}\text{Nd}$ ratio (blue dots along horizontal line). After 2.7 billion years of evolution, these compositionally distinct rocks are measured today and give the blue points near the top of the figure that define a line whose slope gives an age of 2.7 Ga. The other example takes a portion of the 2.7 Ga magma and lets it mix, at 2.7 Ga, with a 3.8 Ga granite that has lower Sm/Nd and $^{143}\text{Nd}/^{144}\text{Nd}$ ratios than the mantle-derived magma. This creates a group of mixed rocks shown by the green squares in the sloped line at the bottom of the graph. After 2.7 Ga of evolution, the rocks formed from the mixed magma create a steep-sloped line whose slope corresponds to 3.8 Ga, not 2.7 Ga

a useful thermochronometer for high-pressure metamorphism (Ducea et al. 2003; Pollington and Baxter 2010; see ► [Thermochronology, Tectonic Processes](#)).

Perhaps the most common application of Sm–Nd dating has been on ultramafic rocks on Earth as these generally have too low K, Rb, and U concentrations for dating by other methods. Good examples of this approach include layered mafic cumulate bodies such as the Stillwater (DePaolo and Wasserburg 1979), Muskox (Stewart and DePaolo 1992) and Great Dyke (Mukasa et al. 1998), ophiolites (Jacobsen and Wasserburg 1979; McCulloch et al. 1981; Shaw et al. 1987; Li et al. 1997), and particularly komatiites (Hamilton et al. 1977; Jahn et al. 1982; Machado et al. 1986; Puchtel et al. 2009).

The use of Sm–Nd dating to determine the age of komatiites opens the discussion of the benefits/risks of isochrons constructed from compositionally distinct whole rocks as opposed to isochrons created by separating the constituent minerals from a single rock. In most cases, komatiite Sm–Nd ages involve whole rock isochrons. There are two reasons for turning to whole rock isochrons. First, many old mafic/ultramafic rocks have been subjected to sufficient alteration/metamorphism that little of their original igneous mineralogy remains. In the case of komatiites, the original pyroxenes and olivines often have been transformed into amphiboles and serpentines by the addition of water during metamorphic reactions upon their burial in the deep crust. In these cases, the Sm–Nd ratios of the metamorphic minerals will not be the same as the original igneous minerals and hence will not define an isochron that gives the igneous age of the rock. Second, heating of minerals causes their constituent elements to move, diffuse, through the crystal lattice. Burial of rocks in the deep crust can raise their temperature by hundreds of degrees. At these temperatures, fast-diffusing elements can move millimeter distances over billions of years. The diffusional movement will serve to mix the Nd in nearby minerals, erasing, or lessening, the Nd isotopic difference caused by the decay of ^{147}Sm in the minerals due to their different Sm/Nd ratios.

Fig. 4 Model time evolution in $^{143}\text{Nd}/^{144}\text{Nd}$ (left) and transformed to $\epsilon^{143}\text{Nd}$ (right). The thick black line in each plot shows the ingrowth of ^{143}Nd in a material that has chondritic Sm/Nd ratio (CHUR). In this example, a melting event takes place at 3 Ga that creates a melt with low Sm/Nd ratio (CC) and a residue (DM) with high Sm/Nd ratio. The different Sm/Nd ratios of the two rocks formed in this event cause their $^{143}\text{Nd}/^{144}\text{Nd}$ to diverge from the CHUR line. Measuring the $^{143}\text{Nd}/^{144}\text{Nd}$ and Sm/Nd ratio of the samples of CC and DM today allows reconstruction of their Nd isotope evolution lines back in time. The slope of the isotope evolution line is proportional to Sm/Nd ratio. The intersection of these lines with the CHUR evolution line defines the chondritic model age (T_{CHUR}). In this model, a second melting event occurs to CC at 1 Ga to create a new rock with lower Sm/Nd ratio (CM). Measuring the Sm/Nd ratio and $^{143}\text{Nd}/^{144}\text{Nd}$ of this sample today allows the calculation of the green line. The extrapolation of this line to the CHUR and DM evolution lines provides two different model ages. In this case, both are substantially older than the 1 Ga melting event and show that CM was derived by reworking/remelting of CC, not as a new melt from the material evolving with either CHUR or DM Sm/Nd ratio

By moving to the many centimeter-size hand-sample scale of whole rocks, the consequences of this diffusional resetting of the Sm–Nd clock will be minimized.

Equation 3, however, requires that all the samples used to define an isochron must have started with the same initial $^{143}\text{Nd}/^{144}\text{Nd}$ ratio in order for that line to provide an accurate age. While the expectation that all minerals crystallizing from a magma will inherit the same $^{143}\text{Nd}/^{144}\text{Nd}$ from the magma usually, but not always (Prevec et al. 2005), is met, the limited Sm–Nd fractionation during partial melting and fractional crystallization often requires including a wide range of rock compositions on a Sm–Nd whole rock isochron in order to obtain enough spread in Sm/Nd ratio to define a precise isochron. If all the rocks used to construct the isochron indeed started with the same initial $^{143}\text{Nd}/^{144}\text{Nd}$, and formed at the same time, then the whole rock isochron will give the correct age (Fig. 3).

Magmas moving from source to eruption, however, often interact with the surrounding rock. If the surrounding rock is isotopically distinct from the magma, then mixing between the two can create hybrid magmas that have isotopic compositions between the two end-members as shown in Fig. 3. Allowing these mixtures to evolve through ^{147}Sm decay with their different Sm–Nd and initial $^{143}\text{Nd}/^{144}\text{Nd}$ ratios to the present day will produce a linear array of data that gives a meaningless age somewhere between the age of magmatism and that of the wall rock contaminant. This problem was first highlighted when whole rock Sm–Nd dating of komatiites from Kambalda, Australia, gave an age 500 Ma older than their stratigraphic age constrained by U–Pb geochronology of over- and underlying rock strata (Chauvel et al. 1985). Although presenting a major obstacle for Sm–Nd whole rock dating, using Sm–Nd systematics to detect and understand

the process of crustal contamination has been an important application of the Sm–Nd system in rocks where the age can be constrained by other means (Carlson et al. 1981; DePaolo 1981; Stewart and DePaolo 1992; Lambert et al. 1994).

Sm–Nd Tracing of Geologic Processes

Because the processes that most strongly fractionate Sm from Nd are partial melting and crystal fractionation, the Sm–Nd system is particularly useful for determining the time at which a rock, or its source materials, had its Sm/Nd ratio changed from that of some model for mantle Nd isotope evolution. Figure 4 shows an example of how Nd isotope measurements can be used to understand the source history of igneous rocks. In this model, the $^{143}\text{Nd}/^{144}\text{Nd}$ of the mantle is evolving with a Sm/Nd ratio equal to chondritic, often called the “chondritic uniform reservoir,” or CHUR. If a portion of CHUR melts to produce a melt and residue, the different Sm/Nd ratios of these complementary components cause their Nd isotope evolution to diverge from the CHUR Nd isotope evolution line. If nothing else happens to either melt or residue, the age of this differentiation event can be calculated from the measured $^{143}\text{Nd}/^{144}\text{Nd}$ and Sm/Nd ratios of either melt or residue using the equation

$$T_{\text{CHUR}} = 1/\lambda \times \ln \left(\left(^{143}\text{Nd}/^{144}\text{Nd} \right)_{\text{M}} - \left(^{143}\text{Nd}/^{144}\text{Nd} \right)_{\text{CHUR}} \right) / \left(\left(^{147}\text{Sm}/^{144}\text{Nd} \right)_{\text{M}} - \left(^{147}\text{Sm}/^{144}\text{Nd} \right)_{\text{CHUR}} \right)$$

where “M” stands for the measured values. While the model age approach is straightforward mathematically, interpretation of the age obtained depends on the number of differentiation steps involved in producing any given rock sample and particularly on the Nd isotope evolution path chosen for the model primitive reservoir. Early applications of Sm–Nd model ages usually referred to a primitive mantle evolution characterized by a chondritic Sm/Nd ratio. As Nd data became more abundant, mantle-derived rocks through time defined a mantle evolution characterized by higher than chondritic $^{143}\text{Nd}/^{144}\text{Nd}$ (Shirey and Hanson 1986). Interpretations of this result ranged from assuming that the Sm/Nd ratio of the mantle had been raised due to extraction of the low Sm/Nd ratio continental crust (DePaolo et al. 1991) to the possibility that the mantle never had a chondritic Sm/Nd ratio (Boyet and Carlson 2005). Whichever explanation is correct, Nd model ages now are mostly calculated relative to a “depleted mantle” instead of CHUR evolution. There is some variability in the values used for the Sm/Nd evolution parameters in calculating depleted mantle model ages, but a good compromise, and a well reasoned argument for the choice of values, is that presented by DePaolo et al. (1991). These authors suggest replacing $(^{143}\text{Nd}/^{144}\text{Nd})_{\text{CHUR}}$ with $(^{143}\text{Nd}/^{144}\text{Nd})_{\text{DM}} = 0.51307$ and $(^{147}\text{Sm}/^{144}\text{Nd})_{\text{CHUR}}$ with $(^{147}\text{Sm}/^{144}\text{Nd})_{\text{DM}} = 0.2105$ for calculating Nd model ages using equation 8 where “DM” is depleted mantle. While uncertainties of this nature in the Nd evolution of the “model” in Sm–Nd model age dating have a significant effect on the ages calculated, they do not detract from the usefulness of such “mantle separation ages” in helping to distinguish whether a given rock was newly added to the continental crust via melting of the mantle or instead reflects reworking/remelting of older crust (see entry on ► [Sm–Nd Model Ages](#)). This type of information has been particularly useful in constructing maps showing crustal age terranes that define the borders of new crustal additions.

Conclusion

Forty years of application of the Sm–Nd dating system has established it as a crucial component in the geochronology/geochemistry toolbox. While hard-pressed to provide dating precision comparable to techniques such as U–Pb in zircon, the Sm–Nd systems can be applied widely across a variety of rock types. This characteristic has led it to be used extensively in dating mafic and ultramafic rocks, be they from Earth or elsewhere. In addition, Sm–Nd has become a useful chronometer for high-pressure and high-temperature metamorphic events. Among its many uses, perhaps the most common is its ability to illuminate the history of crust–mantle differentiation through model age approaches that follow rocks from an early origin in a hypothetical undifferentiated bulk planet to the differentiated crusts and mantles that we find on Earth, Moon, Mars, and asteroids today.

Rhenium–Osmium Dating (Meteorites)

Richard J. Walker*

Isotope Geochemistry Laboratory, Department of Geology, University of Maryland, College Park, MA, USA

Synonyms

¹⁸⁷Re–¹⁸⁷Os isotopic dating; Osmium isotopic dating

Definition

The Re–Os isotopic system is used for determining formation ages and constraining ages of secondary alteration of meteorites and meteorite components, especially in relation to metals and sulfides.

Introduction

The rhenium-osmium isotopic dating system as applied to geo- and cosmochemical materials is based on the negatron (β^-) transition of ¹⁸⁷Re to ¹⁸⁷Os. The decay constant (λ) for ¹⁸⁷Re is $1.67 \times 10^{-11} \text{ year}^{-1}$, which is equivalent to a half-life ($t_{1/2}$) of approximately 42 billion years. This value has been determined through the comparisons of precisely defined isochrons for cosmochemical and terrestrial materials to absolute ages for the same materials determined using the U–Pb system (Smoliar et al. 1996; Selby et al. 2007). The Re–Os isotopic system has been of interest to the cosmochemical community for more than 50 years because of the unique geochemical characteristics of both elements, as compared to elements comprising other long-lived chronometers. Both elements partition nearly quantitatively into metal relative to silicates; hence, they are termed highly siderophile elements (HSE). In addition, both elements also tend to strongly partition into sulfides and sulfide melts relative to silicates; hence, they are also chalcophile elements. Consequently, the system has been long pursued as a means of determining the ages of early solar system metals, such as iron meteorites, and the metal and sulfide components of some primitive meteorites. Because of the relatively high abundances of Re and Os in primitive and iron meteorites, and their relatively low abundances in the silicate mantles and crusts of differentiated planetary bodies, the system can also potentially serve as a tracer of the chemical natures and quantities of late accreted materials to planetary bodies (Chou 1978; Morgan 1986; Morgan et al. 2001).

Historical Development of System to Dating Meteorites

Early studies of the Re–Os system, as applied to both geo- and cosmochemical problems, were hindered by extreme analytical limitations. These limitations mainly stemmed from the very high first ionization potentials of Re and Os, resulting in extremely low thermal ionization yields, when using the standard thermal ionization mass spectrometric methods available in the 1950s–1980s. Despite the analytical limitations, the first detailed application of the Re–Os isotopic system to dating meteorites was published by Hirt et al. (1963). In that study the authors examined variations in $^{187}\text{Os}/^{186}\text{Os}$ and $^{187}\text{Re}/^{186}\text{Os}$ for a variety of iron meteorites. The low-precision data were found to form a linear trend that was interpreted to be an isochron. The generation of isochrons in this and subsequent studies of iron meteorites were advantaged by the large range of Re–Os ratios typically present within iron meteorite groups. Most such variations are consistent with solid metal–liquid metal fractionation on the parent bodies of the meteorites (e.g., McCoy et al. 2011). Hirt et al. (1963) applied a ^{187}Re half-life of 43 billion years to their iron meteorite isochron and suggested a general crystallization age for irons of approximately 4.0 billion years. Subsequent studies of the Re–Os isotopic systematics of iron meteorites and metal components from chondritic meteorites were published by Luck et al. (1980) and Luck and Allègre (1983). These studies, which utilized secondary ion mass spectrometry of the chemically purified elements, reported much higher precision isotopic and elemental compositions, compared to the prior studies. They also reported good linear trends for meteorites on plots of $^{187}\text{Re}/^{186}\text{Os}$ versus $^{187}\text{Os}/^{186}\text{Os}$, interpreted the correlations to be isochrons, and redefined the decay constant for ^{187}Re so that the isochrons would give ages close to the 4.57 Ga canonical age of the solar system. Regression uncertainties for isochrons slopes in these studies, however, were no better than $\pm 2\%$, equivalent to uncertainties of ± 90 million years for early solar system objects.

Analyses of bulk chondrites, as well as metal separates from chondrites, were found to be characterized by limited variations in Re–Os and $^{187}\text{Os}/^{186}\text{Os}$, compared to iron meteorites (Luck and Allègre 1983; Walker and Morgan 1989), so the generation of precise isochrons for these types of materials was not possible. Further, analyses of some bulk chondrites, determined by resonance ionization mass spectrometry, did not plot within analytical uncertainties of the iron meteorite reference isochron, indicating either incorporation of isotopically diverse Os into primitive meteorites at the time of formation or relatively late-stage open-system behavior (Walker and Morgan 1989).

Iron Meteorites

The development of negative thermal ionization mass spectrometry (NTIMS) techniques in the early 1990s, as applied to the Re–Os system, permitted the measurement of these elements to much higher precision than was previously possible (Creaser et al. 1991; Völkening et al. 1991). Also, at about this time, the common reference isotope for Os was changed from ^{186}Os to ^{188}Os , because of the recognition that ^{186}Os is the decay product of ^{190}Pt and that its atomic abundance, relative to the non-radiogenic isotopes of Os, varies in nature. Coupled with improved chemical processing methods (Shirey and Walker 1995), the NTIMS technique permitted the generation of high-precision isochrons for iron meteorite groups representing five different parent bodies (e.g., Horan et al. 1992; Shen et al. 1996; Smoliar et al. 1996; Cook et al. 2004; Walker et al. 2008; McCoy et al. 2011). For example, Smoliar et al. (1996) reported an isochron age for group IIAB irons of $4,537 \pm 8$ Ma, with a precision of better than $\pm 0.2\%$. Isochron ages with nearly

Fig. 1 Isochron diagram for group IVA iron meteorites. Meteorites from this group display a relatively large range in $^{187}\text{Re}/^{188}\text{Os}$ and corresponding $^{187}\text{Os}/^{188}\text{Os}$. The crystallization age derived from this isochron is $4,540 \pm 17$ Ma (Figure is from McCoy et al. (2011))

comparable precision have been reported for other major iron meteorite groups (IAB, IIIAB, IVA, and IVB), constraining the ages of crystallization to the first 50 Ma of solar system history (Fig. 1). Unfortunately, crystallization ages with uncertainties of 10–20 million years are of limited utility with regard to understanding the chronological sequence of planetesimal formation, melting, differentiation, and crystallization, given that many such bodies evidently underwent some or all of these processes within the first 10 million years of solar system history (e.g., Lugmair and Galer 1992; Misawa et al. 2005; Day et al. 2012b). Application of the short-lived ^{182}Hf – ^{182}W isotopic system ($t_{1/2}$ of ^{182}Hf is 8.9 million years) has revealed that, in most cases, metallic cores *segregated* from silicates within just the first ~3 million years of solar system history (e.g., Horan et al. 1998; Kruijer et al. 2012). It should be noted, however, that ^{182}W model ages of iron meteorites define the timing of metal-silicate segregation, not crystallization. Hence, the Re–Os system retains utility for understanding the cooling rates of cores of larger, more slowly cooled bodies. Further, the system has been used to examine whether or not the HSE within a given iron meteorite have remained closed to elemental migration, due to impact resetting or other processes, since the time of formation (e.g., McCoy et al. 2011).

Primitive Meteorites

The application of the Re–Os system to dating bulk chondritic meteorites and their components has met with mixed success. Even with improved analytical methods, most bulk samples of chondrites from the major groups do not define sufficient spread in Re–Os to permit the generation of precisely defined group isochrons, even assuming that the requirements for isochron dating of different primitive meteorites could be met (same formation ages; derived from isotopically uniform sources). Hence, the system has virtually no utility for dating the formation of primitive meteorites. Further, a major proportion of bulk chondrites analyzed using NTIMS do not plot within analytical uncertainties of a primordial reference isochron (Chen et al. 1998; Walker et al. 2002; Fischer-Gödde et al. 2010; van Acken et al. 2011) (Fig. 2a). Such deviations have largely been interpreted to reflect open-system behavior tens of millions of years to billions of years after the parent bodies formed. Open-system behavior on primitive parent bodies may reflect late-stage impact heating and/or aqueous alteration.

Fig. 2 (a) Isochron diagram for primitive (chondritic) meteorites. Bulk samples of chondrites from the carbonaceous, enstatite, and ordinary chondrite groups are characterized by limited variations in $^{187}\text{Re}/^{188}\text{Os}$ and $^{187}\text{Os}/^{188}\text{Os}$, compared to most within-group variations for iron meteorites (e.g., Fig. 1 above). Analytical uncertainties are typically smaller than the symbols. The considerable variance of data around the 4.57 Ga reference isochrons reflects relatively late-stage open-system behavior of Re and/or Os. (b) Histogram showing the distributions of $^{187}\text{Os}/^{188}\text{Os}$ in the three major groups of chondrites (Data are from Walker et al. (2002), Fischer-Gödde et al. (2010), and van Acken et al. (2011))

As the nature and intensity of open-system behavior appears to be mostly specific to individual meteorites, not chondritic groups or subgroups (Walker et al. 2002), the study of components from a meteorite is a potentially important means for investigating the processes involved in creating the open-system behavior specific to the sampled portion of the parent body. Common components present in primitive meteorites include chondrules, calcium-aluminum-rich inclusions (CAIs), and matrix. As with bulk chondrites, several studies have documented open-system behavior among chondritic components from the same meteorites. For example, Becker et al. (2001) analyzed CAIs from the carbonaceous chondrite Allende and found moderate-scale open-system behavior. Analyses of multiple pieces of a single CAI were characterized by sufficient spread in $^{187}\text{Re}/^{188}\text{Os}$ and $^{187}\text{Os}/^{188}\text{Os}$ to define an errorchron that defined a reset age of $\sim 1,600$ Ma. Presumably a metamorphic event led to the isotopic homogenization of Os within the CAI at that time. Horan et al. (2009) reported large variations in $^{187}\text{Re}/^{188}\text{Os}$, and consequently $^{187}\text{Os}/^{188}\text{Os}$, between magnetic and nonmagnetic portions of chondrules and matrix separated from the relatively low metamorphic grade ordinary chondrites Dhajala and Ochansk. In contrast to the Allende CAIs, they reported relatively minor open-system behavior for these components. Collectively, these studies show that the Re–Os system will continue to play an important role in constraining the timing of late-stage events affecting primitive meteorites.

Perhaps the greatest utility of the Re–Os isotopic system, as applied to primitive meteorites, is for genetic tracing. On average, carbonaceous chondrites have less radiogenic $^{187}\text{Os}/^{188}\text{Os}$ than ordinary or enstatite chondrites (Fig. 2b). This reflects the lower long-term $^{187}\text{Re}/^{188}\text{Os}$ of carbonaceous chondrites, which, in turn, may reflect a nebular fractionation compared with the formational environments of enstatite and ordinary chondrites. The lower $^{187}\text{Os}/^{188}\text{Os}$ of carbonaceous chondrites has been useful, for example, in assessing their role (or lack thereof) in the generation of terrestrial and lunar impact melt rocks (e.g., Puchtel et al. 2008; Fischer-Gödde and Becker 2012).

Achondrite Meteorites

Rhenium–Os isotopic data have been published for a number of types of achondritic meteorites including the shergottite-nahklite-chassignite (SNC) suite, presumed to be derived from Mars

(Birck and Allègre 1994; Brandon et al. 2012); the howardite-eucrite-diogenite (HED) suite, presumed to be derived from the asteroid Vesta (Dale et al. 2012; Day et al. 2012b); as well as angrites and ureilites (Rankenburg et al. 2007; Riches et al. 2012). The system has also been examined in various primitive achondrites, such as brachinites (Day et al. 2012a), as well as lunar meteorites (Puchtel et al. 2008). Given the inherent problems relating different meteorites to one another through a common process and formation time, the system has proved useful from a geochronologic standpoint only for dating individual meteorites from which bulk pieces or separated minerals define substantial variation in Re–Os. Consequently, the Re–Os isotopic system has been only sparingly applied to dating achondrites. For example, Brandon et al. (2012) reported a Re–Os isochron age of 164 ± 12 Ma for the Antarctic shergottite EETA 79001. This age is in good agreement with Sm–Nd and Rb–Sr isochrons ages for the same meteorite and provides important supporting evidence that relatively young ages for some shergottites are true igneous crystallization ages, rather than reset ages associated with impact events.

Most Re–Os data as well as accompanying concentration data for other HSE in achondrites have been used to consider the origins of HSE to the silicate portions of the parent bodies to these meteorites. For example, Day et al. (2012b) concluded that diogenites were variably enriched in the HSE via a process termed late accretion, whereby additional meteoritic material accreted to the parent body after cessation of core segregation, leading to a re-enrichment of HSE in the silicate portion of the body (Walker 2009). Evidence for variable extents of late accretion is present in the terrestrial mantle (Meisel et al. 2001; Becker et al. 2006), the lunar mantle (Day et al. 2007), and the Martian mantle (Brandon et al. 2012).

Summary and Conclusions

Since the 1960s the Re–Os isotopic system has been used for dating various cosmochemical materials. The system has primarily been applied to constraining crystallization ages of large metal masses, such as asteroidal cores, via the analysis of chemically related iron meteorites. However, due to the limited precision of isochron ages for irons, the system has proved more important for demonstrating long-term closed-system behavior for the HSE in those metals studied. The system has little utility for precisely dating the absolute formation ages of bulk chondrites and their components, but is quite valuable for constraining periods of open-system behavior in chondritic components, such as CAIs and chondrules.

Crustal Sulfide Minerals (Re-Os)

Robert A. Creaser*

Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada

Definition

The rhenium-osmium (^{187}Re - ^{187}Os) radioactive isotope system can be used to determine absolute age dates for some sulfide minerals formed in a variety of crustal geologic environments, including those associated with igneous, sedimentary, and metamorphic processes. Sulfide minerals that have yielded reliable Re-Os age dates include molybdenite (MoS_2), pyrite (FeS_2), and arsenopyrite (FeAsS), although many other sulfide minerals have potential for yielding Re-Os age dates. This entry deals with Re-Os geochronology of crustal sulfide minerals typically formed from aqueous fluids, either hydrothermal or diagenetic, and does not consider orthomagmatic sulfide minerals.

Introduction

Following the discovery of the natural radioactivity of ^{187}Re by negatron decay (Naldrett and Libby 1948), some of the earliest applications of ^{187}Re - ^{187}Os geochronology involved the crustal sulfide mineral molybdenite (MoS_2 – Hirt et al. 1963; Luck and Allègre 1982). During these early years, the analytical methods available were such that only molybdenite, a mineral that contains parts-per-million (ppm) level Re abundances, was realistically the sole crustal sulfide mineral amenable for Re-Os isotopic analysis. Following major analytical breakthroughs in mass spectrometry (Creaser et al. 1991; Volkening et al. 1991), sample digestion, and spike-sample equilibration methods (Shirey and Walker 1995; Cohen and Waters 1996; Birck et al. 1997), other crustal sulfide minerals such as pyrite, typically containing parts-per-billion (ppb) level of Re and parts-per-trillion (ppt) level of Os, became amenable for isotopic analysis, with potential application as geochronometers. Given the widespread geological occurrence of crustal sulfide minerals such as pyrite, development and application of the Re-Os method for these minerals is an important recent development in isotopic dating, particularly for research areas such as ore deposit geology, in which the mineralogy can be dominated by sulfide minerals and for which obtaining accurate and precise ages dates for mineral formation can be problematic (Richards and Noble 1998).

Methodology: Analytical Protocol

The majority of modern analyses for Re-Os in crustal sulfide minerals involve mineral separation and purification, spiking with isotopically enriched tracer solution(s) and chemical digestion in inverse *aqua regia* using Carius tube methodology (Shirey and Walker 1995). Chemical purification of Re and Os typically uses organic solvent extraction, ion-exchange, and microdistillation

*Email: robert.creaser@ualberta.ca

methods (Cohen and Waters 1996; Birck et al. 1997) and is followed by isotope dilution negative thermal ionization mass spectrometry for isotopic analysis of both Os and Re (NTIMS – Creaser et al. 1991; Volkening et al. 1991). Sample preparation – crushing and milling of rock to purify sulfide minerals – uses nonferrous materials such as ceramic and agate, to avoid contamination by Re and Os present in steel. The choice of isotopically enriched tracer depends on the nature of Os present in the sulfide mineral. For example, molybdenite rarely contains measurable “common Os” – Os incorporated at the time of formation – and consists entirely of radiogenic ^{187}Os . In this case, a “double spike” of $^{188}\text{Os} + ^{190}\text{Os}$ is preferred, combined with ^{185}Re (e.g., Markey et al. 2003) to permit accurate mass bias correction during isotopic analysis and to monitor possible common Os in the sample. In some cases, crustal sulfide minerals such as arsenopyrite also contain little or no common Os (Morelli et al. 2005), and the “mixed double-spike” method is also used. In these cases, uncertainties in the quantification of ^{188}Os can be large, as it is dominated by blank ^{188}Os , so uncertainties in $^{187}\text{Re}/^{188}\text{Os}$ and $^{187}\text{Os}/^{188}\text{Os}$ are highly correlated on a traditional isochron plot. In this case, the correlation coefficient ρ must be used for isochron regression analysis (Morelli et al. 2005) or a modified plot used that eliminates ^{188}Os (Stein et al. 2000). Many crustal sulfide minerals like pyrite typically do contain trace amounts of common Os, and a mixed $^{185}\text{Re} + ^{190}\text{Os}$ spike is typically used for quantification of Os and Re abundances in these cases. Re and Os abundances can be very low in many cases (Ootes et al. 2011), and laboratory blank levels for Re and Os must be extremely low (<1 pg) and monitored for blank $^{187}\text{Os}/^{188}\text{Os}$ value. Age quantification for samples with no common Os uses the simplified equation:

$$t = \ln \left(^{187}\text{Os}/^{187}\text{Re} + 1 \right) / \lambda$$

from which a single age is calculated based on the measured ^{187}Re and ^{187}Os abundances, whereas for samples with common Os, the isochron approach using multiple co-genetic samples is applied. The value of the ^{187}Re decay constant (λ) of $1.666\text{e}^{-11} \cdot \text{a}^{-1}$ (Smoliar et al. 1996) is used. Although a relatively new method, Re-Os geochronology of crustal sulfide minerals has progressed to the point of establishing reference age materials for inter-laboratory comparison (Markey et al. 2007).

Re-Os Geochronology of Molybdenite

Molybdenite (MoS_2) is ideal for geochronology using the ^{187}Re - ^{187}Os isotope system, as it is enriched in Re and is usually devoid of common Os, so nearly all ^{187}Os is radiogenic, derived from the decay of ^{187}Re . Although some early studies concluded Re-Os age dating of molybdenite to be inaccurate or easily disturbed (Luck and Allègre 1982; McCandless et al. 1993; Suzuki et al. 2001), Stein et al. (2001) found that this likely relates to internal spatial decoupling of radiogenic ^{187}Os from Re within molybdenite grains and that accurate age dates could be obtained if sufficiently large sample sizes were analyzed. Investigation of Re-Os in molybdenite at the micron scale using laser ablation ICP-MS methods confirmed these findings, by producing highly inaccurate ages of very small sampled volumes (Stein et al. 2003; Kosler et al. 2003; Selby and Creaser 2004). Since this limitation was discovered and suitable analysis methods adopted, the Re-Os geochronometer in molybdenite has proven to be highly robust, showing excellent cross-calibration to U-Pb zircon ages for igneous-associated molybdenite deposits back to Archean time (Selby et al. 2007). Bingen and Stein (2003) found that the Re-Os system in molybdenite has a thermal resetting temperature (closure or blocking temperature) well above 800 °C. Molybdenite Re-Os geochronology has developed into an invaluable dating method in metallic ore deposit research, as it is a common

accessory mineral in porphyry Cu-(Mo-Au) deposits, pegmatite and rare metal deposits, iron oxide-Cu-Au-U (IOCG-type) deposits, and intrusion-related Au deposits. It provides direct age control for the formation of sulfide minerals in a variety of ore-forming systems to evaluate the general tectonomagmatic affinity of ores (Chiaradia et al. 2009; Mao et al. 2003), to test the igneous affiliation of ores (Reid et al. 2013; Selby et al. 2002), and to investigate the temporal connections between mineralization and volcanism (Rosera et al. 2013). The precision of Re-Os molybdenite ages is typically $\sim 0.4\%$ (2σ , e.g., Stein et al. 2001), equating to age uncertainties of ± 5 to 10 Ma in Archean time for individual molybdenite age dates and thus not comparable to the precision attained by U-Pb dating of minerals like zircon (e.g., Piercey et al. 2008). However, in geologically young ore systems, Re-Os age dates of molybdenite can have age precision of < 50 Ka, providing temporal control within the history large mineralized intrusive complexes (e.g., Deckart et al. 2013). Although rare, multiple age components have been described within molybdenite crystals (Aleinikoff et al. 2012). Molybdenite paragenesis is mostly related to hydrothermal ore deposition, but it has also been found to form under high-grade metamorphic conditions associated with partial melting reactions and leucosome formation (Stein 2006).

Re-Os Geochronology of Pyrite and Arsenopyrite

Following the major advancements in the analysis of Re-Os isotopes made in the 1990s, analysis of crustal sulfide minerals other than molybdenite became feasible, with several early papers investigating Re-Os geochronology of pyrite (Stein et al. 1998; Mathur et al. 1999; Stein et al. 2000; Arne et al. 2001). These studies found Re levels in pyrite ranging up to a few tens of ppb, in some cases with little common Os present (Stein et al. 2000) enabling direct Re-Os age dating of a very common ore sulfide mineral in massive sulfide and gold vein deposits. Since then, the Re-Os geochronometer in pyrite has been used widely in ore deposit research to date the timing of vein versus massive ore formation in sedimentary exhalative-type deposits (SedEx; Morelli et al. 2004), to connect orogenic gold deposits with deep crustal metamorphism (Ootes et al. 2011), and to link polymetallic deposits to magmatism (Zhu et al. 2013). In terms of thermal resetting, Brennan et al. (2000) found that Os diffusion in pyrite is very slow, leading to estimates of 500°C for 10 Ma to affect the cores of 500 μm pyrite crystals, and Morelli and Creaser (2007) studied metamorphosed sulfide ores to estimate Re-Os resetting temperatures above 600°C for pyrite. Beyond ore deposit research, synsedimentary to early diagenetic pyrite from carbonaceous shales has been used to provide age constraints within Proterozoic sedimentary basins (Hannah et al. 2004).

Arsenopyrite (FeAsS) is typically restricted to hydrothermal vein and contact metamorphism occurrences, but As is an important pathfinder element for gold ores (Nude et al. 2012) as arsenopyrite is a host for many refractory gold deposits. Thus, the ability to precisely date arsenopyrite with Re-Os is an invaluable tool for gold deposit research. This was first reported by Arne et al. (2001) who used the method to confirm an Ordovician age for the historical Bendigo gold reefs in Australia. Arne et al. (2001) found arsenopyrite to have Re contents above 10 ppb, with little common Os and high Re/Os ratios, thus ideal for geochronology. Morelli et al. (2005) presented a detailed study of arsenopyrite geochronology from the Meguma terrane, Canada, where they identified two distinct ages of mineralization at ~ 380 Ma and 408 Ma. Within the deposits studied, some arsenopyrite contained no common Os, and the ages determined from those samples using the “mixed double-spike” approach were identical to other samples from which the age was determined using the conventional isochron approach. The Re-Os method in arsenopyrite has been used to establish the age of giant gold ore deposits worldwide (Yu et al. 2005; Morelli et al. 2007;

Morelli et al. 2010) and to evaluate models for their origin. An important cross-calibration to the U-Pb zircon geochronometer was presented by Scherstén et al. (2012) who reported Re-Os ages from arsenopyrite of $2,636 \pm 23$ Ma and U-Pb ages from metamorphic zircon of $2,633 \pm 6$ Ma, both of which formed during the same episode of metamorphism at that time. This implies that the closure temperature for Re-Os in arsenopyrite is, like molybdenite, high and well above 500°C (e.g., Morelli et al. 2010). Davies et al. (2010) found that Re-Os ages recorded by arsenopyrite ($1,768 \pm 11$ Ma) overlaps with U-Pb ages recorded by monazite ($1,781 \pm 4$ Ma) in a metamorphosed Proterozoic gold deposit, again implying a high closure temperature for Re-Os in arsenopyrite ($>600^\circ\text{C}$) that is demonstrably higher than the Ar-Ar mica closure temperature ($\sim 350^\circ\text{C}$) which records cooling ages of ca. 1,720 Ma from the deposit studied.

Re-Os Geochronology of Other Crustal Sulfide Minerals

Several copper sulfide minerals including chalcopyrite (CuFeS_2) and bornite (Cu_5FeS_4) have been investigated for Re-Os geochronology. A detailed study by Selby et al. (2009) found extremely high Re contents in both minerals up to 5,000 ppb, with little common Os, in sediment-hosted Cu deposits from Alaska, and bornite, chalcopyrite, and pyrite yielded a precise Re-Os age that resolved possible origin models for the deposit. Extremely high Re contents also characterized bornite and chalcopyrite from sandstone-hosted Cu deposits of Dzhezkazgan, Kazakhstan (Box et al. 2013). In this study, bornite and chalcopyrite yielded similar ages from one deposit but disparate ages from another. Zhu and Sun (2013) used Re-Os geochronology of chalcopyrite to provide the age of formation of IOCG deposits from China and again found Re levels above 1,000 ppb and low common Os contents. Thus, the copper sulfide minerals hold significant promise for Re-Os geochronology, and both Selby et al. (2009) and Zhu and Sun (2013) report retention of Re-Os ages in these minerals despite low-grade metamorphic overprints for each deposit.

Hydrothermal pyrrhotite ($\text{Fe}(1-x)\text{S}_x$) was analyzed by Morelli et al. (2010) from the Homestake Au deposit, from which a precise 1,736 Ma Re-Os arsenopyrite age was produced. In comparison to arsenopyrite, the pyrrhotite Re-Os data were highly scattered and did not yield useful age information. Brenan et al. (2000) measured Os diffusion in pyrrhotite and found it to be much faster than pyrite, yielding a likely closure temperature for pyrrhotite of $300\text{--}400^\circ\text{C}$. The Re-Os pyrrhotite results of Morelli et al. (2010) fit broadly with these experimental findings. Similarly, sphalerite (ZnS) was found to yield scattered Re-Os data from veins studied by Morelli et al. (2004) from which pyrite yielded a precise Re-Os age.

Few minerals contain Re as major component of their structure, but reeniite (ReS_2) has been reported in modern volcanic centers and remarkably has yielded isotopic Re-Os ages as young as 79 ± 11 a (Tessalina et al. 2008).

Summary

The common occurrence of sulfide minerals in metallic ore deposits (e.g., those of Cu, Au, Zn, and Pb) makes Re-Os dating of these minerals a key method in ore deposit research, particularly given the difficulty of directly dating ore minerals with other isotopic methods. It is relatively a new field of geochronology, enabled by significant advancements in analysis methods, that is becoming widely applied. Many crustal sulfide minerals (molybdenite, pyrite, arsenopyrite, chalcopyrite, bornite) have been found to provide reliable Re-Os ages, whereas some do not (pyrrhotite, sphalerite).

Wollongong, NSW, Australia

Synonyms

Single-grain D_e distribution; Single-grain equivalent dose distribution

Definition

A single-grain dose distribution refers to the spread in measured dose values (and their associated uncertainties) for individual mineral grains in luminescence dating; usually these are independent dose estimates for tens to hundreds of single grains from the same sample.

Introduction

In luminescence dating, an estimate is made of the equivalent dose for a single grain or for a group of mineral grains, the latter commonly referred to as an “aliquot.” The equivalent dose (expressed in grays, Gy) corresponds to the radiation energy absorbed by a mineral grain, and stored in the form of trapped electrons, since the grain was last exposed to sunlight (“bleached”) or was last heated to a high temperature. But this only holds true for an aliquot if each and every grain on the aliquot had been bleached or heated to the same, sufficient extent. For this reason, a single grain is the smallest meaningful unit of analysis in luminescence dating, because each grain in a sample may, in principle, have had a different bleaching, heating, or postdepositional history.

An equivalent dose estimate for a single grain, or for a single aliquot composed of multiple grains, is obtained experimentally, so it has an associated uncertainty. The uncertainty is usually expressed as the standard error, at the 1-sigma (1σ) or 68 % confidence interval. The estimate of uncertainty is as important as the estimate of the equivalent dose itself, and this is especially true for single grains, because the size of the uncertainty can vary greatly from grain to grain. A set of bivariate observations (of equivalent dose and standard error) are, therefore, commonly obtained for each sample, and the distribution of these observed values should be examined before calculating the burial age of the sample or some other event of interest.

As a general note of caution, it is important to ensure that the quoted standard error encapsulates all of the measurement uncertainties associated with estimation of the equivalent dose. For single grains, the standard error includes uncertainties associated with photon counting statistics, instrumental reproducibility, mathematical fitting of the dose–response curve to the measured luminescence data, and corrections for any spatial heterogeneity in the laboratory beta sources. Equivalent dose values might appear more scattered than is actually the case if the standard errors are

Fig. 1 Histograms of equivalent dose values and scatter plots of their standard errors for 120 single aliquots of a fluvial sample. The plots in the *left-hand* column use a linear scale for the equivalent dose and show the absolute standard errors in Gy. The *right-hand* panels use a logarithmic scale for the equivalent dose (i.e., equal divisions of log dose) and show the relative standard errors in % (From Galbraith and Roberts (2012))

underestimated, whereas dose distributions may look misleadingly homogeneous if the standard errors are overestimated.

Graphical Displays of Equivalent Dose Distributions

Researchers often wish to plot the distribution of equivalent dose estimates, and there are several means of doing so. Galbraith and Roberts (2012) review some of the most popular approaches to displaying equivalent dose values.

Frequency Distributions

A commonly used form of data display is the histogram. This requires equivalent dose values to be sorted into “bins” of some fixed size and then the number of observations summed for each bin to generate a frequency distribution. In Fig. 1, the bottom left-hand plot is a histogram of the equivalent dose values for 120 aliquots composed of sand-sized quartz grains from a fluvial sample. Most values cluster between 20 and 30 Gy, with a few smaller values and some much larger ones. The distribution appears to be asymmetric and positively skewed.

Despite their apparent simplicity, however, histograms present various problems of implementation and interpretation. The bin size, for example, is an arbitrary choice, so the shape of the histogram can be affected by the choice of bin size. Furthermore, equivalent dose histograms include information about the distribution of the “true” doses (i.e., the doses that would have been observed if we could do so without measurement error) and the distribution of the standard errors, among other things.

In Fig. 1, the chosen bin size is 5 Gy. This is larger than the standard errors for most of the equivalent dose estimates, which are displayed in the top left-hand plot. The combination of these two plots is useful, as it allows the reader to see the distribution of equivalent doses and the size of their standard errors, which is not something that can be judged from the histogram alone. The

standard errors of this sample show an interesting feature that is typical of many luminescence samples: the size of the uncertainty increases with the size of the equivalent dose. Because of this, larger equivalent dose values will tend to scatter more in a histogram than smaller values and thereby create a positive skew, regardless of the bleaching and burial history of the grains.

To compensate for this effect, it is useful to take the natural logarithm of each equivalent dose value and to express the standard error as the relative standard error (i.e., the standard error in Gy divided by the equivalent dose in Gy). Logarithmic transformations are commonplace in statistics and exploit the fact that the relative standard error of an estimate is approximately equal to the absolute standard error of its natural logarithm.

The two right-hand plots in Fig. 1 show the same data as in the left-hand column but with the relative standard errors plotted in the top right-hand panel and the equivalent doses presented on a logarithmic scale. The relative standard errors do not increase with the size of the equivalent dose, and the equivalent dose distribution is much closer to normal (Gaussian) in shape. As the latter may be interpreted differently from the bottom left-hand histogram, it is worthwhile displaying data in different ways before drawing conclusions about the likely bleaching and burial history of a sample from its equivalent dose distribution.

Another form of the histogram, often referred to as a “probability density function,” is sometimes used in luminescence dating. Probability density functions have the appealing appearance of “smoothed” histograms, but they suffer from many statistical shortcomings, and their use is strongly discouraged (Galbraith 1998, 2010; Galbraith and Roberts 2012).

Radial Plots

The preferred form of data display for equivalent dose values is the “radial plot” (Galbraith 1988; Galbraith et al. 1999; Galbraith and Roberts 2012). This plot is particularly useful to display single-grain (and single-aliquot) dose distributions because both the equivalent dose value and its standard error are shown for each and every grain (or aliquot), and this allows a number of other features of the distribution to be discerned at the same time. Figure 2 is a radial plot of the same data as shown in Fig. 1. Each of the open circles denotes the equivalent dose value and relative standard error for a single aliquot. The equivalent dose can be read by drawing a line from the zero point on the “standardized estimate” axis (on the left-hand side), through the data point of interest, to intersect the radial axis on the right-hand side. The point of intersection is the equivalent dose (D_e). The relative standard error on this estimate is read by drawing a vertical line from the same data point to intersect the horizontal axis at the bottom. The relative standard error is shown in % (i.e., as the standard error divided by the equivalent dose, multiplied by 100), and the “precision” is the reciprocal of the relative standard error.

A benefit of displaying the data in this form is that the equivalent dose values measured with the highest precision (i.e., the smallest relative standard errors) fall furthest to the right, whereas those measured with least precision lie furthest to the left. In addition to this self-sorting of values by precision, the use of the standardized estimate allows other aspects of the distribution to be conveniently assessed at a glance. The standardized estimate represents the unit standard deviation applicable to all of the data points. For each point, it is calculated as the equivalent dose minus a chosen reference value (such as the average equivalent dose for the entire distribution), divided by the relative standard error for that point. Accordingly, any band of width ± 2 units projecting from the standardized estimate axis will capture 95 % of the points if they are statistically consistent at 2σ .

In Fig. 2, the equivalent doses are plotted on a log scale (as in the right-hand panels of Fig. 1), so the standardized estimates and relative standard errors are based on the log equivalent dose values. Clearly, no single band extending ± 2 units from the standardized estimate axis can capture 95 % of

Fig. 2 A radial plot of the same data as displayed in Fig. 1. The equivalent dose values are plotted on a log scale, and the relative standard errors (in %) are indicated on the horizontal axis (From Galbraith and Roberts (2012))

the equivalent dose values, so there is some additional spread, which can be expressed in terms of the “overdispersion.” The latter term is used to describe the scatter among the equivalent dose values over and above that due to the measurement error associated with each observation (Galbraith et al. 2005; Galbraith and Roberts 2012). The data in Fig. 2 are overdispersed by $32.0 \pm 2.3\%$, as calculated from the “central age model” (see below). Two other noteworthy features of this distribution are visually apparent. First, there is a high density of data points consistent with equivalent dose values of 20–30 Gy, so the “frequency” aspect of the histogram is inherent in the radial plot also. Second, the plot shows clearly the existence of three very high equivalent dose values and one very low value, each measured with reasonable precision (i.e., a relative standard error of less than 10 %).

The use of log values may not be appropriate for young samples that contain grains with equivalent dose values close to zero or negative dose estimates within error of zero. In such instances, the unlogged or modified log-transformed versions of the radial plot can be used (Arnold et al. 2009; Galbraith 2010; Galbraith and Roberts 2012). Example radial plots for samples deposited in a variety of contexts are provided by Jacobs and Roberts (2007) and Galbraith and Roberts (2012), the latter summarizing the many appealing features of radial plots as follows:

- Equivalent dose values can be viewed simultaneously with their standard errors.
- Data are sorted automatically so that the equivalent dose values can be distinguished easily in terms of their relative precisions.
- Any overdispersion can be identified at a glance.
- Patterns in the data, such as the clustering of equivalent dose values, the presence of outliers, or the existence of multiple, discrete dose components (see below), can be recognized before calculating the sample age.

Age Models for Equivalent Dose Distributions

After a visual inspection of the equivalent dose distribution, it is common for researchers to then estimate the equivalent dose for the population of grains (or aliquots) related most closely to the

event of interest. This may be the burial time of the most fully bleached grains in the sample or the last time that the grains were heated to a high temperature. In sediment dating, the value often sought is the equivalent dose corresponding to the most recent bleaching event. But if a sample had been disturbed after burial and become contaminated by younger or older intrusive grains, then it is useful to be able to identify and exclude these grains before calculating the sample age.

To allow for these and other possibilities requires a range of models based on sound statistical principles. Several parametric models, developed originally for fission track dating (Galbraith and Green 1990; Galbraith and Laslett 1993), have been adapted for luminescence data and are now in widespread use. Galbraith and Roberts (2012) review these different “age models,” although it should be borne in mind that they are rarely applied to ages per se in luminescence dating. Instead, these models are applied to equivalent dose values, because the information required to determine single-grain ages – namely, the environmental dose rate specific to each grain – is not generally known. At present, the same (sample mean) dose rate is usually employed for all grains, while research continues into methods of measuring and modeling grain-specific dose rates.

A critical element of any decision-making process involving statistical models is sample context. This should dictate which, if any, of the models may be the most appropriate for the sample of interest. On the basis of its depositional context, for example, one could ask if a sample is likely to have been fully or incompletely bleached at the time of deposition. Similarly, one could consider if there is any independent evidence that the stratigraphic integrity of the site has been compromised, perhaps resulting in postdepositional disturbance of the sample. In short, statistical models should not be applied without first taking into account the archaeological or geologic context of a sample, stratigraphic considerations, and other relevant information, such as independent age control (Galbraith et al. 2005; Galbraith and Roberts 2012).

Common and Central Age Models

These two models represent the most straightforward case in luminescence dating: one in which the “average” equivalent dose is the quantity of interest. This may be a useful value to estimate for samples composed of grains that have been well bleached before deposition, exposed to the same environmental dose rate after burial, and remained unaffected by any processes of postdepositional sediment mixing. The equations for the common and central age models are given in Galbraith et al. (1999) and Galbraith and Roberts (2012), together with worked examples in the former. The two models are identical insofar as they both weight each equivalent dose by the inverse square of its standard error, which is a standard statistical method of averaging values with differing precisions. A major difference, however, is that the central age model also calculates – and explicitly includes in the standard error – the extent of any overdispersion among the equivalent dose values. If there is zero overdispersion (i.e., all of the spread among the equivalent doses can be accounted for by the individual measurement uncertainties alone), then the central age model reduces to the common age model. But even for samples of quartz grains that are known or are thought to have been fully bleached at deposition, overdispersion values of 10–20 % are commonplace (Galbraith et al. 2005; Jacobs and Roberts 2007; Arnold and Roberts 2009), so the central age model is usually the more appropriate of the pair.

As illustrated by comparing the two lower plots in Fig. 1, log equivalent doses typically produce a much closer approximation to a normal (Gaussian) distribution than do their unlogged counterparts. This is due to the size of the absolute standard error increasing in concert with the equivalent dose (see top left-hand panel), a common feature of many luminescence samples. For this reason, the most widely used form of the central age model utilizes log equivalent dose values and the relative standard errors; the resulting model estimate of equivalent dose approximates the geometric mean. If

the measured equivalent doses are zero or negative, as can occur with some young samples and with modern samples, then log transformations are not applicable, and the unlogged version of the central age model could be used instead (Arnold et al. 2009).

Minimum Age Models

The assumption of complete bleaching before deposition and lack of disturbance thereafter will not be true for many samples. For example, sediment grains transported underwater may not be fully bleached, and some deposits may be subject to bioturbation or human disturbance. In such cases, the “average” equivalent dose will be of little interest. For samples that are thought to contain some grains that were fully bleached before deposition and others that were only partially bleached, the minimum age model can provide a useful means of estimating the equivalent dose associated with the subset of well-bleached grains. Details of this model are given in Galbraith et al. (1999) and Galbraith and Roberts (2012). Alternative approaches that are philosophically similar to the minimum age model are rarely based on well-established statistical principles, so the statistical properties of the resulting equivalent dose and uncertainty estimates are ambiguous, at best.

The most widely used version of the minimum age model assumes that the log equivalent doses form a truncated normal distribution, with the lower truncation point corresponding to the average log dose of the subset of fully bleached grains. This assumed distribution is one of several that could be made, but it is convenient to assume a normal distribution in the absence of independent support for another type. The minimum age model was originally developed with four adjustable parameters, but it has been shown that data sets with small numbers of equivalent dose values or less dispersed distributions are often fitted better using a three-parameter model, in which the lower truncation point equals the mean of a normal distribution. As with the central age model, the unlogged version of the minimum age model may be more appropriate for samples with zero or negative measured equivalent doses (Arnold et al. 2009).

When implementing the minimum age model, allowance needs to be made for the extent of inherent overdispersion among the equivalent dose values of the subset of fully bleached grains. That is, well-bleached samples commonly exhibit some amount of overdispersion in their equivalent dose values, so an estimate of this overdispersion should be added to the relative standard error of each equivalent dose before running the model. This estimate could be obtained from a well-bleached sample of the same mineral that is similar in age and derived from the same source. In the absence of independent data, one could conduct a sensitivity test of the model using overdispersion values of 10 % and 20 %, for example.

Minimum age models have been tested in numerical simulations and in comparisons against independently dated Holocene samples from a variety of geomorphic settings (Olley et al. 2004; Arnold et al. 2009). The latter studies utilized single grains of quartz, but the minimum age model can also be applied to single aliquots with one additional caveat: the estimate of the minimum dose may still be larger than the equivalent dose of the most recently bleached grains unless at least one aliquot consists entirely of fully bleached grains. For aliquots composed of relatively few fully bleached grains, the minimum dose may be much too large, and single-grain analysis may be required to obtain an accurate estimate of depositional age.

Finite Mixture Model

For some samples, neither the mean nor minimum estimates of equivalent dose may correspond to the event of interest. This may be so for deposits affected by bioturbation or for sites disturbed by human activities, both of which may result in mixing of grains between units of different ages. In such circumstances, the finite mixture model may be able to discern the existence of multiple,

discrete components in a single-grain equivalent dose distribution (Roberts et al. [2000](#); Galbraith and Roberts [2012](#)).

In the finite mixture model, the log equivalent doses for single grains are assumed to represent a mixture of discrete populations, each of which is normally distributed with the same relative overdispersion. The extent of overdispersion is one of the parameters in the model, as is the number of discrete populations. In practice, the model is run by initially fixing the number of components at 2 and then inserting some reasonable overdispersion values (such as 10 %, 15 %, and 20 %). The number of fitted components is then increased to 3, using the same overdispersion values as previously, and so on. The model uses maximum likelihood to estimate the mean equivalent dose and standard error for each fitted component and the proportion of grains in each component. When the number of components is set at 1, the finite mixture model is mathematically identical to the central age model.

The goodness-of-fit of the model to the data can be assessed using the Bayes Information Criterion (BIC), which takes into account the maximum likelihood estimates and the number of fitted components; the smallest BIC indicates the minimum number of components needed to explain the dose distribution. It is important to also check that the model estimates are sensible and to compare them with the distribution of equivalent doses on a radial plot, as no model should be used as a “black box.” Straightforward explanations and worked examples of the finite mixture model fitting procedure are given in David et al. ([2007](#)) and Jacobs et al. ([2008](#)).

For 2- and 3-component mixtures of single grains that were bleached and then given known laboratory doses, the model could successfully recover the correct number of discrete components, their relative proportions, and the corresponding equivalent dose values, provided the overdispersion parameter was small, known, or similar for each component (Roberts et al. [2000](#); Jacobs et al. [2006](#)). But the finite mixture model may be unable to identify discrete components in more complex equivalent dose distributions, such as those associated with heterogeneously bleached grains that have been mingled subsequently. The model should also not be applied to the equivalent dose distributions of multigrain aliquots, even for those consisting of very few grains. If aliquots contain luminescent grains from more than one parent population, then “phantom” components with intermediate doses can easily be generated – that is, equivalent dose components that are not present in any of the single-grain parent populations (Arnold and Roberts [2009](#)).

Summary or Conclusions

The graphical display of single-grain or single-aliquot equivalent dose values can be accomplished in various ways, of which the radial plot provides an effective means of assessing all of the salient information at a glance. After an initial visual inspection of the distribution, one or more statistical “age models” can be used to estimate the equivalent dose for the population of grains (or aliquots) related most closely to the event of interest. Such models should be supported by well-established statistical theory, but the choice of model depends fundamentally on the scientific context of each sample and on the purpose of the investigation (Galbraith and Roberts [2012](#)).

Molecular Rate Variation (Molecular Clocks)

Robert Lanfear*

Ecology, Evolution, and Genetics, The Australian National University, Canberra, ACT, Australia

Molecular Rate Variation

The rate of molecular evolution is the rate at which substitutions accumulate in an organism's genome. Rates of molecular evolution can vary dramatically, for example, the rate of molecular evolution in some viruses is around one substitution per base pair per 1,000 years (Pagán et al. 2010), while in mammals the rate is around one substitution per base pair per 1,000 million years (Nabholz et al. 2008). Even closely related plants and animals can have rates of molecular evolution that vary by more than an order of magnitude (Thomas et al. 2006; Smith and Donoghue 2008; Welch et al. 2008; Lanfear et al. 2013). Accounting for molecular rate variation is important in methods that use molecular sequence data to date the divergences between species (molecular dating).

There has been a great deal of research into the causes of variation in rates of molecular evolution. This research has identified a range of factors which may cause variation in the rate of molecular evolution (Bromham 2011), and these factors can be broken up into those that affect the mutation rate and those that affect the rate at which new mutations are fixed in a population (the fixation rate). An increase in either the mutation rate or the fixation rate can potentially increase the overall rate of molecular evolution, although there are some situations in which these increases will leave the rate of molecular evolution unchanged (de Visser et al. 1999).

Many factors have been suggested to increase mutation rates in DNA sequences, including temperature, UV radiation, oxygen radicals, recombination, genome copying, and natural selection (Martin and Palumbi 1993; Davies et al. 2004; Wright et al. 2006; Lanfear et al. 2007; Thomas et al. 2010; Hodgkinson and Eyre-Walker 2011; Wright et al. 2011; Lourenço et al. 2013; Lanfear et al. 2013). In principle, variation in any of these factors could cause variation in the rates of molecular evolution between species, although the evidence for this is weak for UV radiation and oxygen radicals in particular (Davies et al. 2004; Lanfear et al. 2007; Joyner-Matos et al. 2011; Lanfear et al. 2013). However, there is good evidence that the many mutations occur during genome-copying events (meiosis and mitosis) and that variation in long-term rates of genome copying may explain much of the variation in the rates of molecular evolution between species (Smith and Donoghue 2008; Welch et al. 2008; Thomas et al. 2010; Lanfear et al. 2013). Intriguingly, it has also been suggested that natural selection may play a role in determining mutation rates and rates of molecular evolution, either through selection for increased longevity (Nabholz et al. 2008; Welch et al. 2008; Galtier et al. 2009) or through the reduced efficacy of natural selection in small populations (Lynch 2010, 2011).

Anything that increases the fixation rate of new mutations can also increase the substitution rate. Two factors combine to determine the fixation rate of a new mutation: the effect of that mutation on the carrier's fitness and the effective population size of the host population. As fitness effects

*Email: rob.lanfear@gmail.com

become more beneficial and effective population sizes get larger, fixation rates increase (Woolfit 2009). This is because a population's effective population size determines the balance of power between natural selection and genetic drift. The larger the effective population size, the stronger natural selection is relative to genetic drift, and the faster beneficial mutations are fixed in the population, and deleterious mutations removed. Because we expect most mutations to be deleterious, it is generally thought that organisms with smaller effective population size should have faster rates of molecular evolution. Some studies have supported this idea and have shown that organisms with smaller effective population sizes tend to evolve more quickly, at least by some measure of the rate of molecular evolution (Moran 1996; Woolfit and Bromham 2003, 2005). However, other results suggest that the relationship between population size and the rate of molecular evolution can be much more complex than this simple model suggests (Charlesworth and Eyre-Walker 2007; Wright et al. 2009).

We have a fairly good understanding of the most important causes of variation in rates of molecular evolution. But despite this, we can often explain less than half of the variation that we can measure, suggesting that we still have a lot to learn. A better understanding of molecular rate variation is important because it can help improve molecular dating methods. Perhaps the best example of this is the development of new methods which leverage what we know about the causes and correlates of molecular rates to directly improve our estimates of divergence dates from DNA sequence data (Lartillot and Poujol 2011; Lartillot and Delsuc 2012). As our understanding of molecular rate variation continues to increase, we will be able to continue to improve the accuracy of molecular dating methods.

[Acasta gneisses](#)

Definition

The Acasta gneiss complex in northwestern Canada contains some of the oldest dated rocks on earth and the oldest dated using U-Pb in zircon. They therefore potentially preserve clues to the nature and history of earth's oldest crust. The geology of the gneisses reflects a complex multistage history of magmatism, metamorphism, and deformation over more than 400 million years, and the entire complex should be viewed as a small fragment of Hadean to Archean continental crust. The gneisses are compositionally diverse and range from granite and tonalite to gabbro and serpentinized ultramafic rocks. The oldest published crystallization age. There are isotopic and inherited zircon data consistent with the involvement of crust as old as 4.2 Ga. There is no single age of the Acasta gneiss complex (Bowring and Williams 1999).

Introduction

Components of the Acasta gneiss complex are among the oldest known rocks on earth. They are exposed in northwestern Canada (65° 10' N and 115° 30' W) along the western margin of the Archean Slave craton (>2.58 Ga), in the core of a north-trending fold in the foreland of the Wopmay orogen, a 2.02–1.84 Ga-old orogenic belt. The Acasta gneisses range in age from 4.03 to ca 3.6 Ga (Bowring and Williams 1999; Iizuka et al. 2006, 2007; Stern and Bleeker 1998). All age groups are compositionally diverse and range from granite to quartz diorite to tonalite. The deformational history is complex with several episodes resulting in well-developed foliations. In low-strain domains, crosscutting relationships can be observed (Fig. 1), but in general, deformation has obscured primary relationships between different rock types. Lens-shaped boudins of serpentinized ultramafic rocks occur throughout the gneisses; some are 100's of meters in long dimension. No ca. 4.0–3.6 Ga metasedimentary rocks have been discovered although sparse outcrops of quartzite, iron formation, and pelite are found locally tightly folded into older gneisses. A wide variety of weakly deformed granitic dikes that intrude older gneisses are ca 3.6, 3.4, 2.9, and 2.6 Ga (Stern and Bleeker 1998; Bleeker and Stern 1997). During 1.88 Ga Calderian orogeny to the west, thrust sheets of 1.9–2.5 Ga rocks were thrust over the western edge of Slave craton resulting in a set of north-trending folds and metamorphism of underlying Archean rocks. Ar-Ar biotite and U-Pb

apatite dates record complex reheating and cooling during this event and are as young as ca 1.77 Ga (Sano et al. 1999)

Age Constraints

U-Pb geochronological studies indicate that the Acasta gneisses range in age from 4.03 to ca. 3.6 Ga with distinct groupings at 4.03–3.94, 3.74–3.72, and 3.66–3.58 Ga, although this may be an artifact due to a relatively small number of published analyses. U-Pb zircon dates indicate that the oldest igneous crystallization ages for Acasta gneiss protoliths that range from granite to tonalite/diorite are 4.012 ± 0.006 to 4.030 ± 0.003 Ga. Many zircons from all rock types contain older cores with the oldest at 4.065 ± 0.016 and 4.2 Ga (Iizuka et al. 2006), consistent with the involvement of even older crust in their generation by partial melting or assimilation (Bowring and Williams 1999). In general, the geochemistry of the Acasta gneisses is not distinctive from other Archean and younger rocks; they are on average enriched in light rare-earth elements with variable depletion in heavy rare-earth elements thought to reflect the involvement of garnet in the source area. Radiogenic isotope

systematics in whole rocks (Sm-Nd) and zircon (Lu-Hf) are also consistent with the involvement of older continental crust. Many of the rocks have zircons with thin overgrowths likely related to episodes of metamorphism that range from 3.8 to 3.4 Ga.

Concluding Remarks

The formation and preservation of continental crust early in earth history is of broad interest to earth and planetary scientists as the oldest continental crust records the only history of magma formation and the role of water in generating granitic magmas more than 4 billion years ago. With estimates for the age of the earth-moon system between 4.5 and 4.4 Ga and the oldest detrital zircon from Australia, 4.374 ± 0.0006 Ga (Valley et al. 2014), the Acasta gneiss complex with igneous rocks as old as 4.030 Ga with evidence for involvement of even older crust offers important insights into early crustal evolution. Finally, many of the rocks in the Acasta gneiss complex are very similar in composition to those formed much later in earth history by plate tectonic processes, and there is no compelling evidence of the late heavy bombardment (Mojzsis et al. 2014) preserved in the Acasta gneisses.

Molecular Clocks

Simon Y. W. Ho*

School of Biological Sciences, University of Sydney, Sydney, NSW, Australia

Definition

Molecular clock. A hypothesis that predicts a constant rate of molecular evolution among species. It is also a method of genetic analysis that can be used to estimate evolutionary rates and timescales using data from DNA or proteins.

Introduction

The tempo and mode of evolution are central themes of biological research. This places importance on the estimation of evolutionary timescales, which provide the backdrop for our interpretations of evolutionary patterns and processes. Traditionally, such inferences were made from the fossil record, coupled with radiometric dating. Fossils can provide an estimate of when different lineages first appeared and when species diverged from each other. In many cases, however, such data are unavailable, forcing us to look elsewhere for a source of temporal information. The “molecular clock,” proposed in the 1960s (Zuckerkandl and Pauling 1962, 1965), allows evolutionary time-scales to be estimated using genetic data. Molecular clocks have provided insights into significant evolutionary events such as human evolution and the radiations of birds, mammals, and flowering plants. Molecular-clock methods continue to undergo improvement, which is crucial if we are to take advantage of the growing wealth of genomic data (Kumar 2005).

The molecular-clock hypothesis posits that rates of molecular evolution, as reflected in changes in DNA or protein sequences through time, are constant among lineages (but not across different regions of the genome). Nucleotide mutations cause DNA sequences to change over time, whereas mutations of amino acids lead to evolution in proteins. These mutations occur with a constant probability rather than at a constant frequency – that is, the molecular clock is stochastic rather than metronomic (Zuckerkandl and Pauling 1965). The occurrence of mutations in a DNA sequence is often modelled using a Poisson process.

A corollary of the molecular-clock hypothesis is that the genetic difference between any two species is proportional to the time since they last shared a common ancestor. This is a useful relationship because it allows evolutionary timescales to be estimated from genetic data, provided that the rate of molecular evolution is known. The molecular clock represents the only method for studying the evolutionary timescales of organisms that have failed to leave any trace in the fossil record, including many groups of invertebrates, bacteria, and viruses. It also allows us to estimate the timing of events that are too recent to be resolved by fossil evidence, such as divergences among conspecific populations (Arbogast et al. 2002).

*Email: simon.ho@sydney.edu.au

Fig. 1 Plot of amino acid identity of fibrinopeptides from various pairs of mammals, plotted against time since divergence. The divergence times are based on estimates from the fossil record (Data are from Doolittle and Blomback (1964))

History of the Molecular Clock

The molecular-clock hypothesis was put forward by Emile Zuckerkandl and Linus Pauling (1962), who assumed a constant evolutionary rate in their analysis of globin proteins from vertebrates. They observed about 18 differences in amino acids between horse and human and estimated the mutation rate by assuming that the divergence between these two species occurred 100–160 Ma ago. Upon extrapolating this rate, Zuckerkandl and Pauling (1962) estimated that humans diverged from gorillas about 11 Ma ago. They also estimated that different copies of globin genes first diverged from each other in the late Precambrian. When reporting these estimates, Zuckerkandl and Pauling (1962) warned about the possible confounding effects of a number of factors, including natural selection, variations in population size, and mutational saturation.

In the following years, further studies produced evidence of clocklike evolution in other proteins. Doolittle and Blomback (1964) found a simple relationship between sequence identity and time since divergence in mammalian fibrinopeptides (Fig. 1). A year later, Zuckerkandl and Pauling (1965) coined the term “molecular evolutionary clock.” It promised to be a useful tool in biological research, as demonstrated shortly afterward by Sarich and Wilson (1967a, b) in their pioneering studies of the evolutionary timescale of hominids and other primates.

At the time, the idea of a constant substitution rate was controversial (Morgan 1998). The molecular clock was received unenthusiastically by George Gaylord Simpson (1964), among others. Criticisms of the molecular clock were partly motivated by the apparent lack of uniformity in the pace of morphological evolution, which was presumably linked to molecular evolution. There was no evidence to suggest that adaptive change occurred at a uniform rate and it seemed implausible that the complex process of molecular evolution could be described by such a simple statistical model.

Meanwhile, there was growing evidence of high evolutionary rates in various proteins, suggesting that a large proportion of the changes in amino acids must have a negligible impact on evolutionary fitness. As a response, Motoo Kimura (1968) proposed the neutral theory of molecular evolution, which states that many mutations have such a small effect on the fitness of an organism that they can be considered as “neutral.” This can be explained by the fact that many amino acids in a protein can be exchanged for other amino acids with similar biochemical

properties, with negligible impact on the overall function or structure of the protein. At the level of DNA, many mutations in protein-coding genes are “synonymous” because they do not result in any changes in the amino acid sequence of the protein. The fate of these “neutral” mutations is determined stochastically by a process known as genetic drift. The neutral theory was proposed independently by Jack King and Thomas Jukes (1969), who cited a range of evidence to support their hypothesis.

One of the predictions of the neutral theory is that rates of molecular evolution are constant among lineages. However, this prediction refers specifically to the rate of genetic change per generation. As a consequence, we expect to see a generation-time effect, whereby species with shorter generations tend to evolve more quickly per unit of time. For example, a higher rate would be observed in rodents than in whales. This is based on the assumption that most mutations occur during the replication of germline DNA. Such a generation-time effect was observed in the analyses of non-coding DNA (Laird et al. 1969; Kohne 1970). This was in contrast with the rate of protein evolution, which appeared to be independent of generation time.

In response to the shortcomings of the neutral theory, Tomoko Ohta (1972, 1973) proposed the nearly neutral theory of molecular evolution. In this framework, there is a large class of “nearly neutral” mutations that have small effects on an organism’s fitness. In contrast with the results of the neutral theory, the nearly neutral theory states that the population sizes of species have a significant influence on the molecular evolutionary process. Many mutations are slightly harmful and are gradually removed from the population. In large populations, natural selection is effective at removing mutations that are detrimental to the organism’s fitness. In small populations, natural selection tends to be ineffective and most genetic change is driven by genetic drift. Generally, drift acts more quickly in small populations than does selection in large populations. However, a greater number of mutations appear each generation in large populations, simply because there are more individuals that can experience mutations. These two effects offset each other, leading to a relatively constant evolutionary rate among species per unit of time.

Through the ensuing decades, the molecular clock was used to study the evolutionary timescales of a range of organisms. Some of the most prominent studies involved analyses of the metazoan evolutionary timescale, with a focus on the divergences among animal phyla. In considerable conflict with the “Cambrian explosion” scenario supported by the fossil record, estimates from the molecular clock suggested a protracted Precambrian timescale for basal metazoan divergences (e.g., Dickerson 1971; Runnegar 1982; Doolittle et al. 1996). Similarly, molecular evidence pointed to much deeper diversifications of avian and mammalian orders than those suggested by paleontological evidence (e.g., Cooper and Penny 1997; Springer 1997). These discrepancies remain some of the key sources of debate about the accuracy of the molecular clock (Bromham and Penny 2003).

Meanwhile, there was a growing body of evidence that pointed to rate variation among lineages. This came partly from various statistical tests that had been developed to test for clocklike evolution in genetic data (Wu and Li 1985; Tajima 1993). Departures from the molecular clock provided a challenge for studies of evolutionary timescales. It was not until the late 1990s, however, when molecular-clock methods were developed that were able to account for variation in evolutionary rates (Sanderson 1997; Thorne et al. 1998). Known as “relaxed” molecular clocks because they relax the assumption of rate constancy among lineages, these have become the standard techniques in molecular evolutionary analysis.

Fig. 2 Phylogenetic tree showing the relationships of species from three genera, A, B, and C. Genera A and B are found on the mainland, whereas species of *Genus C* are found on an offshore island that was formed by volcanic activity. The tree is drawn to an unspecified timescale, so that the branch lengths are proportional to time. The tree illustrates the use of two molecular-clock calibrations. First, a fossil taxon has been assigned to the lineage leading to *Genus A*. This places a minimum age constraint on the divergence of A from B and C. Second, a geological calibration is placed on the divergence between B and C. The split between these genera is assumed to coincide with the formation of the offshore island on which *Genus C* is found. The age of the island is estimated using radiometric dating. The uncertainty in this date estimate is incorporated into the calibration, as indicated by the *black bar*. *Gray error bars* represent the uncertainty in the molecular-clock estimates of lineage divergence times

Rates of Molecular Evolution

Absolute rates of molecular evolution vary among regions of the genome because of differing constraints. Functionally important genes often evolve at an extremely slow pace, because many new mutations are detrimental to the organism and are rapidly removed by natural selection. As a consequence, such genes are often conserved even among distantly related organisms, making them useful genetic markers for studying deep evolutionary relationships. For example, histones, which are proteins that play an important role in binding and packaging DNA, have a very low substitution rate. In contrast, non-coding DNA has fewer functional constraints and can evolve at a higher rate than protein-coding DNA.

The mitochondrial genome evolves rapidly in animals and experiences about 10^{-8} substitutions per nucleotide per year, which is an order of magnitude higher than the average rate in the nuclear genome. This is in contrast with the pattern of molecular evolution in plants, where nuclear genomes evolve more quickly than either chloroplast or mitochondrial genomes. Rates of change in the genomes of viruses are higher by several orders of magnitude. In rapidly evolving RNA viruses, such as influenza virus and human immunodeficiency virus (HIV), mutation rates can exceed 10^{-3} mutations per nucleotide per year, and measurable genetic change can occur over a matter of weeks.

There is substantial variation in rates of molecular evolution across the tree of life. This variation is possibly driven by biological factors such as generation time, population size, longevity, and body temperature, as well as abiotic factors such as ultraviolet radiation. The relative importance of each of these factors is still poorly understood (Bromham 2009). Studies have found evidence that molecular evolutionary rates are associated with longevity in mammals (Welch et al. 2008), with generation time in invertebrates (Thomas et al. 2010), and with height in plants (Lanfear et al. 2013). Research into the factors governing rate variation among organisms is ongoing.

Molecular Clocks and Phylogenetic Analysis

Molecular clocks are typically used in phylogenetic analyses, which aim to reconstruct evolutionary trees that show the relationships among species of interest (Fig. 2). Internal nodes in the tree represent evolutionary divergence events. The timing of these events can be estimated using molecular clocks. A number of statistical methods are available for testing the molecular-clock hypothesis for a given set of DNA or protein sequences. When the molecular clock is rejected for a data set, one can use a statistical model to account for rate variation when estimating evolutionary timescales (Welch and Bromham 2005).

When estimating evolutionary timescales in a phylogenetic analysis, the molecular clock needs to be “calibrated.” This can be done by assigning an absolute age to one or more nodes in the phylogeny, which can then act as a reference point for estimating the ages of the remaining nodes. Calibrations are often based on the fossil record, which can provide date estimates for the divergence events in the phylogeny (Fig. 2). If a fossil taxon can be reliably assigned to one of the lineages in the tree, then the divergence of that lineage from its sister lineage must be older than the age of the fossil. Calibrations can also be based on geological events, including the separation of continents or the emergence of islands, if they are linked to evolutionary divergences. An example of this might involve two sister genera, one of which is endemic to the mainland and the other endemic to an offshore island that formed as a result of volcanic activity (Fig. 2). The timing of the divergence between the two genera can be estimated by the age of the island which, in turn, can be estimated using radiometric dating. In some cases, previous genetic estimates of dates are employed as calibrations. These are known as “secondary” calibrations and are generally used when other calibrating information is unavailable.

Once the phylogenetic tree is calibrated by fixing or constraining the ages of one or more nodes in the phylogeny, the ages of the remaining nodes can be estimated using a molecular-clock analysis of the genetic data. This process is referred to as “molecular dating” or “divergence-time estimation.” There is a large range of methods and models that have been developed for this purpose, implemented in various statistical frameworks. These methods are available in a range of computer programs, including most standard phylogenetic software.

Universal Molecular Clocks

There is abundant evidence of evolutionary rate variation among species, dispelling any hope of a universal molecular clock across the tree of life. However, some researchers entertain the idea of homogeneous rates of mitochondrial evolution within certain groups of organisms, such as birds, mammals, and arthropods. This is a convenient assumption because it allows evolutionary rates to be applied in molecular-clock analyses when fossil or geological calibrations are otherwise unavailable.

Many studies of birds assume that the mitochondrial genome evolves at about 1 % per million years, a value that was initially based on a study of five species of geese (Shields and Wilson 1987). Various analyses of avian mitochondrial DNA have supported this estimate, including an extensive study involving 74 calibrations and genetic data from 12 orders of birds (Weir and Schluter 2008). The avian mitochondrial clock has been used to investigate key questions in the evolution of birds, including the impact of Pleistocene glaciation on the diversification of passerines. Some have questioned the reliability of this clock, citing evidence of significant rate variation among lineages

and across timescales (García-Moreno 2004; Ho 2007). Despite this criticism, the avian mitochondrial clock is still widely used.

In a similar fashion, a universal mitochondrial clock of 1 % per million years is often assumed for mammals. This rate was initially based on a mitochondrial study of primates and rodents (Brown et al. 1979), but it soon found support from estimates derived from other organisms (Wilson et al. 1985). Comprehensive analyses of mammalian DNA have demonstrated that there is substantial variation in rates among species, partly driven by differences in longevity (Nabholz et al. 2008; Welch et al. 2008).

Studies of evolutionary timescales in arthropods have often employed a rate of 1.15 % per million years, which is based on an analysis of insects and crustaceans (Brower 1994). This arthropod mitochondrial clock is widely used, partly because of the relative paucity of reliable fossil calibrations for many invertebrate taxa. However, this clock was based on a very small number of data points, leading to its validity being questioned (Papadopoulou et al. 2010; Ho and Lo 2013). Moreover, there is strong evidence of mitochondrial and nuclear rate variation among invertebrate species (Thomas et al. 2010).

The employment of “standard” mitochondrial clocks, such as those described above, has often been criticized. This is because the mitochondrial genome is subject to differing degrees of natural selection among species, which can lead to heterogeneity in evolutionary rates. Similar reasoning applies to evolutionary rates in the nuclear genome. Given that rates can show substantial variation even among closely related species, the use of standard clocks has the potential to yield date estimates that are highly misleading.

Controversies

The molecular clock has had a long history of controversy, beginning with the criticisms of the assumption of rate constancy and continuing with the debate over the relative merits of the neutral theory compared with natural selection. Current debates include the use of calibrations in genetic dating analyses and the constancy of evolutionary rates across timescales (Pulquério and Nichols 2007).

The choice of calibrations has a substantial influence on the outcome of a molecular-clock analysis. Inadequate modelling of calibrations can lead to highly misleading estimates of evolutionary timescales. Accordingly, recent work has focused on accounting for the uncertainty in fossil and geological calibrations (Ho and Phillips 2009). There is also ongoing development of methods for modelling and quantifying the uncertainty in fossil calibrations (e.g., Marshall 2008; Wilkinson et al. 2011). Some aspects of calibration methodology are poorly understood, such as the impact of using different methods for modelling the uncertainty in calibrations. One of the key points of agreement is that best practice involves the use of multiple calibrations throughout the phylogenetic tree.

The use of secondary calibrations in molecular dating has been the target of strong criticism (Graur and Martin 2004). Although the use of secondary calibrations is sometimes unavoidable, good practice involves taking into account the uncertainty in previous molecular-clock estimates. Ignoring this uncertainty can lead to artificially precise estimates of evolutionary timescales. Instead, the uncertainty should be incorporated into the dating analysis so that it can be included in the resulting estimates. This can readily be done in a Bayesian framework, in which the user can choose prior distributions that reflect the degree of uncertainty in the parameters and node times.

There is growing evidence that estimates of rates depend on the timescale of observation. Low rates of evolution are seen across long evolutionary time frames, such as those analyzed in phylogenetic analyses of distant species. In contrast, high evolutionary rates have been estimated in studies of populations and pedigrees (Howell et al. 2003). The exact causes of this disparity remain unclear, although they are likely to include the effects of natural selection and inaccurate modelling of the molecular evolutionary process (Ho et al. 2011). If the time dependence of molecular rates is not taken into account, evolutionary timescales can be under- or overestimated by an order of magnitude.

Conclusions

The molecular clock has undergone considerable evolution during its long history. It is useful as a hypothesis in molecular evolution and as a tool for estimating evolutionary rates and timescales. New molecular-clock methods are being developed in order to take advantage of the large amounts of genomic data that are being generated. With further refinement and development, the molecular clock will continue to play an important role in understanding the evolution of life on Earth.

Molecular Clocks, Relaxed Variant

Simon Y. W. Ho*

School of Biological Sciences, University of Sydney, Sydney, NSW, Australia

Definition

Relaxed molecular clock. A statistical model of molecular evolution that allows the evolutionary rate to vary among organisms. Relaxed molecular clocks can be used to estimate rates and timescales of evolution using data from DNA or proteins.

Introduction

Evolutionary timescales can be estimated from genetic data using molecular clocks. The molecular clock hypothesis, developed in the early 1960s (Zuckerkandl and Pauling 1962, 1965), predicts a constant rate of evolutionary change among organisms. A natural consequence of this is a linear accumulation of genetic change over time, meaning that the genetic difference between two species is proportional to the time since they diverged from their most recent common ancestor. In some cases, the age of this divergence event can be inferred from independent data (such as fossil evidence), making it possible to estimate the rate of molecular evolution. If this rate is assumed to be constant among lineages (i.e., a “strict” or “global” molecular clock), we can use genetic data to estimate the divergence times for other species. Such analyses are normally done in a phylogenetic framework, which takes into account the evolutionary relationships among the organisms being studied. Most genetic dating methods assume that a reliable estimate of these evolutionary relationships is available.

Evidence of departures from clocklike behavior became apparent soon after the molecular clock was proposed (e.g., Laird et al. 1969). It is now generally accepted that genetic data rarely conform to a strict-clock model. A variety of statistical tests have revealed significant rate heterogeneity among lineages, even among closely related species. From a biological perspective, it is unsurprising to see such variation in molecular rates. Different species vary in body size, longevity, body temperature, generation time, and other heritable traits. Some of these factors have been shown to affect rates of molecular evolution (Bromham 2009). Even within species, such variation can be seen among populations. For example, different human populations have experienced differing demographic histories and are subject to heterogeneous environmental stresses, such that mutation rates vary among human lineages (Henn et al. 2009).

For several decades, the strict clock provided the only statistical framework for estimating evolutionary rates and timescales using genetic data. One of the first approaches for dealing with rate variation among lineages was to remove any data that violated the assumption of rate constancy (Li and Tanimura 1987; Takezaki et al. 1995). However, it is preferable to avoid discarding potentially valuable data and to model rate variation explicitly, particularly if it is an

Fig. 1 Three different classes of molecular clocks are available. The thickness of each line reflects the magnitude of the evolutionary rate along a branch. *Strict or global clocks* assume a constant rate throughout the tree. *Local clocks* allow a limited number of rates throughout the tree. In this example, the left side of the tree has a different evolutionary rate from the right side of the tree. *Relaxed clocks* allow each branch in the tree to have a distinct evolutionary rate

integral property of the molecular evolutionary process (Gillespie and Langley 1979). Various methods have been developed to account for variation in molecular rates. They can be broadly divided into local molecular clocks and relaxed molecular clocks, which differ in how they assign rates to branches in the phylogeny (Fig. 1). Genetic dating methods that can accommodate such rate variation have been the subject of several reviews (Renner 2005; Welch and Bromham 2005; Rutschmann 2006).

Local Molecular Clocks

Local molecular clocks assume that evolutionary rates vary among branches in the phylogeny but that this variation can be described using only a few discrete rates. In many cases, this would be considered a reasonable assumption because we expect closely related species to evolve at similar rates. As a result of common ancestry, species tend to share many biological features with their relatives, including heritable traits that influence rates of evolution. Local-clock methods permit different molecular clocks to exist in different groups of organisms. For example, one might distinguish between rates in baleen whales (mysticetes) and toothed whales (odontocetes), because the latter tend to evolve much more rapidly (Dornburg et al. 2012).

Local-clock methods retain some of the advantages of a strict molecular clock, without the restrictive assumption of a single rate of evolution across all lineages. However, there are significant difficulties in implementing local-clock methods, particularly in choosing the number of local clocks and determining how they are assigned among the species being studied. Recently, methods have been developed to conduct some of these steps objectively (Drummond and Suchard 2010; Paradis 2013), but their performance has not yet been examined comprehensively.

Rate-Smoothing Methods

Given that the rate of evolution is likely to be influenced by heritable traits, we can also treat the rate as a biological character that evolves over time (Gillespie 1991). Consequently, we would expect rates to be similar, but not necessarily identical, between neighboring branches in the phylogeny.

One way of putting this assumption into practice is to penalize large changes in rates between neighboring branches. A number of such “rate-smoothing” methods have been developed, including nonparametric rate-smoothing (Sanderson 1997) and penalized likelihood (Sanderson 2002).

The nonparametric rate-smoothing method operates by minimizing an objective function based on the sum of rate changes between branches in the phylogeny (Sanderson 1997). In penalized likelihood, rate changes between branches incur a penalty (Sanderson 2002). The weight of this penalty is governed by a smoothing parameter, the value of which can be optimized objectively. Both of these methods assume that the phylogeny is known or has been estimated reliably.

Bayesian Relaxed Clocks

Some relaxed-clock methods use an explicit model of rate variation among branches. These models are statistical rather than mechanistic, in that they model rate variation without making any statements about the causes of this variation. Relaxed-clock models tend to be parameter rich and have been implemented in Bayesian methods for phylogenetic analysis. The models of rate change can be broadly divided into two classes, based on whether evolutionary rates are assumed to be correlated between related lineages (Ho 2009).

In autocorrelated models of rate change, the rate is assumed to “evolve” gradually along branches of the tree (Thorne et al. 1998; Aris-Brosou and Yang 2002). The rate along a descendent branch is drawn from a distribution centered on the rate in its ancestral branch. As a consequence, neighboring branches are likely to have similar evolutionary rates. Various parametric distributions have been used in autocorrelated models of rate change, including lognormal and exponential distributions. The statistical properties of some of these models have been questioned (Welch et al. 2005; Lepage et al. 2006).

In uncorrelated models of rate change, the rate along each branch in the phylogeny bears no a priori similarity to the rates along its neighboring branches (Drummond et al. 2006). However, the rates across the tree are drawn from a single underlying distribution, such as a lognormal, exponential, or gamma distribution.

Models of autocorrelated and uncorrelated rates are probably applicable to different data sets (Ho 2009). When comparing closely related species, much of the rate variation among lineages can probably be explained by differences in biological characteristics. When the analysis involves distantly related organisms, however, it is possible that traces of rate autocorrelation break down. Various statistical methods can be used to choose the best-fitting model of rate variation among lineages for a given data set (Baele et al. 2013; Paradis 2013).

Conclusions

Relaxed molecular clocks make it possible to estimate evolutionary rates and timescales from genetic data even when rates vary among lineages. Various relaxed-clock methods have been developed, with statistical models designed to capture and account for heterogeneity in evolutionary rates. In view of the growing understanding of the factors driving variation in molecular rates, the next step is to incorporate biological knowledge into models of rate variation.

Minerals, (^{40}Ar - ^{39}Ar)

Simon Kelley^{a*}, Clare Warren^a and Camilla Wilkinson^b

^aDepartment of Earth and Environmental Sciences, The Open University, Milton Keynes, UK

^bNorges Geologiske Undersøkelse (NGU), Trondheim, Norway

Definition

Dating potassium-bearing minerals using the ^{40}Ar - ^{39}Ar technique is the most popular approach to determining the rates and timescales of geological processes across a wide range of geological time and is applied to dating igneous, sedimentary, and metamorphic rocks including meteorites and Moon rocks. Dating minerals using the Ar-Ar dating method is performed on purified mineral separates, individual mineral grains, and in situ in thick polished slabs.

Introduction

The earliest Ar-Ar dating studies were analyses of whole rock samples to investigate the age of meteorites and the first Moon rocks returned by the Apollo 11 astronauts (e.g., Turner et al. 1966, 1971). Terrestrial studies quickly applied the new dating techniques to mineral separates (e.g., Lanphere and Dalrymple 1971). Whole rock dates using the Ar-Ar technique are used predominantly for volcanic rocks where they can distinguish between instantaneous eruption ages and those disturbed by alteration of additional excess argon. Whole rock Ar-Ar dates of basalt eruptions are in fact dominated by potassium in the glass phase (potassium is incompatible in the main mineral phases pyroxene, olivine, and plagioclase). Unfortunately glass is also commonly altered to clay minerals, some of which yield ages reflecting the later fluid flow events (e.g., illite) and some do not retain argon quantitatively (e.g., smectite). Moreover argon is more soluble in melt than minerals so glass can exhibit anomalously old ages caused by excess argon. So even in this scenario, understanding mineral Ar-Ar dates can be important.

Mineral dates have been measured for both K-Ar and Ar-Ar dating because of their versatility. For example, muscovite mineral ages have been used to date high-level igneous intrusions, metamorphic cooling, and sediment provenance, and alkali feldspars have been used to date mega-eruptions and metamorphic thermal histories.

Criteria for Successful Mineral Ar-Ar Dating

The fundamental reason for mineral dating is that the ages can be interpreted in terms of geological processes including crystallization and cooling. While some ages yield simple ages of instantaneous events, others yield additional information on cooling patterns and fluid flow. There are several important mineral- and rock-specific parameters that should be considered in order to interpret the ages:

*Email: simon.kelley@open.ac.uk

- *Mineral characterization and analytical approach*: Ensuring mineral separate purity is an essential prerequisite for mineral Ar-Ar dating; in short you have to know what you're dating in order to interpret the age. Mineral identification is normally undertaken optically using thin sections, often combined with elemental composition measured using electron microprobe. Several techniques are commonly used to measure mineral Ar-Ar ages including stepped heating mineral separates of 10–100 mg and laser heating of mineral separates commonly less than 1 mg or as single grains (see “► [Single Crystal Laser Fusion \(\$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ \)](#)”; McDougall and Harrison 1999; Kelley 2002a). In addition, Ar-Ar age variations within individual minerals can be measured using laser ablation (pits 25–200 μm diameter) to extract argon from individual laser pits in mineral grains in rock sections or separately (see “► [Structural Fabrics, \(\$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ \)](#)”; Kelley et al. 1994).

The potassium content and age of minerals are the two key parameters in determining the analytical approach. Higher potassium and older ages make analysis of smaller samples possible. Such samples can usefully be analyzed using UV laser to extract additional temporal and thermal information (e.g., Flude et al. 2013). High-potassium minerals are more commonly dated, but precise and geologically meaningful ages can be measured on minerals with low potassium content (e.g., Renne et al. 1997). In contrast Ar-Ar mineral dating of young volcanic rocks requires multiple grains analyzed as a pure mineral separate (e.g., Ton-That et al. 2001). Greater care is essential in dating all minerals since contamination is more likely to cause problems of interpretation. For example, a young volcanic rock can be dated using plagioclase, but it has become a common practice to briefly etch the grains using acid such as HF to remove any adhering glass or clay minerals because glass is more likely to contain high potassium contents and excess argon (e.g., Esser et al. 1997), and clay minerals may also contain significant potassium and younger ages.

What do mineral ages mean – closure and other models: The key property of mineral is that the ages they yield can be interpreted as a single geological event or a process such as cooling. Only in the case of geologically instantaneous volcanic eruption and cooling do all minerals in a rock yield a single age. When rocks cool more slowly or recrystallize, minerals yield different ages.

The capacity of mineral Ar-Ar dating to date a range of different types of event is the result of differing argon retention properties. Argon is a gas and diffuses through minerals at high temperature, but diffusion rates slow down at lower temperatures. The relationship between diffusion rate and temperature is exponential, so small changes in temperature cause rapid changes in diffusion rate. Considered over geological time, this diffusion rate change can approach a switch-like behavior and the point at which the Ar-Ar clock starts. Dodson (1973) formulated a mathematical solution to this process which made simplifying assumptions but proved to be very powerful tool in quantifying link between thermal closure and age that all later studies followed. The “closure temperature” concept (Dodson 1973) has been central to the popularity of mineral Ar-Ar dating because it provides both time and temperature simultaneously.

The early literature on closure temperatures is characterized by empirical closure temperatures for minerals; for example, biotite closure was considered to be around 300 °C, and most mineral closure temperatures are in geological useful range from around 150 °C to 500 °C. However, reliable experimental argon diffusion data is now available for all common potassium-bearing minerals, so mineral closure should always be calculated using the mineral-specific diffusion parameters (e.g., Baxter 2010), estimated grain size, and cooling rate. While the Dodson (1973) formula was a good estimate for simple cooling, many recent studies use a finite difference model (e.g., Wheeler 1996) both for whole-grain ages and within grain age variation. This type of model is capable of simulating the coupled loss of argon with varying temperature history, and coupled radiogenic production of

^{40}Ar , and has enabled a better understanding of metamorphic ages (e.g., Warren et al. 2012) including partial argon retention of Ar-Ar ages in high-pressure micas cycled through rapid orogenic burial and exhumation.

Another extension of closure temperature is the use of diffusion data derived from stepped or cycled heating of complex alkali feldspar mineral grains from granites and basement metamorphic rocks (e.g., Harrison and Lovera 2013). This approach has produced thermal histories from many individual mineral samples, although the interpretation has sometimes been controversial (e.g., Parsons et al. 1999).

- Not all mineral Ar-Ar ages can be interpreted in terms of closure due to slowing argon diffusion with temperature. In conditions close to the closure temperature, argon loss can also be controlled by deformation, grain-size reduction, and recrystallization (e.g., see “► [Structural Fabrics, \(\$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ \)](#)”). Fluids play a key role in recrystallization and mineral growth and some metamorphic mineral Ar-Ar ages, particularly amphiboles (e.g., Villa et al. 2000) and low-temperature K-feldspar (e.g., Mark et al. 2007).

Argon solubility, excess argon, and mineral Ar-Ar ages: One of the basic assumptions of Ar-Ar dating is that the mineral contains negligible amounts of ^{40}Ar at the point of closure. However, this assumption is “at odds” with experimental noble gas research which indicates that partition coefficients are not zero (e.g., Chamorro et al. 2002). Non-zero argon partition coefficients in turn imply that all minerals that reach equilibrium with silicate melt or hydrous liquid acquire low concentrations of non-atmospheric argon contamination. This conclusion appears to be a fundamental challenge to Ar-Ar mineral dating success, and yet most measurements yield geologically meaningful ages – so why is this?

There are some geological circumstances where Ar-Ar dating works less well and minerals yield anomalous ages caused by high concentrations of radiogenic argon not related to in situ potassium decay (Note that $^{40}\text{Ar}/^{36}\text{Ar}$ ratios of metamorphic fluids are never the same as the Earth’s atmosphere and commonly very high). There are two scenarios in which this can affect the mineral Ar-Ar age, which can be described as fluid present or open system and fluid absent or closed system (Kelley 2002b). In the fluid present system, high concentrations of excess argon in the fluid (melt or hydrous) lead to partition into the mineral or incorporation in a crystallizing mineral. In the fluid absent case, the lack of any fluid means that the minerals become the main reservoir for argon despite the temperatures exceeding those normally associated with closure (e.g., Kelley and Wartho 2000).

Recent work has helped to characterize these scenarios since argon solubility has been measured experimentally in hydrous liquids including sea water (summarized in Kelley 2002), and in silicate melts at high temperature (e.g., Carroll and Stolper 1993), and is in the range ~10–100 ppm for hydrous liquids and ~0.1–1 ppm for silicate melts. Experimental data has now revealed a reproducible pattern of solubility (Brooker et al. 2003; Heber et al. 2007) and discovered significant variations between mineral types (e.g., Jackson et al. 2013). Excess argon should thus be understood in terms of variable solubility and partition, in the same way as other trace elements are understood to partition between minerals.

Minerals Used for Ar-Ar Dating

- Minerals of several classes are used for mineral Ar-Ar dating, some more commonly than others. Orthosilicates have rarely been used for Ar-Ar dating and had a reputation for excess argon, but it

seems this was ill founded and mainly the result of their low potassium contents (100 s of ppm). There are several records of successful pyroxene dates in meteorites and recent work has shown that they can yield useful ages and argon diffusion rates in terrestrial rocks (Cassata et al. 2011). Framework silicates are very commonly dated, particularly alkali feldspars in igneous rocks where sanidine has yielded some of the youngest reliable Ar-Ar ages including the eruption of Vesuvius in AD 79 (Renne et al. 1997). Alkali feldspars have also been used in granites and basement rocks to date cooling and yield thermal histories (e.g., Harrison and Lovera 2013). Plagioclase is also a very commonly dated mineral, although the low potassium contents (0.05–1.0 wt%) make sample purity essential. Feldspathoids (up to 14 wt%) and anorthoclase (3–4 wt%) also yield reproducible ages but are less common. Chain silicates (amphiboles) are commonly dated, although they generally have lower potassium contents (generally 0.05–1.5 wt%). Sheet silicates including biotite, phlogopite, muscovite, and phengite (6–9 wt %) are all common mineral targets for Ar-Ar dating. Finally, clay minerals have also been dated using the Ar-Ar technique and illite is perhaps the most commonly used since it has similar potassium content to muscovite. Clay mineral dating using the Ar-Ar technique involves particular challenges caused by the recoil of ^{39}Ar during the irradiation process, although this has been successfully overcome by encapsulating pure clay mineral separates (see “► [K-Ar/ \$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ Dating](#)” and “► [Clays and Glauconites, \(\$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ \)](#)”).

Interpretation of Mineral Ar-Ar Dates

Mineral ages from igneous rocks: Mineral ages from lavas and volcanic deposits (i.e., tuff and tephra layers) provide chronostratigraphic markers that represent geologically instantaneous events, which are routinely used to calibrate the geological timescale (e.g., Kuiper et al. 2008; Rivera et al. 2011; Storey et al. 2012) and date paleomagnetic events, such as polarity reversals (e.g., Deino et al. 2002). Mineral ages are also used to assess the impact of explosive volcanic eruptions (e.g., Ton-That et al. 2001), correlate stratigraphy and biostratigraphy over large areas, and place an age upon and hominid activities (e.g., Deino and Potts 1992; Storey et al. 2012). High-temperature alkali feldspars, in particular sanidine, appear to be less susceptible to both xenocrystic contamination and excess argon and are readily used in Ar-Ar geochronology to determine the timing of volcanic eruption. Plagioclase is commonly used for dating basaltic igneous rocks where it is often the only K-bearing phase available (e.g., Renne et al. 1995), although their low K contents do mean that the incorporation of inherited and/or excess ^{40}Ar can cause significant increases to Ar-Ar apparent age determinations. Plutonic rocks are also dated using mineral Ar-Ar dates most commonly using micas or amphiboles since the lower-temperature feldspars yield cooling rather than crystallization ages, but even these minerals can yield ages significantly younger than U-Pb ages on minerals from the same intrusion.

Mineral ages from metamorphic rocks: Mineral Ar-Ar ages from metamorphic rocks provide key information on both time and temperature during cooling or crystallization as discussed above. Sequences of mineral ages such as muscovite, biotite, and alkali feldspar can yield extended portions of thermal history in some cases. However mineral Ar-Ar dates can also be complicated by processes that alter the Ar concentration both during and after crystallization (see “► [Metamorphic Terranes, \(\$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ \)](#)”). Measured mineral Ar-Ar ages may therefore relate to the timing of mineral crystallization and recrystallization, cooling following crystallization, and deformation with associated recrystallization. Careful petrographical observations allow the relative timing of (re)crystallization and/or deformation and the pressure-temperature history following crystallization to be estimated.

Geochronological data from other decay systems, such as U-Pb where “age” and metamorphic “stage” can clearly be linked, are useful for providing a solid framework in which to interpret the Ar-Ar data. In situ laser ablation methods allow Ar-Ar ages within grains to be measured to determine whether ages may be linked to changes in chemical composition, textural position, grain size, or regions of grain deformation (see “► [Structural Fabrics, \(\$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ \)](#)”). Numerical modeling provides constraints on the expected ages for different grain sizes at different cooling/decompression rates in cases where an open grain boundary network may be assumed (e.g., Warren et al. 2012). In all cases the relative petrographical framework and geochronological constraints from other systems can be used to determine whether mineral grains degassed efficiently at high temperatures or whether they might contain additional or “excess Ar” sourced from a precursor K-bearing mineral, a neighboring K-bearing mineral in a closed system where fluid absence prevented its escape, or alternatively argon in a concentrated fluid in which the mineral was crystallizing.

Sedimentary rocks: Mineral Ar-Ar ages provide two important types of information, detrital mineral ages from clastic rocks (often muscovite but also occasionally alkali feldspar and biotite) and ages for newly grown low-temperature minerals including clays (see “► [Clays and Glauconites, \(\$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ \)](#)”) and authigenic alkali feldspar. Ar-Ar ages for detrital minerals became popular when techniques were developed for analyzing individual grains (e.g., Kelley and Bluck 1992). Bulk ages were only ever useful as general indicators, whereas dating individual mineral grains enabled comparison not only of the time lag between cooling/erosion and deposition but also age variations within individual samples. This capability has been exploited to understand mountain building and erosion processes including recycling (e.g., Sherlock 2001; Najman et al. 2001) and determining glacial source regions (e.g., Hemming and Hajdas 2003; Reynolds et al. 2004). Mineral Ar-Ar ages for authigenic minerals are less common mainly because of the issues of obtaining pure separates and recoil effects upon the submicron grains (see “► [Clays and Glauconites, \(\$^{40}\text{Ar}\$ - \$^{39}\text{Ar}\$ \)](#)”). However other authigenic minerals are known to yield meaningful ages. Alkali feldspar overgrowths have been successfully dated using UV laser ablation (e.g., Mark et al. 2007) and can indicate both authigenesis and multiple fluid flow events (e.g., Sherlock et al. 2005). Gangue minerals such as cryptomelane have also been successfully dated (Vasconcelos et al. 1992).

Jack Hills Zircon

Simon A. Wilde*

School of Applied Geology, Curtin University, Perth, Australia

Definition

The Jack Hills are located ~800 km north of Perth, Western Australia, within the Archean Narryer Terrane. They became internationally known as the site of the world's oldest crystals (Compston and Pidgeon 1986; Wilde et al. 2001; Mojzsis et al. 2001).

Initial investigation at Mt. Narryer (~50 km southwest of Jack Hills) led to the discovery of a granulite-facies quartzite containing detrital zircons with an age ~4,150 Ma (Froude et al. 1983). Subsequent work on a greenschist facies conglomerate from Jack Hills (W74 site on Eranondoo Hill) led to the identification of two even older zircon grains with ages of $4,276 \pm 12$ Ma (Compston and Pidgeon 1986). A reinvestigation of zircons from that site identified one grain that recorded a $^{207}\text{Pb}/^{206}\text{Pb}$ age of $4,404 \pm 8$ Ma (Wilde et al. 2001), the oldest age obtained from terrestrial material.

Jack Hills' zircons have continued to provide important information on the early Earth. This has included oxygen, lithium, and lutetium-hafnium isotopic data and titanium-in-zircon thermometry, as well as studies at the atomic level on lead distribution. Initial studies of oxygen isotopes identified elevated $\delta^{18}\text{O}$ values, implying zircon growth in rocks previously subjected to interaction with surface waters (Wilde et al. 2001; Mojzsis et al. 2001), leading to the hypothesis of a cool early Earth (Valley et al. 2002).

More controversial is whether the oxygen data require the presence of oceans and continents in the Hadean and whether plate tectonics was operative at this time (Hopkins et al. 2008). This is compounded by the lack of direct evidence on the nature of the protolith of the ancient detrital zircons. However, lutetium-hafnium data are consistent with the protolith being an intermediate to mafic igneous rock, with the possibility that it was formed from consolidation of a magma ocean at ~4.45 Ga (Kemp et al. 2010).

Uranium Series, Ice

Stephanie A. Ewing*

Department of Land Resources and Environmental Sciences, Montana State University, Bozeman, MT, USA

Definition

Use of intermediate decay products within the ^{238}U or ^{235}U radioactive decay chains to evaluate the age or history of glacial ice and ground ice in permafrost.

Introduction

Uranium-series isotope disequilibrium effects provide a means of dating ice in terrestrial environments where mineral particles entrained in ice produce recoil-derived isotopes that are redistributed into the interstitial ice. Detectable recoil-driven disequilibrium in activity ratios of ^{234}U and ^{238}U , here indicated as ($^{234}\text{U}/^{238}\text{U}$), occurs over timescales of 10^3 – 10^6 years and has been extensively observed in natural waters as a function of water–rock contact (see, e.g., Bourdon et al. 2003; Porcelli and Swarzenski 2003). In a few studies, recoil effects have been used to derive age information for ice, based on mineral–ice contact in permafrost and ice cores of sufficient age (Ewing et al. Unpublished data; Fireman 1986; Goldstein et al. 2004; Aciego et al. 2011). Given the growing need for alternative dating techniques to reliably link paleoenvironmental records for the cryosphere over long timescales ($>20,000$ years), particularly in discontinuous frozen cores (Goldstein et al. 2004), it is probable that U-series applications in cryospheric environments will continue to receive attention. Moreover, waters mobilized by thawing ice with inherited U-series disequilibrium may provide a metric for hydrologic outcomes of a warming climate (Kraemer and Brabets 2012), if the extent and duration of mineral–ice contact is known.

Age Equation

When mineral particles at or near secular equilibrium are suspended in ice for sufficient time, disequilibrium of parent–daughter pairs within U-series decay chains occurs as a function of alpha-recoil loss from the mineral particle surfaces into the ice and alpha decay within the ice (Fig. 1). This recoil-driven disequilibrium can be used to derive age information for the ice based on activity ratios (A) of the parent–daughter pair in ice (A_{ice}) and initial water (A_{initial}), the fraction of mineral material subject to recoil loss (f_{α}), and the distribution of U between solids and thaw water (R_s). If a closed system is assumed, the age of the ice (t_{ice}) can be expressed in terms of activity ratios as (Fireman 1986; Aciego et al. 2011):

*Email: stephanie.ewing@montana.edu

Fig. 1 Schematic of recoil accumulation of ^{234}U daughters in ice from a dust particle with surface roughness that increases the recoil fraction relative to the geometric surface area predicted for a smooth surface (Aciego et al. 2011; used with permission). Weathering rinds may alter surface roughness and change mineral-fluid evolution over time (Andersen et al. 2007; Pelt et al. 2008)

$$t_{\text{ice}} = -\left(\frac{1}{\lambda_{234}}\right) \ln \left[\frac{A_{\text{ice}} - f_{\alpha} R_s - 1}{A_{\text{initial}} - f_{\alpha} R_s - 1} \right] \quad (1)$$

where λ_{234} is the decay constant for ^{234}U and R_s is the ratio of ^{238}U in the solid to ^{238}U in the ice. An example of the evolution of $(^{234}\text{U}/^{238}\text{U})$ values in ice simulated over time using an appropriate range of f_{α} and R_s values can be seen in Fig. 2, with reference to observed values in permafrost.

Ice Cores

A key study in the development of U-series as an indicator of ice age focused on ice from the Allan Hills area of Antarctica (Fireman 1986), where dusty ice samples were observed to contain ^{222}Rn in proportion to dust content. Longer-lived U-series isotopes were then examined in order to date the ice based on its dust content. Activities of ^{226}Rn , ^{230}Th , and ^{234}U were used to obtain a date of $210\text{--}330 \times 10^3$ years for the ice based on a presumed recoil fraction (f_{α}) of 0.25; however, subsequent work has argued for younger ages (30,000 years) based on improved leaching techniques and inheritance from precipitation ($(^{234}\text{U}/^{238}\text{U})_{\text{initial}} = 1.4$) (Goldstein et al. 2004). More recently, $(^{234}\text{U}/^{238}\text{U})$ values were evaluated for samples from the EPICA (European Project for Ice Coring in Antarctica) Dome C ice core (Aciego et al. 2011), resulting in model ages of $83\text{--}870 \times 10^3$ years for sections within the $\sim 3,200$ m core, based on micro-BET measurements and consideration of a fractal dimension to compute recoil fractions ($f_{\alpha} = 0.14\text{--}0.22$), as well as an assumed initial $(^{234}\text{U}/^{238}\text{U})$ of 1.14. In this analysis, $(^{234}\text{U}/^{238}\text{U})$ values increased with depth as expected for ice core, and derived ages were consistent with other measures of age in the core, although uncertainties were $\sim 25\text{--} > 50\%$ due to uncertainty in recoil fractions (f_{α}) and uranium distributions (R_s).

Fig. 2 Evolution of $(^{234}\text{U}/^{238}\text{U})_{\text{ice}}$ values in central Alaska permafrost samples from borehole A9 at depths of 102–2,069 cm (indicated in sample number), assuming a starting value in precipitation of 1.161 (Ewing et al. [unpublished data](#)). Values increase with depth (time) as expected for syngenetic permafrost (French and Shur 2010) and are consistent with ice-core depth trends (Aciego et al. 2011). Curves represent modeled activity ratios over time in ice, derived using Eq. (1), and the observed $(^{234}\text{U}/^{238}\text{U})_{\text{ice}}$ values at the indicated depths in cm, the appropriate combinations of recoil fraction based on BET surface area ($f_{\alpha} = 0.11\text{--}0.23$), and a fitted ratio of U concentrations in the mineral particles versus ice ($R_s = 5.7\text{--}32.3$) based on a leaching experiment. Variation in values of f_{α} and R_s explains variability in the degree of increase in activity ratios with depth (corresponding to time). Calibration of the $(^{234}\text{U}/^{238}\text{U})_{\text{ice}}$ -derived age model was provided by an analysis of dissolved organic carbon in the sample at 102 cm (A9.0102), which had a radiocarbon age of 8,100 years

Permafrost

Evidence of elevated $(^{234}\text{U}/^{238}\text{U})_{\text{ice}}$ values in thawing permafrost has been inferred from surface water data (Kraemer and Brabets 2012; Koch et al. 2013) and measured directly in syngenetic (ice-rich) loess permafrost cores from central Alaska (Fig. 2; Ewing et al. [Unpublished data](#); Koch et al. 2013). In the permafrost core study (Ewing et al. [Unpublished data](#)), model ages of $\sim 2,000\text{--}80,000$ years were derived from $(^{234}\text{U}/^{238}\text{U})_{\text{ice}}$ values in sections of core obtained from 0.8 to 20 m depth. The observed $(^{234}\text{U}/^{238}\text{U})_{\text{ice}}$ values increased with depth in multiple cores, consistent with expectations based on syngenetic permafrost formation through upward propagation of permafrost with concurrent loess deposition. Modeled age results were based on R_s values of 5–18 derived from a leaching experiment on five samples and f_{α} values of 0.11–0.23 derived from BET measurements in five samples with organic matter removed (assuming no fractal effect in calculation of recoil fractions). As observed for Antarctic ice cores, uncertainties in the analysis of permafrost samples were also substantial (up to an order of magnitude), reflecting the need for improved assessment of surface area, secondary phases, and U distribution.

An important distinction from ice cores is that syngenetic loess permafrost has mineral contents of $\sim 50\%$ by volume, or roughly 700 mg of loess per kg of total sample, whereas even dusty ice core has on the order of 1 mg dust per kg sample, resulting in lower mineral surface area on a sample volume basis and much lower U abundance throughout. Additionally in permafrost, the starting value of precipitation may be less easily inferred than in continuous ice core due to active layer freeze–thaw dynamics (Ewing et al. [Unpublished data](#); French and Shur 2010).

Complications

Several complications in the assessment of ice age using U-series isotopes merit further study. The first is the starting value of precipitation, which can dramatically affect model age values (Goldstein et al. 2004). Second, the recoil fraction (f_r) is a function of surface area and recoil distance, with complications related to the scale of surface roughness and particle shape, such that mathematical derivation from BET measurements is needed (Bourdon et al. 2009; Aciego et al. 2011). Moreover, the measurement of BET in very small dust samples within ice cores poses challenges, but has been addressed in one study (Aciego et al. 2011). A third key complication arises where liquid water is present due to abundant mineral surface area in relatively shallow permafrost environments, and weathering rinds may develop on particle surfaces over time, altering surface roughness (Andersen et al. 2007; Pelt et al. 2008). Finally, the separation of ice from mineral phases for analysis can be challenging, and buffered solutions (e.g., EDTA, ammonium) have been used to prevent redistribution of U-series elements during separation as a result of their geochemical character (Goldstein et al. 2004; Aciego et al. 2009, 2011).

Summary

The validity of dating ice with U-series model ages has been demonstrated, but with substantial uncertainty derived from difficulties in measuring surface area and U distribution. Complementary dating methods are needed to corroborate this approach in permafrost and ice core studies. Nevertheless, field and stratigraphic evidence suggests that ground ice can be preserved for hundreds of thousands of years despite large changes in climate over that time span (Froese et al. 2008; Reyes et al. 2010). Consequently, it is likely that application of U-series age models for ice in conjunction with other dating tools (radiocarbon, luminescence, amino-acid racemization) will continue to be investigated in cryosphere environments. Moreover, chronological constraint of ice-preserved paleoecological histories continues to be an important area of climate-change investigation and may benefit from age evaluation based on U-series isotopes in ice cores.

Luminescence, Geomorphological Processes

Stephen Tooth*

Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, Ceredigion, Wales, UK

Definition

Geomorphology is the science that studies the origin and development of landforms and how those landforms combine to form landscapes. Landforms are shaped by *geomorphological processes*, many of which involve the weathering, erosion, transportation, and deposition of surface materials (rock, sediment) by gravity, ice, wind, or water. Both erosional and depositional landforms can be identified, and study objectives may include establishing (1) the initial timing of surface material movement (hence, landform age), (2) the timings of subsequent surface material movement (hence, landform development rate), and (3) the nature of surface material movement (sediment dynamics). Using a similar threefold breakdown, the focus here is on how *luminescence dating* can contribute to these objectives. Luminescence dating is a family of techniques most suitable for investigating fine-grained (typically silt, sand) depositional landforms. The basic principles of luminescence dating and the various techniques are explained in other entries (e.g., see “► [Luminescence Dating](#)”), and the emphasis here is mainly on optically stimulated luminescence (OSL) dating, which typically can be applied to quartz-rich sediment ranging in age from a few years to several hundred thousand years.

Principal Applications of Luminescence Dating in Geomorphology

Luminescence dating relies on the exposure of transported sediment to light prior to deposition and burial of that sediment. Consequently, OSL and other luminescence techniques are best suited to the investigation of depositional landforms originating and/or developing as a result of one or more of the following processes, all of which involve varying degrees of sediment exposure to light: aeolian (e.g., loess sheets, dunes), colluvial (e.g., aprons, glacis), fluvial (e.g., alluvial fans, river terraces), and wave and tidal action (e.g., beach ridges, spits). Luminescence techniques have been less widely applied to the investigation of glacial, deeper marine, tectonic and volcanic processes because of reduced exposure of sediment to light and/or less suitable (coarser or finer) grain sizes or minerals, although techniques are being developed to cater for these issues (see “► [Luminescence, Deep Sea Marine and Lacustrine](#)”, “► [Luminescence, Glacial Sediments](#)”, “► [Luminescence, Earthquake and Tectonic Activity](#)”). Numerous recent reviews have outlined the applications of luminescence dating in specific areas of geomorphological research (e.g., Duller 2004; Singhvi and Porat 2008; Fuchs and Lang 2009; Cunningham and Wallinga 2012), and the following provides only a brief outline of three main, possibly interrelated, applications.

*Email: set@aber.ac.uk

Fig. 1 Examples of possible strategies for luminescence sample collection and the insights into geomorphological processes and landform dynamics that may result: **(a)** Cross-sectional view of aeolian linear dunes **(b)** Cross-sectional view of an incised river and flanking alluvial deposits

The Initial Timing of Sediment Deposition

Commonly, luminescence dating is used to establish the initial timing of sediment deposition, thereby providing information on landform age. Examples include OSL dating of the timing of aeolian deposition in deserts (e.g., Hollands et al. 2006); in such instances, the ages for the basal aeolian sediments provide *maximum* ages for the overlying dune landforms (Fig. 1a). Similarly, luminescence dating of basal sediment can help establish the maximum ages of a variety of other landforms including colluvial aprons (e.g., Botha et al. 1994), lacustrine beach ridges (e.g., Nanson et al. 1998), and river floodplains and terraces (e.g., Keen-Zebert et al. 2013). In addition, dating of the initial timings of deposition in adjacent landforms may be used to provide bracketing ages for geomorphological processes that partly involve erosion; for example, the timing of river incision can be bracketed by establishing an age for the alluvial sediments into which a river has incised, and an age for the sediments subsequently deposited within the incision slot (Fig. 1b). The former provides a maximum limiting age for incision and the latter a minimum limiting age for incision, thereby bracketing the actual timing of incision (e.g., Keen-Zebert et al. 2013).

Fig. 2 Examples of possible strategies for luminescence sample collection where the focus is on establishing landform development rates: **(a)** Cross-sectional and plan view of a laterally migrating and longitudinally extending aeolian linear dune **(b)** Cross-sectional and plan view of a laterally migrating meander, with scroll bars formed on the inside bend. OSL ages for scroll bars and the oxbow lake infill are derived from Rodnight et al. (2005) and Tooth et al. (2009) **(c)** Plan view of a prograding coastal spit and back barrier complex **(d)** Side view of a vertically accumulated loess-paleosol succession

The Timings of Subsequent Sediment Deposition

Typically, establishment of the initial timing of deposition is coupled with the investigation of the timings of subsequent deposition, thereby providing information on landform development rate. Examples include using multiple luminescence ages from sediment bodies to establish vertical accretion rates (Fig. 1), but sampling strategies also can be designed to establish dune lateral migration and/or forward extension rates (Fig. 2a), meander bend growth rates (Fig. 2b), or coastal progradation rates (Fig. 2c) (e.g., Bristow et al. 2005; Rodnight et al. 2005; Hollands et al. 2006; Roberts and Plater 2007; Rink and López 2010; Telfer 2011). In cases where single or multiple bracketing ages for river incision can be established (e.g., across a flight of alluvial terraces), these can be coupled with the depth of incision to provide a mean long-term incision rate (Fig. 1b). Establishing OSL ages for relatively unmodified sediments above and below paleosols can also help to bracket soil formation rates (Fig. 2d), as has been demonstrated in studies of loess, aeolian dunes, and sand ramps (e.g., Roberts 2008; Fujioka et al. 2009; Telfer et al. 2012).

Fig. 3 Schematic comparison between OSL ages for bedload sand in paleochannels of the Klip River, South Africa, and the generally younger ^{14}C ages for overlying organic-rich sandy muds (modified from Rodnight et al. 2006)

The Nature of Sediment Movement

Some recent applications of luminescence techniques have focused less on the timing and rates of landform development and more on sediment dynamics. For instance, OSL dating has been used in combination with hydraulic modelling to provide fundamental insights into the nature of storage and flushing of fine-grained matrix sediments in small mountain streams in southeast Australia (Thompson et al. 2007), and investigations of downstream quartz sensitivity (brightness) change in larger, lower gradient Australian rivers potentially may provide information on river style and associated fluvial processes, including bedload transport rate, and water depth and turbidity (Pietsch et al. 2008). In other geomorphological contexts, a variety of analytical approaches have been employed to investigate other aspects of local sediment dynamics, including bioturbation and its implications for depositional stratigraphy and luminescence chronologies (Bateman et al. 2007).

Key Issues in Applications of Luminescence Dating in Geomorphology

The following outlines some overarching considerations that arise from applications of luminescence dating in geomorphology.

Sampling Design and Age Consistency

Careful sampling designs can help to provide an internal check on luminescence age consistency. For instance, luminescence ages for the underlying sediments upon which the basal aeolian or fluvial sediments have been deposited provide a *maximum* limiting age for subsequent development of the dune or floodplain and clearly should be older than the maximum ages established by dating of the basal aeolian or fluvial sediments underlying the landform of interest (Fig. 1). In addition, where several samples have been collected in vertical, lateral, or longitudinal sequence within or across landforms, normal stratigraphic principles apply; the luminescence ages for sediment that is superimposed upon, laterally adjacent to, or cross-cutting pre-existing sediment should be younger than the ages for the preexisting sediment (Fig. 2b).

Comparison with Independent Geochronometers

Confidence in the veracity of luminescence ages also can be provided by comparisons between different luminescence techniques and by comparison with other geochronometers. For Australian fluvial sediments, comparisons have been made between OSL and TL ages (see “► [Luminescence Dating, History](#)”, for TL); in these instances, the ages commonly overlap within error and have been used to argue for the veracity of TL ages in those settings (Nanson et al. 2005; Maroulis et al. 2007). More commonly, luminescence ages have been compared with chronologies obtained using different techniques on the same sediment layers or from underlying or overlying sediment layers

(e.g., Madsen et al. 2005; Rodnight et al. 2006). For instance, in the Klip River wetlands, South Africa, OSL dating was used to establish the age of sandy paleochannel sediments, while ^{14}C dating (see “► [\$^{14}\text{C}\$ Dating](#)”) was used to establish the age of post-abandonment, organic-rich infills (Rodnight et al. 2006). As expected, the ^{14}C ages tended to be younger than the OSL ages (Fig. 3), thus providing support for the OSL analyses.

Comparison with Other Paleoenvironmental Datasets

Luminescence dating can establish the timing, rates, and nature of sediment movement, but a common aim of geomorphological enquiry is to identify the drivers of change. Drivers of change may be intrinsic to the system dynamics; for example, vertical accretion, lateral migration, and/or forward extension of aeolian dunes, meander bends, or coastal spits (Fig. 2a–c) can occur under conditions of constant sediment supply and steady wind regime, discharge, or wave energy. Commonly, however, drivers of change are extrinsic to the system and result from wider paleoenvironmental changes, including those related to climatic, sea level, tectonic, volcanic, or anthropogenic perturbations. Where paleoenvironmental changes lead to marked increases in the magnitude and frequency of river flooding, for instance, this may lead to increased rates of floodplain vertical accumulation or meander bend migration. These changed rates may be established by OSL dating, but inferences regarding the drivers of change require comparison with independently dated paleoenvironmental datasets. Uranium-thorium-dated (see “► [U-Series Dating](#)”) or ^{14}C -dated lacustrine, cave, or marine deposits, for instance, are commonly used to derive proxy records of paleoclimate change (e.g., past precipitation, temperature, and/or vegetation, or some combination thereof, such as indices of moisture availability). A lack of close correspondence between the timing and rates of landform changes established by luminescence dating and the changes in these proxy records might suggest that the dynamics have been driven independently of paleoclimate, such as by intrinsic system dynamics or by some other paleoenvironmental factor (e.g., past tectonics). Where close correspondence exists, however, this provides a basis for paleoclimatic interpretation of the landform changes, and this line of reasoning has been widely adopted in geomorphological enquiries.

Limitations of Luminescence Dating in Geomorphology

Although the comparison of luminescence chronologies with other paleoenvironmental datasets is common in geomorphological enquiry, potential problems may impinge on this objective. Two common problems are outlined below.

An Inability to Establish Finite Luminescence Ages

Where the sediment being dated has a depositional age that approaches or exceeds the age range of the luminescence technique, then saturation of the luminescence signal may occur (see “► [Luminescence Dating, Uncertainties and Age Range](#)”). In such instances, it may not be possible to determine a finite age, and only a minimum age for deposition can be reported (e.g., >XX years). Although this may provide useful information – for instance, in confirming that basal sediments have minimum ages older than finite ages for overlying sediments – it does not allow calculation of finite vertical accumulation, lateral migration, or forward extension rates and precludes detailed comparison with other paleoenvironmental datasets.

Fig. 4 Hypothetical but realistic illustration of the problems in attempting to correlate luminescence ages (in this instance, from fluvial samples) and associated error bars with the paleoenvironmental changes (paleomoisture index) recorded in higher-resolution datasets for the last 50 kyr. Errors associated with OSL ages generally increase farther back in time and so may encompass one or more peaks and troughs in the paleomoisture index. Consequently, it may not be clear whether periods of fluvial activity identified by the OSL ages have been driven primarily by relatively wet, relatively dry, or transitional (wet-dry, dry-wet) conditions

Limited Precision of Luminescence Ages

Luminescence ages are reported with errors that reflect random and systematic uncertainties; for OSL ages, errors at one sigma (68 % confidence interval) are typically around 5–10 % of the sample age (e.g., see Figs. 2b and 3). Hence, although the central age is the most likely, there is actually a 68 % chance that the sample age lies within the reported error range. In some instances, this means that OSL ages for adjacent landforms will overlap within error, causing uncertainty when calculating rates of change. For instance, across a scroll bar sequence in the Klip River floodplain, South Africa, most OSL ages were in the correct order and did not overlap, thereby indicating an approximately steady lateral migration rate of ~0.16 m/year over the last ~1 kyr. Two ages in the middle of the sequence, however, overlapped within error (Fig. 2b – samples 3 and 4). In such situations, it may be unclear whether the overlapping ages reflect increased analytical uncertainty associated with particular ages or whether they reflect a short-term increase in the lateral migration rate, although the latter explanation was preferred in the Klip River case (see Rodnight et al. 2005). The limited precision of OSL ages also limits the potential for comparison with high-resolution paleoenvironmental datasets derived from, say, lacustrine, cave, or marine sediments; errors on OSL ages may overlap with identified fluctuations in past precipitation, temperature, vegetation, or moisture availability (see Fig. 4), even those occurring over multimillennial scales, such that paleoenvironmental drivers are hard to establish. In the case of alluvial fans in Death Valley, California, USA, Dorn (1996) has argued that imprecision in many geochronometers means that climatic hypotheses of fan formation are not testable; with some caveats, this argument could be extended to OSL analysis of other landforms. Commonly, however, the lack of precision is acknowledged, and correlation with paleoenvironmental datasets is made using the central ages (e.g., Macklin et al. 2010).

Awareness of these limitations is important when considering the applicability of luminescence dating in geomorphological enquiry, and some may be partially overcome by future developments. For instance, ongoing analytical work using thermally transferred OSL (TT-OSL) is attempting to extend the luminescence dating age range (Rhodes 2011); in future, this may enable comparisons with longer paleoenvironmental datasets, possibly including those extending back ~500 kyr or farther, although any finite ages are still likely to be associated with large errors. In other instances, the use of luminescence dating in combination with other geochronometers may provide the best approach. In central Australia, for instance, relatively young luminescence saturation ages (typically <100 ka) mean that OSL cannot be used to determine the age of aeolian linear dunes that may

be many hundreds of thousands or even millions of years old. Hence, Fujioka et al. (2009) combined cosmogenic burial dating (see “► [Cosmogenic Nuclide Dating](#)”) and OSL dating to investigate histories of dune building; cosmogenic (^{10}Be – ^{26}Al) burial dating of the basal sediments helped to determine that the first dunes formed in the western Simpson Desert ~1 Ma, while dating of younger, overlying sediments using OSL indicated that episodic dune reworking and building occurred during late Quaternary glacial intervals. Similarly innovative sampling designs that employ complementary geochronological techniques may be a hallmark of future geomorphological enquiries.

Conclusions

Over the last few decades, luminescence dating has contributed to a revolution in our understanding of the timing, rates and nature of many geomorphological processes, and their implications for landform and landscape development. Despite some limitations, this increased understanding has occurred in parallel with increasing insight into the paleoenvironmental drivers of change. Further innovations in luminescence sampling approaches (e.g., adoption of “range-finder” OSL dating – Durcan et al. 2010) and ongoing analytical advances (e.g., wider application of single grain OSL dating, the increasing use of feldspars as chronometers, and the development of TT-OSL – Rhodes 2011) mean that luminescence dating is likely to remain an essential part of the geomorphologist’s “toolkit” in the decades to come. This will provide fertile ground for interdisciplinary work in scientific and applied contexts, such as in archaeology, paleoanthropology, paleoseismicity, and environmental management (e.g., Rittenour 2008; McCarthy et al. 2010; Barré et al. 2012; see also “► [Luminescence Dating of Archaeological Sediments](#)”, “► [Luminescence, Dispersion of Early Modern Humans](#)”).

[Tree-ring dating](#)

Definition

Dendrochronology is literally “the study of tree time” and is the science of assigning calendar-year dates to the growth rings of trees. It is based on the fundamental principle of cross dating (Fig. 1), which is classically defined as “the procedure of matching ring width variations. . . among trees that have grown in nearby areas, allowing the identification of the exact year in which each ring formed” (Fritts 1976, p. 534). Cross dating “utilizes the presence and absence of [ring] synchrony from different cores and trees to identify the growth rings that may be misinterpreted” (Fritts and Swetnam 1989, p. 121). Three aspects warrant emphasis. First, tree-ring dating requires ring pattern matching, not ring counting. Second, sample sizes must be large, so that tree-growth variability in a given region is well understood. Third, one begins by studying living trees in a given area, cross dating their ring series internally, and working back in time to successively older specimens that are usually found as dead snags on the landscape or as construction beams in ancient dwellings (Nash 1999).

Methods

The process of dating an archaeological tree-ring specimen requires, first and foremost, creation of a smooth surface on which all the growth rings are clearly visible. This smoothing is achieved using standard wood-working equipment and progressively finer-grit sandpaper (up to American National Standards Institute 400 grit; 20.6–23.6 μm or thousandths of a millimeter), such that individual cell walls on the specimen can be seen. Once a smooth, clear surface is prepared, the dendrochronologist can measure individual ring widths using specialized hardware (like a Velmex™ measuring stage, precise to 0.001 mm, or similar equipment) interfaced with a computer running specialized software (like MeasureJ2X™ software or similar programs). Once all rings have been accurately and precisely measured, open-source COFECHA software is used to compare the ring-width measurement series to previously developed local or regional tree-ring chronologies in order to suggest dating possibilities, which must then be checked against the original wood specimen. If all goes well, calendar dates may then be assigned to each growth ring on that specimen. In places like the American Southwest, where tree growth is often quite sensitive

*Email: stephen.nash@dmns.org

Fig. 1 Cross dating, the basic principle of tree-ring dating, illustrated. The landscape across the American Southwest has living trees, dead but exposed snags and remnant trees, and archaeological wood preserved in existing structures and cliff dwellings. A dendrochronologist begins by analyzing long ring growth patterns in cores from living trees (represented by “A” in the top portion of the figure). He/she then analyzes long ring series in successively older specimens from dead snags and remnant trees (represented by “B” in the top portion of the figure), taking care to make sure that the ring series overlap by at least 50 years. Finally, he/she analyzes ring series in archaeological wood (or charcoal) specimens (represented by “C” above), again making sure that the ring series overlap by at least 50 years, to develop a long master chronology. Once a master tree-ring chronology (represented by A + B + C above; in reality chronologies are based on dozens of specimens) has been developed, newly collected archaeological and historic tree-ring specimens (represented by specimens A through J in the lower portion of the figure) may be analyzed and dated against this master ring-width chronology (Courtesy of the Laboratory of Tree-Ring Research)

to precipitation, cross dating can be performed by hand, as it was originally developed by Andrew Ellicott Douglass in the early 1900s (Douglass 1929; Nash 1999).

In the Douglass method, the dendrochronologist prepares a smooth surface as above but then creates a summary graphic representation of the specimen’s ring-width variability known as a skeleton plot, in which long lines are written on graph paper to indicate relatively narrow rings, a “B” indicates a relatively large ring, and in which other unique attributes (e.g., wide or narrow earlywood or latewood bands) are noted that may assist in dating (Fig. 2; see Stokes and Smiley 1968). The skeleton plot is then visually compared to the previously developed local or regional master tree-growth chronology. When the ring-width pattern summarized on the skeleton plot matches the local or regional growth pattern on the master chronology and all missing, double, or locally absent rings on the specimen have been identified, an accurate and precise date can be assigned to all rings on that specimen.

From a dendrochronological perspective, all cross-dated and verified tree-ring dates are created equal; there is no statistical uncertainty associated with cross-dated tree-ring dates, which are the most precise chronometric data available to archaeologists in the absence of historic records (Jacoby 2000). Unfortunately, and for a variety of reasons including chaotic or complacent ring growth, poor preservation, and other factors, many tree-ring specimens simply cannot be dated,

Fig. 2 A skeleton plot for a wood specimen collected from a cliff dwelling in the American Southwest. Especially long lines on the graph represent especially narrow rings on the specimen, which are caused by especially dry years in the tree's existence. The date for the last ring present on the specimen is A.D. 1273; the "vv G incom." suffix describes noteworthy specimen attributes that modify the outside date. The "vv" indicates that it is a noncutting date and that there is no way of estimating how far it is from an actual date-of-death of the tree. The "G" indicates, however, that galleries from wood-boring beetles are present on the outside of the specimen; the "incomp." indicates that the outer growth ring is incomplete, suggesting that the tree was cut down during its growth season, usually late spring or early summer (Courtesy of the Laboratory of Tree-Ring Research)

either quantitatively or by the Douglass method. In this situation, dendrochronologists should not succumb when archaeologists ask for a "likely date" for a specimen, nor should they use independent archaeological data to propose a probable date for an undated specimen (Baillie 1995). Once a cross-dated tree-ring date is determined, the interpretation of that date within its archaeological context becomes the archaeologist's responsibility (Dean 1978). From this perspective, all tree-ring dates are *not* created equal, and an extensive body of theory has been developed to guide the proper interpretation of archaeological tree-ring dates (Bannister 1962; Dean 1978; Hillam 1987, 1998).

Tree-ring dating is most commonly used in the North American Southwest, where ponderosa pine (*Pinus ponderosa*), Douglas fir (*Pseudotsuga menziesii*), pinyon pine (*Pinus edulis*), and juniper (*Juniperus scopulorum*) are sensitive to variations in precipitation, are well preserved in the archaeological record, and were commonly used by indigenous populations. Dated sites include cliff dwellings like those at Mesa Verde National Park, standing architecture at Chaco Canyon National Historical Park, and pit houses across much of the region. In the southeastern United States, researchers focus on dating baldcypress (*Taxodium distichum*), juniper (*Juniperus sp.*), white oak (*Quercus alba*), and other species. Dated sites include standing historic structures and a very small number of archaeological sites, which remain poorly dated because wood specimens are not well preserved in wet environments and because historic deforestation in the region makes it difficult to build long chronologies going back in time. In Western Europe and the Mediterranean, dating efforts focus on oak (*Quercus sp.*), juniper (*Juniperus sp.*), and other species, which are used to date churches, dwellings, ship wrecks, and a wide variety of other archaeological and historic features (Nash 2002).

In theory, tree-ring dating is a relatively straightforward process; in practice it can be astonishingly difficult. It requires rigorous sample collection and preparation, methodical attention to

detail, and deep knowledge of tree-growth characteristics and wood attributes across vast regions. For additional information and resources on the method, theory, and results of tree-ring dating, see Henri Grissino-Mayer's excellent *Science of Tree-Rings* website (<http://web.utk.edu/~grissino/>; accessed 14 August 2013).

Origins

Andrew Ellicott Douglass, the father of dendrochronology, introduced tree-ring dating in “Talkative Tree-Rings and the Tales They Tell,” published in the December, 1929, issue of *National Geographic* magazine (Douglass 1929). He offered tree-ring dates for dozens of archaeological sites in the American Southwest. As a result, archaeologists were forced to revise their interpretation of southwestern prehistory, for they had grossly overestimated the age of the ruins (Nash 1999). Nearly as important, however, was Douglass' inference that a “Great Drought” had occurred across the American Southwest from A.D. 1276 until 1299 and that it had affected pre-Columbian populations living in the area, thus, also began the field of dendroclimatology.

Types of Information

The analytic and interpretive utility of tree-ring dating stems from the fact that it can inform archaeological research in three broad arenas: chronometric, environmental, and behavioral (Dean 1996a). The chronometric aspect of tree-ring dating has the longest history and is the most commonly known – tree rings can be used to date objects, features, dwellings, and sites. By extension, tree-ring dates can be used to date abstract archaeological entities such as periods, stages, phases, and styles. The environmental aspect of modern tree-ring dating today enjoys the most worldwide application, as tree rings can be used to reconstruct numerous environmental variables, including temperature, precipitation, stream flow, drought severity, fire frequency and intensity, insect infestation, atmospheric circulation patterns, and others. The behavioral aspect of tree-ring dating allows archaeologists to make inferences regarding wood-use practices, trade, and other economic variables (Dean 1996b; Towner and Clary 2001; Towner et al. 2009; Towner and Creaseman 2010; Windes 2010).

Cutting Dates, Noncutting Dates, and Date Clusters

The difference between cutting dates and noncutting dates is important, as is the concept of date clustering. *Cutting* dates are assigned to cross-dated wood or charcoal specimens that possess evidence that the last ring present on the specimen was the last ring grown by the tree before it died. *Noncutting* dates are assigned to cross-dated specimens if there is no evidence indicating that the last ring present on the specimen is the last one grown before the tree died. Note that cutting and noncutting dates are not mutually exclusive – a noncutting date *may* actually record the date of a tree's death, but there happens to be no discernable, definitive criteria (e.g., bark, beetle galleries, patinated surfaces) present on the specimen that allow the “cutting date” designation. Noncutting dates are therefore potentially biased estimates of beam procurement and use events because they underestimate the actual date-of-death of the tree (Ahlstrom 1997).

The archaeological interpretation of noncutting dates is complicated because there is no way of knowing, a priori, how many rings are missing from the outside portion of the specimen. The vagaries of tree growth, site formation processes, specimen preservation, and wood-use behavior ensure that only a fraction of tree-ring specimens submitted for analysis date and, of those that do, most yield noncutting dates because the outer portion of a beam is more likely to be lost due to decay, insect infestation, or anthropogenic removal. Despite recent efforts to alleviate the interpretive difficulties associated with noncutting dates, they remain the most recalcitrant of tree-ring dates for archaeological purposes (Nash 1997).

Another concept useful for the interpretation of tree-ring dates is *date clustering* (Ahlstrom 1985; Baillie 1995). If a number of tree-ring dates from a given site or provenience cluster in one to three calendar years, one can infer that some construction event occurred and has been dated by the tree rings. For the archaeologist interested in determining an accurate and precise date of construction for a given room or site, the ideal date distribution curve would consist of a vertical line of x number of cutting dates in a given year. Because of activities such as beam stockpiling, manipulation, reuse, and structure repair, actual date distribution curves are often skewed left, with long tails, as noncutting dates dominate the distribution (Ahlstrom 1997, p. 343; Ahlstrom and Smiley 1998, p. 150).

Cutting Date Estimation

Dendrochronologists have attempted to estimate cutting dates for specimens that yield only noncutting dates, the logic being that if the number of missing rings can be estimated with some reasonable degree of probability, one can then simply add the estimated number of rings to the existing outer ring date to obtain an estimated cutting date. In general, there are three techniques for estimating cutting dates (Hughes et al. 1981). The first is to determine some statistical relationship between the number of sapwood rings, and therefore the number of rings that might be lost, and various tree-growth parameters. The second is merely to assume an immutable number of sapwood rings. The third is to calculate the mean and standard deviations of the number of sapwood rings from frequency distributions of samples assumed to be from the same statistical populations.

Nash (1997) used heartwood and sapwood data from living-tree cores to calculate regression equations that predict the number of sapwood rings on a specimen based on the number of heartwood rings. Using case studies from the well-dated protohistoric, historic, and modern dwellings at Walpi, Arizona, he concluded that because of the statistical uncertainty associated with estimated cutting dates, they are best considered in the aggregate, in terms of the site's entire date distribution curve.

Cutting-dating estimation is much more common in Europe than in North America. Empirical research has now been extensive enough to document a decreasing west–east gradient in the number of sapwood rings found in European oaks: In Ireland, mature oaks tend to have 32 ± 9 sapwood rings; German oaks tend to have 19 ± 8 sapwood rings, while Finnish oaks have 14 ± 3 (Baillie et al. 1985; see Pilcher 1987).

Recent Research

Nash (2002) and Towner (2002) published their perspectives on the status of American archaeological tree-ring dating at the turn of the millennium; Baillie (2002) and Kuniholm (2002) did so for

Europe and the Mediterranean, respectively. Since then, the bulk of published research on the dendrochronology of ancient dwellings has occurred in the southern and eastern United States, in Western Europe, and, to a lesser degree, in the greater Mediterranean area. In a stunning recent development, the full implications of which will take years to realize, Morales et al. (2013) dated pre-Hispanic *chullpas* (burial towers and storage chambers) in the Andean Altiplano, marking the first time that reliable tree-ring dates have been obtained for archaeological structures in South America.

Grissino-Mayer (2009; see also references therein) and colleagues led the effort to date historic structures in the eastern and southern United States, publishing a special issue of the journal *Tree-Ring Research* in the process. The effort to use tree rings to date historic structures often begins with a disagreement about the purported age of the structures, which often stems from a lack of concordance between documentary evidence and oral histories. Dendrochronological specialists are then called in to provide a complementary dataset. Much to the chagrin of local heritage specialists, however, tree-ring dates can undermine previously held ownership histories for individual structures. How, for example, can the John Sevier Cabin have been occupied by Tennessee Governor Sevier, who died in 1815, if tree-ring dates indicate that the cabin was built sometime between the summer of 1835 and the early spring of 1836 (Slayton et al. 2009, p. 35; for additional examples see also Grissino-Mayer and van de Gevel 2007; Towner 2008)?

In other instances, tree-ring dates confirm, or at the least do not contradict, previously held interpretations about settlement origins and histories, including a slave cabin at The Hermitage, President Andrew Jackson's estate (Lewis et al. 2009), an antebellum plantation house in Arkansas (Therrell and Stahle 2012), an antebellum house in Georgia (Wight and Grissino-Mayer 2004), and structures in southeastern Nova Scotia (Robichaud and Laroque 2008), among many others.

In Western Europe (and also in the American Southwest), much archaeological tree-ring dating is driven by heritage resource management; tree-ring dates and interpretive results are therefore often published in proprietary reports. English Heritage has, however, made available more than 100 tree-ring dating reports (search "tree-ring dating" and "dendrochronological analysis" at <http://research.english-heritage.org.uk/>; accessed 21 May 2013) on dwellings, churches, and other structures throughout the United Kingdom. Hoffsummer (2009; see also Lambert 2009; Trenard 2009; Haneca and Debonne 2012) discussed the issues complicating tree-ring dating of European structures in an edited volume on the typology and development of roof frames in Belgium and northern France from the eleventh to the nineteenth centuries. Tegel et al. (2012) used tree rings to date early Neolithic water wells, which they describe as the earliest wood architecture but is more accurately described as the earliest *tree-ring-dated* wood architecture. Further to the east, Bernabei and Bontadi (2012) used tree-ring dating to identify previously undocumented, or poorly documented, construction activity at the Church of the Nativity in Bethlehem. They dated previously undocumented repair events between A.D. 1000 and the early 1200s and conclusively identified the source of wood, far afield in the Republic of Venice, for a massive mid-fifteenth-century repair event. The Aegean Dendrochronology Project, formerly based at Cornell University, has moved to the Laboratory of Tree-Ring Research at the University of Arizona in Tucson, where it continues a long tradition of dating ancient dwellings in the greater Mediterranean region.

Summary

Nearly a century after Douglass (1929) demonstrated that tree rings could be used to date ancient dwellings, the interpretation of archaeological tree-ring dates has become more sophisticated with

respect to understanding prehistoric wood-use behavior and the discrepancies that sometimes occur between historic documentation, oral history, and tree-ring data. Arguably even more impressive, however, is the fact that tree-ring dating is now routinely applied in areas like eastern and southern North America, in which scholars once believed tree-ring dating would not be successful. The expansion of tree-ring dating to South America and the tropics has the potential to be revolutionary, if sites with well-preserved wood can be found in quantity.

Luminescence, Volcanic Rocks

Sumiko Tsukamoto*

Leibniz Institute for Applied Geophysics (LIAG), Hannover, Germany

Definition

Luminescence dating methods are applicable to estimate ages of past volcanic eruptions using (1) volcanic phenocrysts (quartz and feldspar) and glass within volcanic rocks (including unconsolidated tephra) and (2) rocks heated by lava or pyroclastic flow. Unlike luminescence dating of light-exposed sediments, the luminescence clock is reset by heating or is naturally zero at the time of crystallization. Another resetting mechanism of temperature-assisted hydrostatic pressure by phreatic eruptions has been also proposed (Zöller et al. 2009).

Introduction

The first attempt of luminescence dating of volcanic rocks has been done by Wintle (1973) using thermoluminescence (TL) of rhyolites and basalts containing plagioclase phenocrysts. She found, however, a significant signal loss in artificially irradiated samples after a storage, which is known as anomalous fading, leading to an age underestimation. Since then, luminescence dating studies using quartz, feldspar, and volcanic glass have been done both using TL and optically stimulated luminescence (OSL). A comprehensive review of luminescence dating of volcanic products was published by Fattahi and Stokes (2003).

Quartz

Dating applications using quartz is possible for both quartz-bearing tephra having rhyolitic composition and rocks heated by lava or pyroclastic flows. Quartz-bearing tephras were dated initially by TL in the blue detection wavelength (e.g., Ichikawa et al. 1982; Takamiya and Nishimura 1986). Later, Hashimoto et al. (1986) found that volcanic quartz has a TL peak in the orange-red region (~ 620 nm) at around 380°C . This peak has a higher saturation dose than that of the blue TL peak at ~ 470 nm (Hashimoto et al. 1987; Miallier et al. 1991). Since then, red TL has been used to date volcanic quartz successfully both using multiple-aliquot (e.g., Miallier et al. 1994; Pilleyre et al. 1992) and single-aliquot (e.g., Toyoda et al. 2006) approaches. The high saturation dose (characteristic saturation dose, $D_0 \sim 6,500$ Gy) made it possible to date a tephra older than 1 Ma (Fattahi and Stokes 2000). However, the measurement of red TL needs a PM tube which is more sensitive to longer wavelength (trialkali or GaAs tubes), and the tube has to be cooled to reduce dark counts. A high blackbody radiation is also expected. In order to subtract the blackbody radiation more easily from the red TL signal, the use of isothermal TL, by keeping

*Email: sumiko.tsukamoto@liag-hannover.de

temperature the same for a prolonged time, has been proposed (Tsukamoto et al. 2007; Ganzawa and Maeda 2009). Dating of tephra using red TL has been also done using quartz single grains from tephra (Ganzawa and Ike 2011). OSL using single-aliquot regenerative dose (SAR) protocol has been tested for dating volcanic rocks (Bonde et al. 2001). However, OSL of volcanic quartz has been found to fade and has lower thermal stability than sedimentary quartz (Tsukamoto et al. 2007). But these problems do not exist in the case of quartz which originated from nonvolcanic bedrocks. OSL dating was successfully applied for samples from Eifel volcanic field, Germany, where high-pressure shock waves during phreatic eruptions had probably reset the OSL signals (Preusser et al. 2011).

Feldspar

After the finding of anomalous fading by Wintle (1973), there have not been many studies on luminescence dating of volcanic feldspars until very recently, because of the difficulty in dealing with high fading rates. May (1977) investigated TL of plagioclase feldspars from alkali and tholeiitic basalts with known ages from Hawaii and found a correlation between normalized natural signal intensities and expected ages up to 200 ka, despite the presence of significant anomalous fading. Guérin and Valladas (1980) studied TL in the UV detection wavelength at high temperature ($>580^{\circ}\text{C}$) from volcanic plagioclase from France and concluded that the high-temperature TL peak is not significantly affected by anomalous fading. TL from sanidine in the far-red region ($\sim 710\text{ nm}$) was also found to be not affected by anomalous fading (Zink et al. 1995; Visocekas and Zink 1999). Recently, the possibility of luminescence dating on the Martian surface has been suggested (McKeever et al. 2003), and since then a growing number of studies have been published (e.g., Kalchgruber et al. 2006; Jain et al. 2006). Morthekai et al. (2008) and Tsukamoto and Duller (2008) compared fading rates of various luminescence signals from Martian analog materials on Earth. While Morthekai et al. (2008) obtained the lowest fading rate from red TL (630–670 nm) signal from andesite and basalt samples, Tsukamoto and Duller (2008) reported relatively uniform fading rates of 5–7 %/decade from IRSL signal at 200°C from basalts in the blue detection wavelength. Following this, Tsukamoto et al. (2010, 2011) dated andesitic tephra and basalts using IRSL at 200°C and obtained consistent ages with independent age controls up to $\sim 70\text{ ka}$. Scoria samples from Vesuvius containing leucite and sanidine have been dated using post-IR IRSL method (Tsukamoto et al. 2014), which has been developed to minimize anomalous fading (Thomsen et al. 2008). The fading rate was successfully reduced from $\sim 30\%$ to less than 5% by increasing both preheat and post-IR stimulation temperatures, and the ages after fading correction agreed with known eruption ages of Vesuvius (Tsukamoto et al. 2014).

Volcanic Glass

TL dating of volcanic glass has been first reported by Berger and Huntley (1983) using 2–11 μm fraction of glass. Fine grain volcanic glass was selected, because it was homogeneous and it was certain that it originated primarily from the eruption (without lithic fragments). This work was followed by Berger (1985, 1992) who dated volcanic ashes between 8 and 400 ka using TL in blue-green detection wavelength using multiple-aliquot additive dose technique. TL spectra were measured from volcanic glass from tephra in Japan by Kanemaki et al. (1991). They found that the TL spectra from volcanic glass are similar to those of quartz and plagioclase phenocrysts, and

therefore, the TL from volcanic glass originates from quartz and/or plagioclase microcrystals in the glass. Optical dating of volcanic glass has been tested by Berger and Huntley (1994). The OSL and IRSL signals from volcanic glass from 15 samples are generally dim, and they concluded that the optical dating of volcanic glass is only occasionally feasible. However, Biswas et al. (2013) used fine grain volcanic ashes (4–11 μm) which are presumably dominated by volcanic glass and applied post-IR IRSL protocol. The intensity of post-IR IRSL signal was much larger than IRSL at 50 °C and it showed negligible anomalous fading.

Summary

Red TL dating using volcanic quartz has been proven to be a powerful dating technique to date rhyolitic tephra. Different measurement methods (red TL, UV-TL, and IRSL) have been suggested to be useful in dating volcanic feldspars. Since the post-IR IRSL technique has been successfully applied in dating sedimentary feldspar without a fading correction, this method should be tested more for volcanic feldspars. Volcanic glass has a problem of low luminescence sensitivity, but the post-IR IRSL is helpful in both reducing anomalous fading and increasing luminescence intensity.

Synonyms

¹⁴C dating; Carbon dating; Carbon-14 dating; Radiocarbon dating

Definition

Radiocarbon dating is a method of measuring the age of organic or carbonate phases in radiocarbon years by the level of the nuclide ¹⁴C remaining in the sample. Calibration of the radiocarbon age is done by comparison to known-age records such as tree rings. Stuiver and Polach (1977) define a radiocarbon date to include five things: (a) the use of the 5,568-year half-life (mean life 8,033 years); (b) the assumption of constancy of ¹⁴C atmospheric level during the past; (c) direct or indirect comparison to a known standard, oxalic acid; (d) isotopic fractionation normalization of all sample activities to the base of $\delta^{13}\text{C} = -25\text{‰}$; and (e) the year 1950 which is automatically the base year, with ages given in years BP (i.e., where present is defined as AD 1950).

Introduction

Radiocarbon (carbon-14 or ¹⁴C) is produced in the upper atmosphere by the action of cosmic ray-induced radiation on nitrogen in the atmosphere. The nuclear reaction ¹⁴N(n, p)¹⁴C has a high cross section of 2.5 barns. The production rate of ¹⁴C is estimated to average ~2.2 atoms/cm²/s (Usoskin and Kromer 2005). Once produced, ¹⁴C is rapidly incorporated into the atmosphere as CO and then oxidized to CO₂. In this form it makes its way into the terrestrial biosphere through photosynthesis, through the carbon cycle. The time scale of this process is rapid, so that ¹⁴C in the atmosphere and the biosphere are in equilibrium on a time scale of <1 year (see Fig. 1). Radiocarbon dating is one of the most important isotopic geochronological methods and has an immense range of applications to scientific studies including archaeology, geology, and oceanography. The development of radiocarbon dating changed the way that geologists and archaeologists look at chronology (Renfrew 1979).

The radioactive decay equation gives the relationship between the decay rate and the number of ¹⁴C atoms that will decay with time according to the radioactive decay equation (Rutherford and Soddy 1902):

$$dn/dt = -\lambda N \quad (1)$$

In this equation the decay rate (dn/dt) is directly proportional to the number of radioactive atoms

*Email: jull@u.arizona.edu

Fig. 1 A diagram of radiocarbon dating

present (N). The “decay constant” λ defines the rate of decay. The decay constant is related to the “half-life” $t_{1/2}$ of a radionuclide as the time required for $\frac{1}{2}$ of the remaining atoms to decay. The half-life is related to the decay constant by the relation:

$$t_{1/2} = \frac{\ln 2}{\lambda} \quad (2)$$

By convention, a radiocarbon date implies a half-life of 5,568 years, as originally proposed by Willard Libby (1955). The useful limit of the technique is around 50,000 years in a typical radiocarbon laboratory. This explains the great facility of the method which can be used, for example, to date the most recent global glacial-interglacial advances and retreats, the development of modern humans, and the rise of civilizations. Hence, it covers a time scale of fundamental importance to geology and archaeology. It should be noted that Libby’s half-life determination has since been revised to 5,730 years, but radiocarbon dates are still calculated with the 5,568-year value by convention. This allows for unambiguous comparisons between radiocarbon dates, regardless of

when the measurements were made. This difference introduces a 2 % offset which is compensated for when the dates are calibrated to calendar years (see below).

We can integrate Eq. 1 with appropriate limits to obtain the equation:

$$\frac{N}{N_0} = e^{-\lambda t} \quad (3)$$

Where N_0 is the number of atoms at time $t = 0$ and N is the number of atoms at any time t . This is the common expression of how the remaining amount of carbon-14 relates to time. It is equally valid to use the activity (or the decay rate), since from Eq. 1, these would obey the same equation.

Originally, radiocarbon measurements were performed by counting the radioactive decay of the ^{14}C isotope (Cook and van der Plicht 2007). We can count either the decays of the ^{14}C , because it emits a β -particle, or we can count the atoms themselves. In recent decades, the method of *accelerator mass spectrometry* (AMS) has gradually taken over the measurement of radiocarbon, and now, most measurements are made by AMS (Burr and Jull 2009). The older counter methodology is still used and can be applied to counting of both liquid samples and gas, especially when sufficient material is available (Longin 1971; Cook and van der Plicht 2007).

If we look at Eq. 1, it should be clear that it is more effective to measure atoms than decays: for modern ^{14}C , the decay rate (A_0) is 13.59 decays per minute per gram of C. In AMS, we typically measure a sample of 0.5 mg C, and we can count over 120,000 atoms from a modern sample. If we take a counting rate of 120,000 atoms in 1,080 s, or 111 counts/s – from 0.5 mg of carbon – then this translates to $111 \times 60/0.0005 = 1.33 \times 10^7$ counts per minute per gram.

A basic assumption of radiocarbon dating is that we know the ^{14}C age of the starting material at the time when the sample was formed. This makes it possible to solve the radioactive decay equation (3), which can be expressed as a ratio of the number of atoms, the isotopic ratio relative to a stable isotope, or the activity (decay rate) ratio. We can define the “fraction of modern carbon,” F :

$$F_{(-25)} = \frac{{}^{14}\text{C}/{}^{13}\text{C}_{S[-25]}}{{}^{14}\text{C}/{}^{13}\text{C}_{1950[-25]}} \quad (4)$$

where the subscript $S [-25]$ refers to the sample renormalized to a $\delta^{13}\text{C}$ value of -25‰ and 1950 refers to the standards discussed above, renormalized to 1950 AD, and $\delta^{13}\text{C} = -19\text{‰}$ for OXI and -25‰ for OXII, or other secondary standards referenced to the oxalic acid standard (Stuiver and Polach 1977). An equivalent expression could be written using atomic ratios (N/N_0) or activity ratios (decay rate, A/A_0) for the sample and standard instead of the isotope ratio $^{14}\text{C}/^{13}\text{C}$, in which case N_0 is the number of atoms at time zero, N is the number of atoms remaining, t is the time in years, and λ is the decay constant. We could also substitute the isotopic ratio $^{14}\text{C}/^{12}\text{C}$, also equivalent to activity (A), referenced to a zero-aged value, $^{14}\text{C}/^{12}\text{C}_0$, or A_0 . All these values would be normalized to $\delta^{13}\text{C}$ at -25‰ . As noted above, the decay constant λ used here assumes a half-life of 5,568 years.

To calculate an age, the decay of ^{14}C is written in terms of F as follows:

$$F_{(-25)} = e^{-\lambda t} \quad (5)$$

and rearranging this equation gives an expression for calculating the *uncalibrated radiocarbon age* of a sample:

$$\text{age} = -8033 \ln F_{(-25)} \quad (6)$$

This age is an uncalibrated result, since it assumes that radiocarbon decays from a constant value. This is usually called the “radiocarbon age.” We know that, due to fluctuations in atmospheric production of ^{14}C , we need to correct for the difference from the “zero” age value. In order to do this, we need a suite of materials of known age and their corresponding apparent “radiocarbon ages.” This process is called “calibration” and is an important step for precision dating using carbon-14.

Calibration

One of the potential problems of radiocarbon dating is that it is assumed that the activity (A_0) or number of atoms (N_0) at the time of production of the sample is always the same. This is not the case. We know that ^{14}C in known-age tree rings fluctuates with time due to several factors, including the level of CO_2 in the atmosphere and cosmic-ray fluctuations due to changes in the Earth’s magnetic field and other effects (Burr 2007). To correct for these problems, an international calibration team has made a cross-calibration of ^{14}C against other records – predominantly *dendrochronology*, *U–Th dating* of corals, *U–Th-dated speleothems*, and *varved-sediment* records. These calibrations are published and revised every 4–5 years. The most recent one is INTCAL13 (Reimer et al. 2013), which refines the curves presented previously derived by INTCAL09 (see Fig. 2).

Fig. 2 The calibration curve for the period 10,000–26,000 years (Reimer et al. 2013). The horizontal axis shows the true age based on various records, and the vertical axis displays the radiocarbon age

Fossil-Fuel and Bomb Carbon-14

Another complication is that fossil fuel burning added ^{14}C -free carbon dioxide to the atmosphere resulting in decreased levels of ^{14}C from about 1780 to 1950 AD. Since 1950 AD, we have experienced an increase due to the addition of high levels of ^{14}C from atmospheric nuclear weapons testing. Although most testing was banned after 1963, this is an important signal added to the atmosphere in the last 60 years. The bomb-carbon record is well established and can be used to pinpoint specific dates in the time period since 1950 AD (Burr 2013). Indeed, this signal increases to a maximum of almost twice the pre-bomb level and has since decreased. Various plots of the bomb-curve profile are shown in the bomb-carbon section of this encyclopedia. It is very useful in applications where we need to resolve if a material was produced in the last 60 years – for example, in determining forgeries in the artwork or in forensic applications.

Using Radiocarbon Dating

We can use radiocarbon dating to estimate the age of a wide variety of carbon-containing materials. Both organic and inorganic materials at the Earth's surface and in the oceans form in equilibrium or in steady-state conditions with the atmospheric ^{14}C . This allows us to determine the initial level of ^{14}C and their ages. When an animal or plant dies, the level of ^{14}C decays according to Eq. 3. There are a vast number of applications of ^{14}C , and more details of ^{14}C dating are given in other sections of this encyclopedia.

Sample Preparation

Before measurement of ^{14}C , it is important to clean the sample, so that any ^{14}C that we measure comes from the sample itself and not from contaminants introduced from surrounding environment where the material was found. After we clean the material, we need to convert it to a form suitable to the measurement technique employed: this could be CO_2 gas or benzene for liquid-scintillation counting or solid graphite or CO_2 gas for AMS.

Pretreatment Protocols

The most basic of all pretreatments is the acid-base-acid (ABA) or acid-alkali-acid (AAA) cleaning method for treating a wide range of organic materials, which can include *charcoal*, *wood*, *cellulose*, *plant material*, and *animal remains*. After a physical inspection, samples are cleaned with the addition of a sequence of steps, including (1) HCl acid with a sufficient concentration to dissolve carbonates, usually 1 N HCl, (2) 0.1 % NaOH, and (3) HCl acid. Following each step, the samples are neutralized with distilled water. Following the last step, they are dried. The dried sample is then combusted at 900–1,100 °C with CuO or oxygen gas. There are many refinements of this method. For example, Hatté et al. (2001) identified potential contamination in the ABA pretreatment which can affect wood and paleosol dates and suggested improvements to avoid them. Although charcoals are generally excellent material for dating, Bird et al. (1999) recommended the use of a more severe oxidation step using chromic acid for purification of some old charcoals (Bird et al. 1999). Rebollo et al. (2008) looked at the chemical and structural changes in charcoals pretreated with the ABA

method, and they suggested several modifications to the ABA method based on their findings, including the use of weaker acids, eliminating the initial acid step, treatment with distilled water, and agitation in the alkali step. In another case, Ascough et al. (2011) reported that for some charcoals the alkali-soluble fraction normally removed from the charcoals may be degradation products of the charcoal itself, so removing them does not necessarily improve the cleanliness of the sample.

Other types of samples need other specialized treatment. Carbonate samples are etched using 100 % H_3PO_4 to remove 50–85 % of the carbonate, then dried and acidified with H_3PO_4 , and the carbon is collected as CO_2 . Sediments are treated in a number of ways. One approach is to use selective combustion. After cleaning and drying the sample, the sample is combusted stepwise, at successively higher temperatures to liberate different organic components according to their combustion temperatures (McGeehin et al. 2001).

Radiocarbon dating of works of art and other artifacts is an important application. Usually, textiles, parchment, canvas, and artworks (e.g., canvas from a painting) are cleaned in a Soxhlet apparatus, which utilizes hot solvents to remove contaminants. Typically, a series of solvents such as hexane, ethanol, methanol, and acetone are used (Jull et al. 2004; Hajdas 2008, 2009; Brock 2013). The samples can then be cleaned with distilled water and dried, before combustion at up to 1,100 °C. Iron artifacts can be dated either by melting the sample in an oxygen atmosphere and extracting CO_2 or by using wet-chemical techniques (Park et al. 2010).

There are some excellent examples that illustrate the use of radiocarbon dating for artworks. The most famous is the Shroud of Turin (Damon et al. 1989), but the list also includes the Dead Sea Scrolls and a more recent example is the Voynich manuscript (Zyats et al. 2012) and the *Egyptian Book of the Dead* (Fig. 3).

Fig. 3 An example of radiocarbon dating – Egyptian Book of the Dead. This document dates to 1620–1430 BC based on the calibrated age, or $3,249 \pm 49$ radiocarbon years before present (Image courtesy Brooklyn Museum of Art)

There are many specialized approaches to dating bones. Much attention is given to bone pretreatment because of their critical role in archaeological studies and the complexities of bone chemistry. The standard pretreatment method for bone is the collagen extraction technique of Longin (1971). Collagen is a fibrous protein and the principal constituent of bone. This material degrades with time as a result of postdepositional alteration and eventually breaks down into individual amino acids. Bone collagen may interact with exogenous organics through reactions in the burial environment. As a result, a number of screening procedures have been developed to characterize the degree of preservation for individual samples (van Klinken 1999). The most common screening procedure for AMS is the determination of percent collagen in a sample, usually by measuring the elemental C/N ratio. Modern bone consists of ~22 wt% collagen, and this value decreases with burial age. Samples with as low as 0.5 % collagen may be datable, but often require specialized chemical pretreatment, such as the isolation and analysis of individual amino acids (Van Klinken 1999). Samples with <0.5 % collagen are generally considered unsuitable for obtaining a useful date. Another refinement of the collagen extraction technique has become standard in the past decade, using ultrafiltration to isolate the >30 kD molecular weight fraction. The method is highly selective and has been shown to remove contaminants better than the standard collagen extraction technique (Brown et al. 1988). Brock (2013) has also applied the collagen approach to parchment dating.

Groundwater and surface waters can be dated by extracting dissolved inorganic carbon by acidification, in the same manner as solid carbonates are processed. Additionally dissolved organic carbon can be extracted using either KMnO_4 or $\text{K}_2\text{Cr}_2\text{O}_7$ as an oxidizing agent (Leonard et al. 2013). We can use these values of ^{14}C to better understand the circulation of groundwater and carbon cycling in lakes (e.g., Yu et al. 2007) and determine reservoir ages.

These are just a few examples of pretreatment methods for typical samples. Specialized techniques that are beyond the scope of this discussion have been developed to pretreat a wide range of samples (see, e.g., Hajdas 2009). The goal of the pretreatment in these cases is to isolate a carbon fraction that was in equilibrium with the atmosphere when it formed and has not been contaminated. For AMS, once the carbon has been extracted, it can be converted to graphite (a common target material in AMS machines) by means of a catalytic decomposition reaction, using Fe as the catalyst. For liquid-scintillation spectrometry, the CO_2 must be converted to benzene, which involves several additional chemistry steps (Cook and van der Plicht 2007).

Measurement and Calculations

AMS measurements are made by comparing the count rate of ^{14}C from a sample to the count rate in a known-age standard. For activity (counting) measurements, the normalized activity (A) is compared to that of a known standard. In both cases, we can then compare the measured ratio of the sample to a known standard.

Standards

For ^{14}C , we use a primary (SRM-4990B, OXI) and secondary (SRM-4990C, OXII) standard from the US National Institute of Standards and Technology (NIST) to determine radiocarbon dates. The secondary standard is normalized to the consensus value of OXI. The ratio of OXII/OXI is well defined (Mann 1983). Many other well-established secondary standards are also available, which

can be referred back to the primary OXI value (Scott et al. 2007). Some laboratories use their own internal standards and reference them to the primary oxalic acid standards.

Uncertainties

Burr et al. (2007) have summarized how the uncertainties in radiocarbon dates are determined at the Arizona laboratory. There are several potential problems when considering radiocarbon dating uncertainties. For example, radiocarbon dates are quoted with one standard deviation uncertainties by convention, whereas calibrated radiocarbon dates are normally quoted at two standard deviations. Some laboratories estimate additional errors above counting errors from their laboratory procedures (these are always present), but others do not. Often radiocarbon age uncertainties are published, especially by nonspecialists, with little discussion of how they were determined, and uncertainties in reservoir corrections are often neglected. It is therefore important to quote the original “radiocarbon ages” because they are unambiguous assuming they adhere to the definition given above.

Using Calibration Curves

There are a number of programs available for calibration of the “radiocarbon age” to a calendar age. Some good examples easily accessible on the Internet are Calib (www.calib.org) and OxCal (c14.arch.ox.ac.uk/oxcal). The result of applying the calibration to a radiocarbon result can be shown in Fig. 4a, b, where we see the difference between a radiocarbon date of $2,320 \pm 20$ and $2,320 \pm 30$ years. The difference in the precision of the calibration age is due to the structure of the calibration curve.

$\Delta^{14}\text{C}$ Notation

For certain samples, the initial value for modern (1950 AD) will not be the same as the atmosphere. We know that there are offsets in marine samples (e.g., Dumond and Griffin 2002), and there can also be offsets in other samples such as lakes (Yu et al. 2007), where the radiocarbon content of the carbon in the lake may not be “modern” (i.e., at the level of A_0) due to storage or input of old carbon from other sources. Age offsets of this type are described in terms of the difference between the

Fig. 4 (a, b) The result of a calibration of a radiocarbon date using the Oxcal calibration program (c14.ox.ac.uk/oxcal) for two values of slightly different precision

radiocarbon content of the reservoir and contemporary atmosphere. This is the age-corrected $\Delta^{14}\text{C}$ value. For sample prior to 1950 AD, $\Delta^{14}\text{C}$ is defined as

$$\Delta^{14}\text{C} = 1,000 \left(\text{Fe}^{\lambda(a)} - 1 \right) \% \quad (7)$$

where a is the absolute age of the material in years before 1950 AD (often stated as calendar years BP in radiocarbon literature), which should be independently obtained. An example of this use is Miyake et al. (2012).

A different situation is the case of a sample containing ^{14}C from after 1950 AD, such as a sample containing bomb ^{14}C . In this case, the true $\Delta^{14}\text{C}$ value should be corrected for the decay of the standard, as the standard has some age relative to the material being studied. This increases F to the correct value.

$$\Delta^{14}\text{C} = 1,000 \left(\text{Fe}^{\lambda(a-1950\text{AD})} - 1 \right) \% \quad (8)$$

In Eqs. 5 and 6, the λ used is 1.21×10^{-4} , representing the true half-life (5,730 years) of ^{14}C .

Marine Reservoir Effects

Stuiver et al. (1986) defined the “marine reservoir effect” as the difference between the measured radiocarbon age and the atmospheric age determined independently at a known time (t):

$$R(t) = {}^{14}\text{C age of marine sample} - {}^{14}\text{C age of atmospheric sample} \quad (9)$$

This correction factor can be determined directly from coexisting marine and terrestrially derived plant material at the same location. The value of R can be related to $\Delta^{14}\text{C}$ by the equation (Burr and Jull 2009):

$$R = 8033 \ln \left(\frac{\frac{\Delta^{14}\text{C}_{\text{atm}}}{1,000} + 1}{\frac{\Delta^{14}\text{C}_{\text{mar}}}{1,000} + 1} \right) \quad (10)$$

Also, Stuiver et al. (1986) introduced the concept of ΔR . It is important to understand the definition of ΔR , to quote from Stuiver et al. (1986), who defined a graphical model for this calculation, “*The difference ΔR in reservoir age of the regional part of the ocean from which the users sample is derived, and the reservoir age of our model ocean, is determined through the use of figure 10A.*”

Stuiver et al. (1986) paper defines the oceanic reservoir age value ΔR as

$$\Delta R = R_{\text{measured}} - R_{\text{exp}} \quad (11)$$

where R_{measured} is the R actually measured in the ocean water and R_{exp} is the expected value derived from the model of Stuiver and Braziunas (1993). It is important to be aware that this is a model-dependent expression. Because this is not always easily established, many authors report R_{exp} as the average oceanic value of R which is 400 years (e.g., Cordero et al. 2003). So, the definition of ΔR (as opposed to R) is dependent on the oceanographic model used. This marine model is now incorporated into the calibration software (e.g., MARINE09, Reimer et al. 2009).

Definition

Accelerator mass spectrometry is a technique that combines a particle accelerator with a mass spectrometer in order to measure very low levels (10^{-16}) of cosmogenic and anthropogenic radionuclides employed for dating purposes.

Introduction

Accelerator mass spectrometry (AMS) is widely used to measure rare isotope ratios of cosmogenic and anthropogenic nuclides. Cosmogenic isotopes are produced through the interaction of cosmic rays with atmospheric molecules, rocks at the earth's surface (Dunai, 2010) and in extraterrestrial settings. AMS is the analytical tool of choice for a range of isotopes used for dating purposes, especially radiocarbon dating and surface exposure dating. Table 1 lists a number of these isotopes, hereafter referred to as *AMS isotopes*. These can potentially be used to date samples from years to tens of millions of years old. The chief advantage of AMS over standard mass spectrometry is that it eliminates molecular interferences using particles with 100 s of keV to 10s of MeV energies. In recent years the technological development of AMS instruments has focused on the production of smaller (<1 MV) machines, which are less expensive to fabricate, require less space, and are easier to maintain than larger machines. This trend has seen an expansion of AMS facilities around the world. Currently there are about 100 active AMS machines worldwide (Kutschera, 2013).

History and Development of AMS

The concept and implementation of AMS date to the late 1970s, when Muller (1977) proposed the idea based on a cyclotron experiment conducted in the 1930s to measure ^3H and ^4He (Alvarez and Cornog, 1939). Muller showed that a particle accelerator could be used as a mass spectrometer to drastically reduce sample sizes and counting times and improve precision and background levels encountered in conventional decay counting of ^{14}C (radiocarbon) and ^{10}Be .

Within months, Nelson et al. (1977) and Bennett et al. (1977) implemented the idea using linear particle accelerators. These measurements were made using relatively large accelerators operating

Table 1 Isotopes measured with AMS for dating studies and their half-lives

Isotope	Half-life (yr)	Reference
^{10}Be	$1.387 \pm 0.012 \times 10^6$	Korschinek et al. (2010)
^{32}Si	$1.44 \pm 0.11 \times 10^2$	Fifield and Morgenstern (2009)
^{14}C	$5.700 \pm 0.030 \times 10^3$	Kutschera (2013)
^{41}Ca	$9.94 \pm 0.15 \times 10^4$	Jörg et al. (2012)
^{81}Kr	$2.29 \pm 0.11 \times 10^5$	Baglin (2008)
^{36}Cl	$3.013 \pm 0.015 \times 10^5$	Nica et al. (2012)
^{26}Al	$7.18 \pm 0.18 \times 10^5$	Kutschera (2013)
^{53}Mn	$3.7 \pm 0.4 \times 10^6$	Honda and Imamura (1971)
^{129}I	$1.57 \pm 0.04 \times 10^7$	Tendow (1996)

with terminal voltages of 7 and 8 MV and particles ranging from 35 to 40 MeV. Over the next several years, smaller (3 MV), purpose-built AMS instruments began to appear. Since that time, smaller instruments have been introduced and the trend toward smaller and smaller machines continues. Nowadays, especially for ^{14}C , systems are being designed with accelerator voltages as low as 200 kV. Such systems, designed at ETH Zürich, have already been installed in several laboratories (Suter, 2010). While further developments may reduce this voltage further, some nuclides such as ^{10}Be and ^{36}Cl still require higher energies to eliminate isobaric interferences and maintain high transmission.

AMS Design

Accelerator mass spectrometers all share the same basic components: (1) ion source, (2) injection (low-energy) magnet with an electrostatic field switching device (bouncer), (3) particle accelerator and stripper, (4) high-energy particle filters for magnetic and electrostatic separation, and (5) a particle detector (Fig. 1). All designs of AMS use negative ions that are produced in an ion source and are then accelerated through a potential of up to 50 kV, focused into a particle beam and sent through an injection magnet. The injection magnet performs an initial separation of beams of different masses. However, molecular ions are still present at these lower energies. After the ions pass through the injection magnet, they are further accelerated by the voltage on the AMS terminal. The terminal contains a “stripper” which can be a gas canal or thin film. When the high-energy ions pass through the stripper, molecules are dissociated and the injected particles lose electrons to become positive. In tandem accelerators the resulting positive particles continue to be accelerated in the same direction, back to ground potential. One design, the simplified “single-stage AMS,” places the ion source at the accelerating potential and the detectors are at ground potential. In this device the high-energy ions are analyzed on their way to the detector using a variety of magnetic and electrostatic filters. The ion beam is focused along the path from the ion source to the detector, using different combinations of Einzel, quadrupole, and gridded lenses, accompanied by collimating slits and electrostatic steering devices. The choice of lenses and their placement depend on the design and model of each AMS and vary considerably. The detection system can consist of solid-state devices (surface-barrier detectors) or gas-filled detectors, where further analysis of ion energy and energy loss in a gas can be measured. AMS detectors generally can identify ions by both mass and atomic number, allowing for complete separation of isobaric interferences (Litherland et al., 2010).

Fig. 1 Typical AMS design (From Sinal, 2013)

Dating Applications

AMS dating applications are primarily concerned with the measurement of cosmogenic radionuclides, but also include applications using anthropogenic isotopes. Radiocarbon was the first cosmogenic nuclide to be widely applied as a dating tool using AMS (Elmore and Phillips, 1987). Most radiocarbon is produced in the atmosphere as a result of cosmic ray interactions with atmospheric molecules. These reactions supply thermal neutrons that produce radiocarbon through the $^{14}\text{N}(\text{n},\text{p})^{14}\text{C}$ reaction. Atmospheric radiocarbon rapidly spreads into terrestrial and marine environments around the globe along a variety of organic and inorganic pathways. When a pathway is cut off, for example, when an organism dies, its radiocarbon content begins to drop as it decays away at a known rate. An AMS radiocarbon date can be determined on such material by comparison between the measured radiocarbon content in the sample and in a standard representing the atmospheric value. The limit of the AMS radiocarbon dating technique is about 55 kyr. Anthropogenic (non-cosmogenic) radiocarbon can also be used for dating. Bomb carbon introduced into the atmosphere through aboveground nuclear weapon testing in the late 1950s and early 1960s produced a spike which has been widely exploited for dating samples from the last 60 years (see entry “► Bomb Carbon” by Burr in this volume). In this case excess radiocarbon, above the expected atmospheric value, is determined with AMS. A third production pathway for radiocarbon is through spallation reactions within rocks and meteorites. This radiocarbon is well suited to in situ dating (discussed next) and to determine the terrestrial ages of meteorites (Jull, 2001).

In situ dating is concerned with the buildup of cosmogenic nuclides that occurs when a geologic surface is exposed to cosmic rays (Gosse and Phillips, 2001). Some examples of applications are to determine the age of a lava flow, or the age of a glacial deposit marking the retreat of the glacier. AMS is a truly pioneering method in the case of in situ studies because the sample size requirements, sensitivity, and precision of the AMS technique made in situ dating possible. Most in situ dating studies measure ^{10}Be , ^{14}C , ^{26}Al , and ^{36}Cl . In situ dating has advanced rapidly since the introduction of AMS and has seen a steady expansion of applications. Examples include (1) surface exposure

dating on the earth and moon, (2) determination of erosion and weathering rates, (3) burial dating, and (4) determination of the terrestrial ages of meteorites. The goal of surface exposure dating is to date fresh rock or soil surfaces that have been continuously exposed to cosmic rays since they formed and ideally have experienced only minor erosion (Granger et al., 2013). In situ isotopes can also be used to infer erosion and weathering rates when the age of a surface is known independently. In this case, the amount of material removed by both physical and chemical erosion can be assessed. When two cosmogenic isotopes are measured in the same rock, it can also be possible to determine both surface exposure age and erosion rate (Granger et al., 2013). A recent addition to this group of in situ isotopes is ^{53}Mn , which has been measured in several laboratories and has been used to study both terrestrial and extraterrestrial samples.

Another AMS isotope commonly used for dating applications is ^{129}I . Like radiocarbon, both cosmogenic and anthropogenic sources of ^{129}I can be used for dating. ^{129}I is particularly useful for dating brines and evaporite deposits (Fabryka-Martin et al., 1984) because iodine is very soluble and becomes concentrated in these materials. ^{129}I has a very long half-life (1.57×10^7 years) and has been used to date brine samples as far back as the Miocene (Tomaru et al., 2009). Iodine is a near-conservative element in groundwater and has showed promise as a method suitable for dating young water (Schwehr et al., 2005).

The remaining AMS isotopes given in Table 1 (^{32}Si , ^{41}Ca , ^{81}Kr) are less widely studied but have potential as isotopic chronometers. ^{32}Si has long been recognized as a potentially useful radioisotope for dating oceanographic samples (Lal et al., 1960), but poses significant analytical challenges, in part due to its low abundance. Fifield and Morgenstern (2009) have demonstrated the feasibility of dating glacial ice with AMS measurements of ^{32}Si . The potential for ^{41}Ca has also been long recognized (Paul et al., 1985), but is a challenging isotope to measure. ^{41}Ca has been measured to determine cosmic ray exposure ages of meteorites (Herzog et al., 2011). The strictly conservative nature of krypton in groundwater makes ^{81}Kr a valuable isotope in determining the residence time of ancient groundwater. Collon et al. (2000) developed a specialized sample processing technique to extract krypton from groundwaters of the Great Artesian Basin in Australia and determined ages from about 2 to 4×10^5 years.

Extraterrestrial Materials (K–Ar/Ar–Ar)

Timothy Swindle*

Lunar and Planetary Laboratory, University of Arizona, Tucson, AZ, USA

Definitions

Potassium-argon (K–Ar) dating is a technique of finding the ages of rocks based on the decay of ^{40}K to ^{40}Ar . Argon-argon (^{40}Ar – ^{39}Ar , or just Ar–Ar) dating is a type of potassium-argon dating in which a sample is irradiated with neutrons, converting a fraction of the atoms of ^{39}K , the most abundant isotope of potassium, into ^{39}Ar , enabling both the potassium abundance and the ^{40}Ar abundance to be measured with a single noble gas mass spectrometer (McDougall and Harrison 1999). The extraterrestrial materials to which the potassium-argon and argon-argon techniques have been applied include only meteorites and samples returned from the surface of the Moon by either the American Apollo astronauts or the Russian Luna robotic sample-return missions – age determinations based on the decay of radioactive isotopes have never been attempted in-situ on any planetary surface, but several concepts based on the K–Ar technique have been proposed since 2000.

Introduction

The potassium-argon system, which is at the heart of both K–Ar and Ar–Ar dating, is notable among the major geochronology systems with respect to easy diffusion of the daughter product, ^{40}Ar . As a result, it can be applied in cases where a rock is heated, but not to a high enough temperature for a long enough period of time for other systems to be reset. It is this quality that makes it very useful for impact age determinations.

The rarest of the three naturally-occurring potassium isotopes, ^{40}K , decays to either ^{40}Ca or ^{40}Ar , with a total half-life of 1.25 Ga (Renne et al. 2011). Although the majority of the decays are to Ca, it is the branch involving Ar that is far more widely used as a geochronometer, because Ar is far rarer than Ca.

The possibility of using the K–Ar system for age determinations was discussed in the 1940s, and heavily implemented as K–Ar dating in the 1950s. Although the possibility of something like Ar–Ar dating was discussed late in that decade, the first real Ar–Ar experiment was performed on the Bruderheim meteorite in the mid-1960s (Merrihue and Turner 1966). It was quickly applied to other meteorites, and when the Apollo lunar samples were returned just 3 years later, the technique was already mature enough that it was used heavily.

Because Ar does not engage in chemical bonds, a silicate melt will tend to lose its Ar, so most rocks contain little or no Ar when they form. However, Ar diffuses only sluggishly through solids, so ^{40}Ar will then build up, and in an extremely simple system, a K–Ar age records the length of time since the rock was formed. However, Ar diffusion is temperature-dependent – if a rock is heated up,

*Email: tswindle@email.arizona.edu

Ar will begin to escape long before the rock is melted. How much Ar is lost depends on the diffusion characteristics of the host mineral as well as the time and temperature history of the rock, so in a rock that has been heated at some time after it cooled, some or all of the radiogenic (decay-produced) ^{40}Ar will have been lost, and the K–Ar age will be between the formation age and the length of time since the reheating event. Or, if the time-temperature history is sufficient, the rock can lose all of its radiogenic ^{40}Ar in a thermal event and the K–Ar age will record the time since that event. Actually, it will record the time since the rock was last at a temperature high enough to lose Ar by diffusion, a temperature that depends on the diffusion characteristics of the mineral and on the cooling rate, but is typically a few hundred degrees Celsius. Diffusion characteristics have been determined for many minerals, and this type of calculation is at the heart of “thermochronology” techniques (McDougall and Harrison 1999).

In the most common version of Ar–Ar dating, the irradiated sample is heated to progressively higher temperatures, and the gas released at each step is analyzed. This sort of step-wise heating approach has several advantages over classical K–Ar dating. First, most of the release is through diffusion, so mineral sites from which diffusion occurs more readily, because of the grain size, the diffusion characteristics of the mineral, or the proximity of the site to the edge of the rock or to a fast-diffusion pathway, are degassed more readily. This makes it possible to distinguish Ar from different mineral sites. In addition, the diffusion characteristics can be determined in the experiment itself. Finally, in a situation where the rock has been only partially degassed, or where some mineral sites have been degassed, but not others, different steps will give different ages, so it is possible to determine that it is a complex system, and possibly even to sort out some of the complexity. The most detailed review of Ar–Ar ages of meteorites is given by Bogard (2011).

The heating caused by impact cratering often leads to a complex system. For one thing, the heating can be to a very high temperature but for a very brief period of time, often leading to only incomplete Ar degassing. Furthermore, the time-temperature history can lead to some counter-intuitive results. For example, a glassy vein of impact melt material may retain more Ar than unmelted material nearby (McConville et al. 1988), or a mineral in which diffusion is slower at low temperatures but faster at high temperatures may suffer more Ar loss than one that degasses more readily at laboratory temperatures (Cassata et al. 2011).

Ordinary Chondrite Metamorphism

Ordinary chondrites, the most common types of meteorites, can be divided into three groups, presumably representing different parent asteroids, based on their chemical composition. However, within each group, the ordinary chondrites can be divided into metamorphic types, reflecting the amount of high-temperature processing (such as chemical equilibration and mineral recrystallization) they have experienced. A very simple model to explain the metamorphic types envisions all the meteorites of a single group on a single parent asteroid that heats up and then slowly cools by radiating its heat away from the surface. In this case, the rocks near the surface would experience the lowest heating, and would cool past any particular temperature first, while those in the center would be heated the most and take the longest to cool down. In this case, the Ar–Ar ages, which reflect the time at which the rock cooled past a particular temperature, should be younger for samples that are more highly metamorphosed, reflecting this “onion-shell” structure. An initial study of ordinary chondrites did not find such a relationship overall (Turner et al. 1978). A later study, focused on a single type of ordinary chondrites, the H (high-iron) chondrites, and concentrated on meteorites with little evidence for the complicating effects of impact heating, and found

the predicted correlation between age and degree of metamorphism (Trieloff et al. 2003), both for Ar–Ar ages and Pb–Pb ages, with Ar–Ar ages extending over a ~0.1 Ga period. This suggests that the H chondrite parent body, at least, may have had such an onion-shell structure. However, experiments on the other two groups of ordinary chondrites have not shown such a relationship (Dixon et al. 2004; Turner et al. 1978).

Determining the Ages of Lunar Impact Craters

For most of its history, the dominant geological process on the surface of the Moon has been impact cratering. There are enough craters that it is possible to build up a detailed relative chronology based on the density of impact craters on a surface. Such relative chronologies can be constructed for the surfaces of many planets and moons, but only for the Moon do we have samples on which we can determine ages based on isotopic systems, so the Moon and its cratering rate serve as a standard for the determination on other surfaces (see “► [Planetary Surfaces \(Cratering Rates\)](#)”). The primary way by which ages of craters are determined is Ar–Ar dating, although other techniques can sometimes be applied (Stöffler and Ryder 2001).

Within 4 years of the first samples having been returned from the Moon, it was clear that there is a concentration in the Ar–Ar ages of Apollo samples at about 3.9 Ga (Turner et al. 1973). Almost simultaneously, Tera et al. (1974) determined that many of the Apollo samples, from various sites, appear to have uranium-thorium-lead ages that were disturbed at about the same time. This led Tera et al. (1974) to suggest that there had been a “lunar cataclysm,” a large number of cratering events on the Moon in a relatively short interval of time. Subsequent research has shown that there were events both earlier (Fernandes et al. 2013) and later (Cohen et al. 2005) than the ~3.9 Ga spike in ages seen in the early Apollo data. However, evidence from asteroidal meteorites also suggests that the impact cratering rate in the Solar System was higher between ~4.1 and 3.4 Ga than either earlier or later (see below).

In parallel with the chronology studies, investigations into early Solar System orbital dynamics revealed a plausible mechanism for a cataclysm, involving the migration of the orbits of Jupiter and Saturn (Gomes et al. 2005). As more details of the complexity of the impact cratering history have been revealed, the orbital dynamics models have become more complex, as well (Morbidelli et al. 2012).

Impact Ages of Asteroidal Meteorites

Impact ages have been determined for more than 100 meteorites from asteroids (Bogard 1995; Swindle et al. 2013), including all three groups of ordinary chondrites, the HED meteorites that are presumed to come from the asteroid 4 Vesta, the mesosiderites (a kind of stony iron meteorite) and the IIE iron meteorites. The HED meteorites predominantly give impact ages of 3.4–4.1 Ga, although the impact crater distribution on Vesta observed by the Dawn spacecraft has been interpreted as demonstrating a massive impact event at ~1 Ga (Schenk et al. 2012), an unresolved puzzle. Most other meteorite groups are also roughly consistent with the lunar record, with more impact ages of 3.4–4.1 Ga than either before or after, except for the most recent 1 Ga. In the recent past, the best recorded impact is a large event that affected the L (Low-iron) chondrite parent body at 0.47 Ga, an event that is also recorded in fossil meteorites found in terrestrial quarries of that age

(Schmitz et al. 2001). It is not clear whether the higher number of recent ages reflects an increase in cratering rate or a short average survival lifetime.

Ages of Martian Meteorites

Argon-argon dating has also been applied to meteorites from Mars, although the most important result was not an age. In an attempt to determine the age of Elephant Moraine A79001, one of a group of igneous meteorites with remarkably young crystallization ages based on other chronometers, D. D. Bogard and P. Johnson found that the apparent age of some samples was greater than the age of the Solar System, unless the data was corrected for a “trapped” component with a very large ratio of ^{40}Ar to ^{36}Ar . Further study revealed that the samples with the high ^{40}Ar contents were also enriched in the other noble gases (neon, krypton, and xenon), and had relative abundances of the noble gases, as well as key ratios of isotopes of Ar and Xe, that matched measurements of the Martian atmosphere by the Viking spacecraft in the 1970s (Bogard and Johnson 1983). This was taken as confirmation of an earlier suggestion that this group of meteorites indeed comes from Mars. High amounts of argon, apparently trapped either from the atmosphere or from magmas, are found in many of the Martian meteorites, making it difficult to determine accurate argon-argon ages (Bogard et al. 2009). However, on those meteorites where ages can be determined, it appears that the rocks are relatively young, mostly 1.3 Ga or younger (Nyquist et al. 2001), and were not subjected to high temperatures on Mars (Weiss et al. 2002).

In-Situ K–Ar Dating

Several concepts for performing K–Ar dating in situ on planetary surface, have been suggested (Cohen et al. 2013; Farley et al. 2013; Swindle et al. 2003; Talboys et al. 2009), but none has yet flown on a spacecraft. Mars is a particularly appealing target, because the relative ages of Martian surfaces can be determined by geological superposition relationships or by the relative abundance of impact craters, but the absolute ages are poorly known. Ar–Ar dating cannot be applied because of the high neutron fluences required, but metamorphism is not expected to occur, so K–Ar dating might be expected to date formation ages.

Summary or Conclusions

Potassium-argon dating, specifically the Ar–Ar variant, has been widely applied to extraterrestrial samples. The relative ease of diffusion of Ar, compared to the elements involved in other isotopic dating techniques, has made Ar–Ar the most widely used system to determine the timing of heating events, particularly those from impact cratering.

Radioluminescence (RL)

Tobias Lauer*

Leibniz Institute for Applied Geophysics, Hannover, Germany

Synonyms

[Infrared radiofluorescence](#); [Infrared radioluminescence](#); [IR-RF](#)

The radioluminescence (RL) phenomenon is based on the emission of fluorescent light at a wavelength range of 865 nm occurring when potassium (K-) feldspar grains are exposed to a radioactive source (e.g., Trautmann et al. [1998](#); Erfurt et al. [2003](#)). The ionization leads to electron transfers from an excited state to the ground state of the electron center (Trautmann et al. [2000](#)), and RL is emitted while electrons are captured in free optically active traps. RL is therefore not linked to recombination centers and reflects the charge density within electron traps (Trautmann [2000](#)). RL is most likely related to electron transitions in Pb^+ centers (Erfurt [2003](#)). Contrary to the luminescence signal, the RL signal decreases with irradiation time until a saturation limit is reached, and the RL signal can be increased by exposing the K-feldspars to light <500 nm (>2.5 eV).

The radioluminescence phenomenon can be used for dating applications. Infrared radioluminescence or infrared radiofluorescence (IR-RF) dating is a method which can be used to determine the depositional age of Quaternary sediments (e.g., Trautmann et al. [1999](#); Krbetschek et al. [2000](#)) and therefore provides an alternative to the *luminescence dating* method. As IR-RF dates the last sunlight exposure of feldspar grains before burial, a sufficiently long sunlight exposure of the investigated material during transport (e.g., aeolian, fluvial) is mandatory.

The saturation dose of the IR-RF is at about 1,200–1,500 Gy (Erfurt and Krbetschek [2003](#)), and with an IR-RF single-aliquot regenerative-dose dating protocol, it was possible to date sediments >600 ka (Wagner et al. [2010](#); Lauer et al. [2011](#)). However, bleaching properties, and sensitivity changes of the IR-RF signal in between measurement cycles, have to be checked to obtain accurate age estimates (Buylaert et al. [2012](#)).

Definition

Application of the radioactive decay of ^{87}Rb to ^{87}Sr to determining the age of crystallization of igneous rocks.

Introduction and Background

Both rubidium (Rb) and strontium (Sr) are large ion lithophile elements and over the course of Earth history have become relatively concentrated in crustal lithologies, e.g., gneisses and granites, and sediments derived from these. Because of this, application of the Rb–Sr decay scheme was one of the first radiometric dating systems used to determine the age of rocks and remains a widely used system for dating geological units formed at relatively high temperatures, in particular volcanic, plutonic, and metamorphic rocks formed in the crust. Relatively low closure temperatures for commonly used minerals and susceptibility for disturbance of Rb and Sr complicate the use of the system as a geochronometer, and application of methods such as U–Pb in zircon is often preferred to yield more reliable age information.

Age determination with the Rb–Sr system revolves around the construction of an isochron using minerals or rocks with variable Rb–Sr ratios. Igneous rocks form by the cooling, crystallization, and solidification of magmas. During crystallization, different minerals form depending on pressure and temperature and the composition of the magma. Elements present at trace concentrations ($<1,000$ ppm) in magmas will not normally form their own minerals but will instead be incorporated into minerals by substituting for major elements with similar ionic radii and charge. Rb is monovalent with an ionic radius similar to K^+ so will tend to be concentrated in K-rich minerals, whereas Sr is bivalent and substitutes for Ca^{2+} in mineral lattices. Minerals with high K contents (e.g., biotite, alkali feldspar) will therefore have high Rb/Sr, whereas Ca-rich minerals (e.g., plagioclase feldspar, clinopyroxene, calcite, apatite) will have low Rb/Sr. During construction of an isochron, various mineral phases with variable Rb/Sr ratios are separated from a rock. These minerals are then dissolved and Rb and Sr purified by ion exchange chromatography and analyzed for their Rb and Sr concentrations and Sr isotope composition, typically by thermal ionization mass spectrometry (TIMS). Mineral selections are made so as to aim for as wide a range in Rb/Sr as

*Email: todw@ign.ku.dk

Fig. 1 A combined mineral whole rock isochron for the Habu Granodiorite in Japan; the inset shows the compositions of the whole rock powder, a felsic mineral fraction (mostly feldspar and quartz), and three apatite separates (Data from Tsuboi and Suzuki 2003). $^{87}\text{Sr}/^{86}\text{Sr}_{(i)}$ is the intercept of the isochron with the Y-axis and represents the initial isotopic composition of the magma at the time of emplacement. MSWD (mean square of weighted deviates) is a statistical parameter describing the degree of fit of the data points to a straight line

possible. A whole rock composition (representing an average of all the minerals present in the rock) is also often included in the age determination.

At the time of crystallization, the minerals inherit the original Sr isotope composition of the parental magma. With time the ^{87}Rb in the minerals will decay to ^{87}Sr , such that K-rich (Rb-rich) minerals will become progressively more radiogenic (higher $^{87}\text{Sr}/^{86}\text{Sr}$) with time, whereas the amount of ingrowth in the Rb-poor minerals will be lower or, in the case of Rb-free minerals, absent. For samples that behave as a closed system, plotting the measured $^{87}\text{Sr}/^{86}\text{Sr}$ of the different mineral phases versus their $^{87}\text{Rb}/^{86}\text{Sr}$ composition (isochron diagram) will define a line (an isochron) with a slope that is proportional to the age of the rock (see Fig. 1). The age of the rock can then be calculated using the equation:

$$t = \frac{1}{\lambda} \ln(1 + \text{slope})$$

The intersection of the isochron with the Y-axis (or alternatively analysis of a Rb-free phase) provides the initial Sr isotopic composition of the system $^{87}\text{Sr}/^{86}\text{Sr}_{(i)}$, a parameter that is useful to geochemists for understanding the geological history of the source rocks that melted to generate the magma. Chemical differentiation of the Earth over its history due to partial melting has resulted in the mantle having relatively low Rb/Sr, and thus, over time, it has evolved to relatively unradiogenic $^{87}\text{Sr}/^{86}\text{Sr}$ (ca. 0.7035). In contrast, the continental crust has relatively high Rb/Sr and has thus evolved to have highly variable and typically radiogenic $^{87}\text{Sr}/^{86}\text{Sr}$ (e.g., >0.710). As Sr isotopic compositions are not modified by processes such as melting and crystallization, these signatures can be used to identify the source(s) of magma and to identify processes such as crustal contamination of mantle-derived magmas.

An example of a mineral isochron constructed for the Habu Granodiorite in southwest Japan is shown in Fig. 1. Various mineral phases were separated from the rock and, together with a whole rock powder and a felsic mineral fraction (dominated by feldspar), were analyzed for their Sr

Fig. 2 Rb–Sr whole rock isochron for the Xinhuatun Granite, northeastern China, redrawn from Wu et al. (2003). Two ages are presented, one excluding sample X-5 which is a microgranular enclave and may not be directly related to the magmatic system; both ages are identical within error

isotopic composition and Rb and Sr concentration. Biotite, with a high Rb/Sr, has evolved with time to have a high $^{87}\text{Sr}/^{86}\text{Sr}$, whereas the felsic mineral fraction with a lower Rb/Sr has a much less radiogenic $^{87}\text{Sr}/^{86}\text{Sr}$. The apatite analyses fall off the isochron and were not included in the age calculation as the aim of this study was to assess their suitability for determining the initial isotopic composition of a magma.

In order to obtain meaningful age information from a mineral isochron, three fundamental assumptions must be fulfilled:

- The minerals all formed in equilibrium with each other.
- The minerals all formed from a reservoir of homogeneous isotopic composition ($^{87}\text{Sr}/^{86}\text{Sr}_{(i)}$).
- The minerals have been a closed system (i.e., not been subject to thermal or chemical disturbance) subsequent to crystallization.

It is possible to assess the validity of these assumptions statistically through the degree of fit of the analyses to a straight line regression (MSWD) and in the extrapolated error on the initial isotopic composition.

A Rb–Sr isochron for igneous rocks can also be constructed using whole rock compositions. Magmas become more evolved (i.e., enriched in SiO_2) during crystallization through the process of fractional crystallization, where minerals crystallize and become isolated from the surrounding residual magma. During fractional crystallization, Rb generally behaves as an incompatible element (preferring to remain in the melt phase rather than going into the crystalline phase). Therefore, Rb concentrations will increase in residual melts as the magma progressively crystallizes and becomes more evolved, at least until generally late-stage K-bearing minerals such as alkali feldspar and biotite begin to crystallize. In contrast, plagioclase feldspar, the major reservoir for Sr in an igneous system, crystallizes over a broad range of temperatures, and therefore, Sr concentrations in residual magmas will tend to decrease with increasing differentiation. As a consequence, Rb/Sr will generally increase in residual melts with increasing fractional crystallization and evolution. A series of whole rock samples with variable Rb/Sr can thus be analyzed from a single magmatic series and plotted on an isochron diagram to yield an age. An important assumption in constructing whole rock Rb–Sr isochrons is that the magma crystallized as a closed

Fig. 3 Rb–Sr mineral isochron for a lunar basalt, redrawn from Paces et al. (1991). The different minerals analyzed are plagioclase feldspar (Plag1 and Plag2), ilmenite (Ilm1 and Ilm2), and pyroxene (Px). Also included are a nonmagnetic mineral fraction (NMag1) dominated by plagioclase and pyroxene, a magnetic mineral fraction (Mag1) dominated by ilmenite and magnetic pyroxene, a whole rock powder (WR), and whole rocks of two additional samples (70138 and 71095). Ilm1 is not included in the regression line calculation

system, that is, there was no input from external sources such as contamination by the surrounding country rock, and thus, all rocks crystallized from a magma with a homogeneous initial isotopic composition. An example of a whole rock isochron based on a sequence of variably evolved rocks from a granitic pluton in China is shown in Fig. 2. The studied pluton outcrops over an area of 160 km² and ranges in composition from granodiorite, through monzogranite, to syenogranite and granophyres and is considered to have evolved by closed system fractional crystallization.

In some cases, it is possible to generate Rb–Sr ages are within error when realistic model ages by analysis of a single, highly radiogenic mineral phase; in fact, this is how the Rb–Sr dating system was first developed. Minerals such as biotite and alkali feldspar with high Rb/Sr will evolve to extremely radiogenic $^{87}\text{Sr}/^{86}\text{Sr}$ (values >3) in relatively old rocks. At such radiogenic compositions, extrapolation to an assumed and geologically reasonable initial $^{87}\text{Sr}/^{86}\text{Sr}$ (e.g., between values of 0.7 and 0.75) results in minimal change in the isochron slope and thus enables calculation of a model age based on a single data point. For example, alkali feldspar from the Illímaussaq Intrusion in southern Greenland has a measured $^{87}\text{Rb}/^{86}\text{Sr}$ of 407.1 and $^{87}\text{Sr}/^{86}\text{Sr} = 7.4727$. If an initial $^{87}\text{Sr}/^{86}\text{Sr}$ of 0.70 is assumed, this results in a calculated age of 1,161.9 Ma, whereas assuming an initial composition of 0.71 produces an age of 1,160.2 Ma; both ages are within error when realistic analytical errors are applied to the measurements (Waight et al. 2002).

Rb–Sr geochronology of igneous rocks is most often applied to evolved lithologies (e.g., rhyolites and granites) as their evolved nature promotes crystallization of the high-K (and Rb) phases ideally suited for dating. Application to mafic rocks is more limited as the rocks themselves, and the minerals that crystallize from them, have limited and generally low Rb/Sr. Nevertheless, it is possible as is illustrated, for example, in the study by Paces et al. (1991) on Apollo 17 lunar basalts, where a Rb–Sr mineral isochron yielded a Rb–Sr age of 3.67 ± 0.10 Ga, in good agreement with a Sm–Nd mineral age on the same material, despite a variation in $^{87}\text{Rb}/^{86}\text{Sr}$ of only 0.001–0.02 (Fig. 3).

The Rb–Sr system has been invaluable in determining the ages of ultramafic rocks such as ► **U-Pb, Rb-Sr, kimberlite**, which are the ultimate source of most of the world’s diamonds, and the related ultramafic lamprophyres. These rocks are amenable to Rb–Sr dating because, despite their

Fig. 4 Rb–Sr isochron for an aillikite dike from West Greenland, comprising five phlogopite phenocrysts (phl-A to phl-E) and a whole rock analysis (Reproduced with permission from Tappe et al. (2009))

very primitive compositions, they can crystallize significant quantities of phlogopite, the Mg-rich end-member of the biotite group of minerals with high Rb/Sr (Heaman 2013; this volume). In contrast, bulk rock kimberlite compositions have relatively low Rb/Sr. This difference between bulk rock and phlogopite Rb/Sr was utilized in the study of Tappe et al. (2009) who dated an ultramafic lamprophyre (aillikite) from Greenland by analyzing five phlogopite phenocrysts and a bulk rock to yield a well-defined Rb–Sr age of 157.9 ± 1.1 Ma (Fig. 4), in good agreement with U–Pb perovskite dates obtained on related aillikite dikes from the same region.

Chemical Disturbance

An important source of error in Rb–Sr dating of igneous rocks is post-crystallization disturbance, particularly in the presence of fluids. Both Rb and Sr are large ion lithophile elements and thus relatively mobile in fluids during, for example, hydrothermal alteration and weathering. The ^{87}Sr produced by radioactive decay of Rb is generally not strongly bound into the crystal structure of the host mineral and thus can be relatively easily mobilized. If this occurs, it will modify the $^{87}\text{Rb}/^{86}\text{Sr}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ composition of the investigated phase and potentially move it away from the ideal isochrons, increasing the error on the calculated age or erasing any original age information.

Closure Temperature

All geochronological systems are controlled by closure or blocking temperatures, the temperature at which a mineral system becomes closed to diffusional loss of radiogenic daughter atoms and therefore can begin to accumulate the radiogenic isotopes produced by decay and record age information. In addition to temperature, closure temperatures are also constrained by the diffusivity of the elemental species involved, cooling rates, crystal size, as well as the presence or absence of fluids and tectonic strain.

The closure temperatures for common materials investigated using the Rb–Sr system are relatively well known and are typically relatively low. The high Rb–Sr minerals are most important in constraining geochronological data, and muscovite is typically considered to have a closure temperature for the Rb–Sr system at ca. 500 °C and biotite at ca. 300 °C (Dodson 1973; Villa 1998). Alkali feldspar is less well constrained with a closure temperature of around 475–575 °C (Giletti 1991). In rapidly cooled igneous systems, Rb–Sr ages can be considered to be crystallization ages and generally agree with other geochronological systems with higher closure temperatures (e.g.,

Fig. 5 Geochronological data using various minerals and isotopic systems for the Rønne Granite (Bornholm, Denmark). The *dashed line* is a cooling curve assuming all heat loss is via one-dimensional heat conduction from the intrusion depth (10 km) toward the surface. The *gray symbols* represent various permutations of closure temperatures and decay constants for the ^{40}Ar - ^{39}Ar system (Reproduced with permission from Waight et al. (2012))

U–Pb in zircon). However, in slowly cooled systems this is not the case, for example, the U–Pb zircon system (closure temperature ca. 900 °C) yields an age of $1,456 \pm 5$ Ma for the Rønne Granite (Bornholm, Denmark), yet biotite from the same sample yields Rb–Sr model and two-point isochron ages of about 1,370 Ma and indicates either slow cooling or subsequent disturbance of the Rb–Sr system (Fig. 5). Similarly, the Rb–Sr mineral age presented in Fig. 2 is ca. 10 Myr. younger than U–Pb zircon on the same rock, a discrepancy also attributed to slow cooling by Wu et al. (2003). Age determinations from multiple geochronometers based on different minerals and isotopic systems can thus be used to determine a cooling history for a region. One important consequence of the different closure temperatures for Sr isotopes in various minerals is that slow cooling may result in different minerals passing through their closure temperatures at different times, causing scatter on isochron diagrams. While minerals with higher closure temperatures typically behave as closed systems, other minerals will still be open to diffusional exchange and ongoing radioactive decay prior to closure; thus, the minerals will not have crystallized from a homogeneous reservoir (e.g., Giletti 1991). Similarly, relatively low-temperature thermal disturbances may cause open system behavior and diffusional exchange of elements in some mineral systems, resetting the isotopic systematics and thus erasing any information on the original crystallization age of the magma. However, the low closure temperature for biotite especially has been particularly useful for dating metamorphic events.

Summary

The preferential incorporation of Rb (following K) or Sr (following Ca) into different mineral structures, as well as their differing behaviors during closed system evolution of magmas by fractional crystallization, results in a wide range in Rb/Sr in mineral and whole rock compositions. The radioactive decay of ^{87}Rb to ^{87}Sr can then be exploited to generate an isochron and yield age information about a magmatic system, providing all the analyzed materials crystallized from

a homogeneous parental melt, and the system has not been subsequently thermally or chemically disturbed. Some caution is required when applying the Rb–Sr chronometer to igneous systems; evaluation of the mobility of elements (especially Rb) and whether the strontium isotopic composition has been compromised by fluids (e.g., hydrothermal alteration and weathering) is required and the consequences of the relatively low closure temperature for Sr diffusion in many minerals, especially biotite, must be considered.

Definition

Mass Spectrometer. Instrument for causing separation of ions according to mass.

Introduction

SIMS is a technique for generating ion beams from solid targets. A focused ion beam is used to sputter (= ablate) the target mineral. The primary ion beam is typically quite energetic (10–20 keV) and composed of chemically reactive species (O, Cs) that enhance secondary ion production in electropositive elements (metals) and electronegative species (non metals). SIMS is applied through instruments such as the ion microprobe or ion microscope. For U-Pb geochronology, a negative oxygen ion beam (O^- or O_2^-) is used to generate U^+ and Pb^+ ions. Molecular species UO^+ , UO_2^+ , ThO^+ , etc., are also commonly measured. Sputtering results in complicated mass spectra that include atomic, simple molecule, and complex molecule species.

Instrumentation

In order to distinguish between the relevant Pb^+ and $U(O_n)^+$ species, large mass spectrometers are frequently used. The first mass spectrometer used for this purpose was the SHRIMP (Sensitive High-Resolution Ion Microprobe), which had a magnet turning radius of 100 cm and a total beam path length of approximately 700 cm, allowing both high mass resolution and high sensitivity (Ireland et al. 2008). SHRIMP utilized a double focusing mass analyzer incorporating magnetic and electrostatic sectors, the electrostatic sector compensating for velocity dispersion in the magnet. CAMECA instruments also produce a similarly sized instrument (IMS 1280) based on their ion microscope range, which can be used for geochronology.

U–Pb Geochronology

Studies suggest that instrumental mass fractionation of Pb isotopes is low (~ 0.2 % per amu) allowing use of uncorrected Pb isotope ratios. Therefore, zircons older than $\sim 1,000$ billion years can be dated using directly measured $^{207}\text{Pb}/^{206}\text{Pb}$ ratios. Younger zircons have insufficient ^{207}Pb for $^{207}\text{Pb}/^{206}\text{Pb}$ dating, but a novel calibration technique allows the use of $^{206}\text{Pb}/^{238}\text{U}$ ratios for geochronology (Compston et al. 1984).

The Pb^+/U^+ ratio is fractionated from the true Pb/U ratio because of the differences in ionization yields between U and Pb. Furthermore, the Pb^+/U^+ can be quite variable in an analytical session. Based on a model of local thermodynamic equilibrium, the measured Pb^+/U^+ is found to covary with uranium-uranium oxide speciation. Pb^+/U^+ versus UO^+/U^+ is frequently used to monitor the instrumental fractionation and allow measurement of calibrated $^{206}\text{Pb}/^{238}\text{U}$ ratios to a level of 1 % reproducibility.

Mineral Analysis

The first mineral used for ion microprobe analysis was zircon (Compston et al. 1984). The beneficial characteristics of zircon are that it contains elevated concentrations of U (100–500 $\mu\text{g/g}$), but the crystal structure strongly excludes Pb. Radiogenic Pb produced by the decay of U is strongly retained in zircon during even high-grade metamorphism. Zircons can be strongly zoned with domains representing inherited material, as well as igneous and metamorphic overgrowths. Ion microprobe analysis allows in situ analyses of growth zones that can be characterized through electron imagery (cathodoluminescence) as well as optical imagery (transmitted and reflected light) to optimize petrographic context and avoid areas complicated by inclusions or fracturing (Hanchar and Hoskin 2003). Other U-bearing minerals including monazite, allanite, titanite, and apatite have been dated.

Precision of SIMS U-Pb analyses can be limited by the small amount of material analyzed. A typical analysis consumes only a few nanograms of material. For a 100-Ma-old zircon with 100 $\mu\text{g/g}$ U, only 3 fg of ^{206}Pb are included in an analysis, many orders of magnitude below detection limits of other techniques. Precision can be further limited for materials with low uranium concentrations or young minerals where radiogenic Pb in-growth is limited.

Ion microprobe analysis has been applied to zircons younger than a million years and to zircons formed at the start of the solar system, ~ 4.56 billion years ago.

Conclusion

SIMS analysis allows a reliable means of dating discrete domains in U-Th-Pb-bearing minerals that may have complex histories. In situ analysis allows retention of the petrographic context and is one of the most powerful attributes of the technique. However, because the amount of material sampled is extremely small (few nanograms), precision can be limited, especially in young minerals or those with low uranium concentrations.

Continental Drift (Paleomagnetism)

Trond H. Torsvik*, Pavel V. Doubrovine and Mathew Domeier

Centre for Earth Evolution and Dynamics (CEED), University of Oslo, Blindern, Oslo, Norway

Definition

Paleomagnetism is the study of the Earth's ancient magnetic field through the record of remanent magnetism preserved in rocks. The directions of remanent magnetization are used to deduce the position of the Earth's magnetic pole relative to the study location at the time when this magnetization was acquired. By studying magnetizations of varying age from a single lithospheric plate, one can construct a path of apparent polar wandering (APWP) that tracks the motion of that plate relative to the geographic pole. A well-defined APWP can serve as a geochronological tool, i.e., for dating magnetizations of unknown age through a comparison of their directions with those expected from the reference APWP. Paleomagnetism can be used to date any geologic event that engenders the acquisition of remanent magnetization, including formation of igneous and sedimentary rocks, deposition of ore minerals, episodes of deformation, and other remagnetization processes.

Introduction

The development and broad acceptance of the theory of plate tectonics in the 1960s (e.g., McKenzie and Parker 1967) was the culmination of decades of scrutiny and intense debate among the Earth science community that ultimately witnessed the establishment of a mobilistic paradigm for the Earth's surface, which had first been introduced by Wegener (1912) in the form of "continental drift." Paleomagnetism was a key to this revolution, as it provided unambiguous evidence both for the "drift" of continents (Runcorn 1956) and for seafloor spreading (Hess 1962). The latter was validated by the observation of marine magnetic anomalies, which revealed symmetric, age-dependent stripes of remanent magnetization carried by seafloor that was created at mid-ocean ridges during periods of opposite geomagnetic polarity (Vine and Matthews 1963). While the concept of seafloor spreading provided a qualitative explanation for the mechanism of continental drift, identifications of marine magnetic anomalies allowed quantitative estimates of displacements between continents through geologic time, paving the way for the development of the modern theory of plate tectonics.

The geomagnetic field averaged over a sufficiently long time interval (tens to hundreds of thousands of years) is closely approximated by the field of a geocentric dipole aligned parallel to the Earth's rotation axis (McElhinny and McFadden 2000; Merrill et al. 1996). The dipolar geometry of the time-averaged field allows paleomagnetists to estimate positions of geographic poles relative to the studied locations by analyzing directions of remanent magnetization, provided that these magnetizations were acquired over a time interval that was sufficiently long to average

Fig. 1 (a) The first Phanerozoic polar wander path for “Europe” (Creer et al. 1954) based on six paleomagnetic poles from Britain. These poles – here shown as south poles – differ from the present-day South Pole, and this was originally interpreted as a change in the Earth’s rotation axis through time, i.e., true polar wander (TPW). In this plot, the continent (British Isles) stays fixed, but the polar axis is left to wander and following a path that is dubbed apparent polar wander path (APWP). “Apparent” means that the wandering may not be real and that it could be the result of “continental drift” as in (b). (b) The location of the British Isles at different times (longitude is arbitrary) according to the poles in (a), and here assuming a moving continent with a fixed polar axis. This was originally coined “continental drift.” Note that Scotland and England were actually separated by the Iapetus Ocean before the Silurian (Fig. 2a). This was not known in 1954 and thus the British Isles cannot be plotted as a coherent unit in the Cambrian

out short-term deviations of the geomagnetic field from that of a geocentric axial dipole (paleosecular variation). The poles obtained through measurements of magnetic remanence are commonly referred to as “paleomagnetic poles.” Due to the motion of lithospheric plates relative to the Earth’s spin axis, the position of the paleomagnetic pole in the reference frame of a specific plate varies with age. To an observer on the plate who is not aware of plate motion, it would appear that the spin axis slowly changes its orientation through time, so that the geographic pole moves along a unique path that we refer to as the “apparent polar wander path” (APWP). The motion reflected by APWPs may be due to the “drift” of individual plates, the rotation of the entire planet relative to the spin axis (true polar wander, TPW), or a combination of these two processes.

Creer et al. (1954) were the first to publish an APWP for “Europe” based on paleomagnetic poles from Britain. The paleomagnetic poles (plotted as south poles in Fig. 1a) differed markedly from the present-day pole and left Creer et al. (1954) with two possible explanations: either the pole itself had moved (TPW) or Britain/Europe (Fig. 1b) had moved relative to the pole (“continental drift”). Initially, they interpreted their results as “a slow change in the axis of rotation of the earth with respect to its surface,” in other words, TPW. However, two years later, Runcorn (1956) published an APWP for North America and crucially observed that it was separated from the APWP of Europe by $\sim 30^\circ$ longitude, thus demonstrating that the continents must have moved relative to each other. Specifically, Runcorn (1956) attributed the separation of the APWPs to the “drift” between North America and Europe corresponding to the opening of the Atlantic Ocean. This

Fig. 2 (a) Reconstruction of Laurussia at 420 Ma. Avalonia collided with Baltica at ~450 Ma and later Baltica/Avalonia collided with Laurentia (including North America, Greenland, Scotland, and Northern Ireland) at 430 Ma along the Iapetus Suture. The locations of paleomagnetically dated fault rocks in Western Norway (WN) and mineral deposits in Ireland (I) are shown as *open white circles*. The Irish mineral deposits are located near the Iapetus Suture and about 50 km north of the Variscan Front in Fig. 3b. (b) APWP for Laurentia. Moderately smoothed spherical spline path shown in 10 Ma intervals from the Early Cambrian (530 Ma) to the present. (c) APWP for Baltica/Stable Europe from Early Ordovician to the present. Input poles for both Laurentia and Baltica/Europe are shown with 95 % confidence ovals (*yellow shading*) and detrital sedimentary input poles have been corrected for potential I-errors (after Torsvik et al. 2012)

interpretation was later corroborated by the analysis of marine magnetic anomalies (Vine and Matthews 1963).

Fig. 3 (a) Laurussian (Baltica/Stable Europe and Laurentia rotated to European coordinates) running mean path shown with A_{95} circles (yellow shading). The APWP is corrected for potential inclination shallowing in detrital sedimentary rocks (Torsvik et al. 2012). The APWP is shown in 10-Myr intervals from the Late Carboniferous (320 Ma) to the Cretaceous (120 Ma), and each mean pole is based on a sliding time window of 20 Myr. The APWP is compared with paleomagnetic poles derived from two generations of fault rocks in Western Norway (Torsvik et al. 1992) and Zn–Pb and Ba deposits in Ireland (Pannalal et al. 2008a, b; Symons et al. 2007). These poles are shown with 95 % confidence ovals (dp/dm). (b) The Zn–Pb/Ba and the green breccia poles in (a) dates to around 310–290 Ma; they can potentially be linked to the waning stages of Hercynian orogenic activity

It is now well established that tectonic plates (which may include both continental and oceanic lithosphere) are constantly moving relative to each other, although at times they may coalesce or fragment, and their boundaries are otherwise frequently modified. APWPs from the individual continents attest to their often independent history of motion but also reveal an incessant, but commonly subordinate component of TPW. After more than a half-century of paleomagnetic research, the APWPs of most continents can be traced back to the dawn of the Phanerozoic, although they are generally much better defined for younger time. Consequently, when and where

Fig. 5 (a, b) Laurussia running mean path with A_{95} circles (yellow shading) from the Late Carboniferous (320 Ma) to the Triassic (220 Ma) shown together with a paleomagnetic pole from intrusions in southern Illinois (red square with the pink A_{95} circle) from Domeier et al. (2011) and Zn–Pb mineralization poles from Tennessee (TE) and Wisconsin (WI) (black and green square with light blue and light green A_{95} circles; same as in Fig. 4, but the dp/dm ovals were recalculated into A_{95} circles using the formulations of Cox (1970)). The running mean path is shown in two versions: (a) time window = 20 Myr and (b) time window = 10 Myr. (c, d) Great circle distance and the probability of the McFadden and Lowes (1981) test for the comparisons of the poles with the APWPs ((c) 20-Myr window, (d) 10-Myr window). Red curves correspond to the pole from the southern Illinois intrusions, blue curves to the Tennessee Zn–Pb mineralization pole, and green curves to the Wisconsin Zn–Pb mineralization pole. Thick dashed vertical lines show the best estimates of ages; thin dashed lines indicate their nominal 95 % confidence limits. Shaded bands show the conservative confidence intervals (pink shading for the southern Illinois pole, light blue shading for the Tennessee pole, and light green shading for the Wisconsin pole)

these APWPs are well constrained, it is now possible to invert the traditional workflow of

Fig. 4 (a) Laurentia running mean path with A_{95} circles (yellow shading) from the Late Carboniferous (320 Ma) to the Triassic (220 Ma) shown together with remagnetized carbonate rock poles from North America (Van der Voo and Torsvik 2012) and two Zn–Pb mineralization poles (blue squared is the pole from Eastern Tennessee, Symons and Stratakos 2002; green squared is the pole from Wisconsin, Pannalal et al. 2004). Remagnetized carbonate poles (black squares) are shown without 95 % confidence ovals for clarity. (b) Similar to (a) but the North American poles are compared with the Laurussia APWP (North American frame). (c) Geographic locations of sampling sites poles in (a–b) but plotted for sites with pole latitude $<40^{\circ}\text{S}$ (presumed oldest remagnetizations, i.e., Late Carboniferous when compared with the Laurentia APWP), $40\text{--}50^{\circ}\text{S}$ (Permian), and $>50^{\circ}\text{S}$ (Late Permian–Triassic). Yellow shading denotes regions of remagnetization and mineralization. TE Tennessee, WI Wisconsin, OK Oklahoma, MO Missouri, AL Alabama, AZ Arizona, PA Pennsylvania, MI Michigan, NY New York

paleomagnetic studies and use the APWP as a geochronological tool for dating magnetizations of unknown age.

Constructions of Reference APWPs

APWPs constructed as paths of apparent motion for the northern or southern geographic pole conveniently summarize paleomagnetic data for continents, terranes, and other tectonic blocks. In order to define an APWP, paleomagnetic poles of various ages are plotted on a stereonet and then fitted with a model path of polar motion, either with the use of spherical splines or by applying

a running mean technique. With the spherical spline method (Jupp and Kent 1987), a spline curve constrained to lie on the surface of the sphere is fitted to the paleomagnetic poles providing a regression model that smoothly approximates the positions of the poles at their respective ages (Fig. 2b–c). The paleomagnetic poles that serve as the input data for the regression are assigned statistical weights that are inversely proportional to the precision of the poles (A_{95}) or the paleomagnetic quality factor Q (Van der Voo 1990). In Fig. 2b–c, the input poles were weighted by the value of $7/Q$, which causes the spline path to pass closer to high-quality poles (7 is the highest possible value of Q factor).

In the running mean method, the position on the APWP corresponding to a specific age is calculated as a Fisherian mean (Fisher 1953) of paleomagnetic poles whose ages fall within a selected time window (e.g., 20 Ma) centered on that age. For example, the 160 Ma pole in Fig. 3a averages all Laurussian paleomagnetic poles within the 150–170 Ma age window. In practice, the mean poles are commonly calculated at age increments equal to half the width of the averaging window (e.g., 10 Ma increments for the 20 Ma window in Fig. 3a). An advantage of the running mean technique is that the pole uncertainty, commonly expressed as a circle of 95 % confidence (A_{95}), can be estimated for each mean pole through Fisherian statistics (Figs. 3–5). Both the spline method and the running mean technique effectively average out random biases of individual paleomagnetic poles and allow the basic pattern of APW to be determined.

APWPs have changed dramatically over the course of the past six decades, in part due to a much greater pool of paleomagnetic data. For example, in contrast to the initial compilation of merely five Phanerozoic poles from Britain (Fig. 1a), the most recent Phanerozoic APWP for Europe (Fig. 2c) is based on several hundred paleomagnetic poles. APWP refinements have also been made through the implementation of more sophisticated analytical methods and better instrumentation. Important recent developments include novel techniques to identify and correct for the inclination shallowing errors in data from clastic sedimentary rocks, which are now recognized to be commonly biased (Torsvik et al. 2012). An improved understanding of paleogeography has also driven notable changes in how we group paleomagnetic data. For example, the “European” path in Fig. 2c is constructed only with paleomagnetic poles from Baltica before 430 Myr, but after this time we also include poles from Scotland (originally a part of Laurentia, Fig. 2a), Avalonia (which was a separate terrane in the Ordovician), and progressively younger poles from Europe derived from rocks formed after their accretion to Laurussia. The Laurentian path in Fig. 2b is constructed from North American and Greenland poles; the latter have been rotated to North America after adjusting for the Cenozoic opening of the Labrador Sea and Baffin Bay.

The relative positions between North America, Greenland, and Baltica/Europe are known reasonably well after the Silurian, and paleomagnetic poles from these continents can be combined into a Laurussian APW path (Figs. 3 and 4b, Torsvik et al. 2012). In the following section, we will use this APWP as a reference path to illustrate the essentials of the paleomagnetic dating technique with examples of age estimates from fault rocks in Western Norway, Zn–Pb deposits in Ireland, intrusions in southern Illinois (USA), and remagnetized carbonate rocks and mineral deposits in North America.

Examples of Paleomagnetic Age Determinations

Example 1: Fault Rocks in Western Norway

After the Silurian Caledonide collision of Baltica and Laurentia (Fig. 2a), post-orogenic collapse and extensional shearing was accommodated along the Nordfjord-Sogn Detachment (NSD) in

Western Norway (e.g., Andersen et al. 1991). The NSD and Devonian mylonites are cut by younger brittle faults, most spectacularly exposed in outcrops on the island of Atløy (Torsvik et al. 1992; Eide et al. 1997) where a nearly flat-lying fault-breccia zone comprises a green network breccia crosscut by a red breccia. The magnetic mineralogy of the green breccia is dominated by magnetite, and magnetization components yielded a mean pole position that was originally assigned a Late Permian age (250–260 Ma) by Torsvik et al. (1992). The green breccia pole plots slightly off the APWP for Laurussia, but is within the 95 % confidence circle of the 310 Ma reference pole (Fig. 3a). Considering that the acquisition of fault-related remanence in the green breccia has likely occurred over a time interval that does not fully average the secular variation of the geomagnetic field (Torsvik et al. 1992), the uncertainty of the pole location may be substantially larger than that implied by its nominal 95 % confidence region (shown by a green ellipse in Fig. 3a). Hence, the post-Devonian fault rejuvenation along the NSD can only be loosely constrained to Late Carboniferous (310 Ma) to Early Permian (280 Ma) time. The red breccia pole overlaps with the 140 Ma mean pole for Laurussia (Fig. 3a), suggesting Early Cretaceous fault movements corresponding to the formation of the red breccia along the NSD.

Brittle fault rocks are notoriously difficult to date with conventional isotopic methods and $^{40}\text{Ar}/^{39}\text{Ar}$ whole-rock spectra from the breccias defined several age groups that were interpreted to correspond to separate thermal episodes (Eide et al. 1997). However, the oldest whole-rock ages from the green breccia, 296.2 ± 2.6 Myr (8 steps, 47 % of total $^{39}\text{Ar}_k$ gas) and 296.4 ± 2.8 Myr (4 steps, 58.4 % of total $^{39}\text{Ar}_k$ gas), are in agreement with the age suggested by paleomagnetic data (280–310 Ma). The youngest $^{40}\text{Ar}/^{39}\text{Ar}$ ages range from 96 ± 3 Ma to 163 ± 4 Myr and may reflect argon loss related to low-temperature hematite precipitation during the formation of the red breccia at ~ 140 Ma (Fig. 3a).

Example 2: Zn–Pb Deposits in Ireland

The Lisheen Zn–Pb deposit in Ireland is one of the major Lower Carboniferous carbonate-hosted base metal deposits, but the timing of ore mineralization and its genesis have been debated due to the lack of absolute ages. Paleomagnetic results from twelve Zn–Pb mineralized sites and eight host-rock sites (Pannalal et al. 2008a) yield a combined pole that is indistinguishable from the 300 and 290 Ma mean poles for Laurussia (pole I1 in Fig. 3a). A paleomagnetic pole (Symons et al. 2007) from the nearby Magcobar Ba deposit (pole I3 in Fig. 3a) is virtually identical to the Lisheen pole and a pole from the Galmoy Zn–Pb deposit plots slightly off the 300–290 Ma poles (pole I2 in Fig. 3a). These poles postdate peak Variscan folding and deformation (Fig. 3b), and Pannalal et al. (2008b) argued for an epigenetic model in which mineralization occurred during cooling from the Variscan thermal episode. These Irish Zn–Pb and Ba deposits were previously paleomagnetically dated through a comparison with an APWP published in Torsvik et al. (1996) that suggested a 269–290 Ma range for the age of mineralization. We now favor an Early Permian age of approximately 295 Ma based on our updated APWP (Fig. 3a).

Example 3: Remagnetization and Mineralization of Carbonate Rocks in North America

A well-documented remagnetization event is known to have widely affected Paleozoic carbonate rocks in North America. The cause of this far-reaching event remains enigmatic, but the age of the remagnetization can be deduced by a comparison against reference APWPs. This was most recently done by Van der Voo and Torsvik (2012), who also illustrated how the reference APWP for Laurentia had evolved over the past three decades. Figure 4a shows a comparison of the remagnetization poles listed by Van der Voo and Torsvik (2012, Table 1) with the most recent

APWP for Laurentia (Torsvik et al. 2012) that suggests that the remagnetization events date from the Late Carboniferous (310 Ma) to the Early Triassic (230 Ma). This range of ages is also manifested when the poles are compared with the Laurussian APWP (Fig. 4b), but the majority of the remagnetization poles plot slightly west of the main Laurussian path. This occurs because the Permian poles from Europe differ slightly from those of North America, and the inclusion of the European poles pulls the combined Laurussian APWP eastward. The reasons for this discrepancy are unclear. Because the North American and European poles of both older and younger age are in good agreement, it is unlikely that the discrepancy originates from erroneous relative fits between Laurentia and Baltica/Stable Europe. Nonetheless, this example demonstrates the importance of considering the differences among reference paths, as well as their limitations.

Remagnetization sites are located mostly within 1,000 km of the Alleghanian/Quachitan Sutures, but remagnetization has also been observed in sites as far as 3,000 km away (Fig. 4c), highlighting the broad scale of this protracted, continent-wide event. Spatial trends in the timing of remagnetization are not entirely clear (Fig. 4c), but as pointed out in earlier compilations, the southern states of Alabama, Georgia, and Tennessee near the Appalachian Suture appear to be affected earlier than those of the Central Appalachians (Miller and Kent 1988; Van der Voo and Torsvik 2012). Late Carboniferous (~310–300 Ma) remagnetization and Zn–Pb mineralization events were confined to an area from Alabama, Georgia, and Tennessee to Colorado. By contrast, Permian remagnetizations are much more widespread – from Newfoundland to Nevada – whereas Late Permian to Early Triassic remagnetizations are confined to the Central Appalachians (e.g., New York and Michigan) and the southwestern parts of North America (e.g., Colorado and Arizona). The cause of this pattern of remagnetization and its relation to the emplacement of Mississippi Valley-type deposits (e.g., Zn–Pb deposits) is still mystifying, but a commonly preferred hypothesis invokes tectonically expelled fluids driven from the Alleghanian orogenic belt (Oliver 1986).

Example 4: Intrusions in Southern Illinois (USA)

In the south end of the Illinois Basin, near the Illinois-Kentucky border (USA), a series of dikes, sills, and diatreme breccia bodies are observed to invade Devonian-Carboniferous sedimentary rocks on and around a structural dome (Hicks Dome) that is inferred to be cogenetic with the intrusive rocks. Due to extensive surface weathering and alteration, the intrusive rocks have proven difficult to classify and interpret. Consequently, many outstanding questions remain regarding their relationship to each other and to the greater tectonic framework of the region. Initial attempts to isotopically date the intrusive episode(s) ended in ambiguity, leading Reynolds et al. (1997) to employ paleomagnetism to date the rocks. From an intrusive breccia and a lamprophyric sill, Reynolds et al. (1997) isolated a remanent magnetization carried predominantly by high-temperature-oxidized titanomagnetite, as witnessed by microscopic observations of magnetite-ilmenite intergrowths that suggest a primary igneous origin of the mineral. Matching the resulting paleomagnetic pole with the APWP of Laurentia, Reynolds et al. (1997) concluded that the magnetization was acquired in late Paleozoic-early Mesozoic time during the emplacement of the intrusions. A comparison of the results of a recent paleomagnetic study that revisited these intrusive rocks (Domeier et al. 2011) with the updated APWP for Laurussia indeed reveals a close correspondence between the paleomagnetic pole and the 240–260 Ma mean poles of the APWP (Fig. 5a).

Uncertainties of Paleomagnetic Age Estimates

In the examples of the previous section, we restricted our discussion to qualitative age assignments through a visual comparison of paleomagnetic poles derived from magnetizations of unknown age with a reference APWP. In most cases, however, it is desirable to obtain a formal age estimate and specify its uncertainty. In this section, we will present a simple statistical approach that can be used to estimate the “best-fitting” age and its confidence interval.

The accuracy of ages estimated from paleomagnetic data depends on several factors, and certain conditions must be satisfied for paleomagnetic age estimates to be meaningful. It is critical that the magnetizations used to calculate a pole of unknown age have sampled a sufficiently long time interval to average out paleosecular variation (e.g., at least tens to hundreds of thousands of years) and that tectonic tilts or rotations postdating the acquisition of magnetization have been structurally corrected. When either of these two conditions is not met, the calculated pole may be significantly biased, resulting in an erroneous age estimate. In cases when it is suspected that the paleosecular variation has not been averaged out (as, e.g., in the fault breccias from Western Norway discussed in the previous section) or that there may have been unaccounted structural tilts, the most conservative approach is to conclude that whereas the pole provides some indication for a particular age, the age cannot be constrained with certainty.

Although the reference APWP can vary depending on the construction method, the differences between the spline-fitted and running mean paths that are defined using a large number of high-quality paleomagnetic poles are usually not significant (e.g., Torsvik et al. 2012). It is most common to construct running mean APWPs at 10-Myr intervals with a sliding time window of 20 Myr (e.g., Figs. 3 and 4). Irrespective of whether the reference APWP is a spline or a running mean path, the best estimate of the unknown age of the pole is the age corresponding to a position on the APWP, for which the great circle distance (GCD) between the pole and APWP is minimal. Because the reference APWPs are usually tabulated at rather large age increments (10 Ma in most cases), we recommend resampling the reference APWP at smaller steps (e.g., 1 Ma) by interpolation between the consecutive poles assuming a constant rate of polar motion, calculating GCDs between the pole and APWP at these increments, and defining the age corresponding to the minimum GCD value.

The confidence region for the estimated age can be defined by testing whether the dated pole is statistically distinct from the reference APWP at a specified level of significance (e.g., 5 % to constrain a 95 % confidence interval). In spline models, the uncertainty of the APWP is not known, and it is not possible to rigorously define the confidence region. If the spline curve intersects the 95 % confidence circle (A_{95}) of the pole, the range of ages corresponding to the APWP segment within the circle may serve as a “minimal” confidence region. Without incorporating the uncertainty of the APWP, it clearly underestimates the interval of acceptable ages.

In the running mean APWPs, the uncertainty of a mean pole (A_{95}) depends on the directional dispersion (Fisher precision parameter K) and the number (N) of the individual poles within the averaging window that have been used to define the mean. The directional dispersion reflects both the random deviations of the individual poles from the “true” mean and the differences of their ages from the mean pole age. If the ages of individual poles are evenly distributed within the averaging window (which is normally the case), the mean age is expected to be nearly identical to the median age of the window. Hence, in our simplified approach, we will not consider the age uncertainties of the mean poles separately and will treat each pole of a running mean APWP as an “unbiased estimate” of the pole corresponding exactly to the nominal age (median age of the averaging window).

The range of acceptable ages can be defined by comparing the pole of unknown age and the reference poles from the APWP and deciding whether the differences are significant at the 95 % confidence level. First-order conclusions can be made through a visual comparison of confidence regions. If the A_{95} circles of two poles do not overlap, it can be concluded that the poles are distinct at the 95 % confidence level. When one of the poles is within the A_{95} circle of the other, the difference between them is not significant. In the remaining cases, when the confidence regions overlap, but neither of the two poles is within the A_{95} of the other, the significance of the observed difference can be assessed through a formal test for a common mean (McFadden and Lowes 1981).

Suppose that the pole of unknown age was estimated from a dataset comprising N_1 individual measurements (VGPs) that yielded a resultant vector $\mathbf{R}_1$ (sum of unit vectors corresponding to the individual VGPs) and the reference pole is based on averaging N_2 paleomagnetic poles, with a resultant vector $\mathbf{R}_2$. Assuming Fisherian-distributed data, the precision parameters of the underlying distributions of VGPs and poles can be estimated as

where R_1 and R_2 are the lengths of the respective resultant vectors. In cases when the R values have not been presented in original studies (which is common for the running mean APWP compilations), they can be computed from the Fisher (1953) equation for A_{95} :

The statistics f for testing the null hypothesis that the two directional datasets (VGPs and poles averaged by the running mean) can be drawn from Fisherian distributions sharing a common mean is calculated using the equation

where R_c is the length of the resultant vector for the combined dataset ($\mathbf{R}_c = \mathbf{R}_1 + \mathbf{R}_2$). McFadden and Lowes (1981) showed that this statistic is approximately distributed as the F distribution with 2 and $2(N_1 + N_2 - 2)$ degrees of freedom, and the probability of observing the test statistic as large as f or larger is

The probability $P(F \geq f)$ corresponds to the significance level for retaining the null hypothesis. Hence, if it is smaller than 0.05, we can conclude that the poles are distinct at the 5 % significance level. Otherwise ($P \geq 0.05$), the poles should be considered indistinguishable at that level of significance.

Considering that the ages of the reference poles that are not distinguishable from the pole of unknown age at the 95 % confidence level should be within the confidence interval for the estimated age, and the ages of the reference poles that are distinct from the pole should be outside this interval, the confidence limits can be defined by the range of ages for which the probability values calculated using Eqs. (3) and (4) are equal or greater than 5 %. In practice, we recommend performing the McFadden and Lowes (1981) test for all poles of the reference APWP, plotting the calculated probability as a function of age, defining the age interval for which the probability curve is above the 5 % value, and using this interval as a nominal 95 % confidence region. A more conservative estimate can be obtained by using the ages of the two closest reference poles that significantly differ from the dated pole (i.e., fail the test) as the upper and lower confidence limits. The “conservative region” may in fact be preferable because of the simplifying assumptions for the treatment of pole uncertainties discussed above and the approximate nature of the test itself (see McFadden and Lowes 1981, for discussion).

To illustrate this technique, we will now derive formal age estimates and their confidence limits for some examples discussed in the previous section (examples 3 and 4). In Fig. 5a and b, we show

the Laurussia APWPs calculated at 5-Myr increments with two different time windows, 20 and 10 Myr. The pole from the southern Illinois intrusions (example 4) plots directly on the APWPs, and the analysis of GCD values suggests an age of 244 Ma for both comparisons (Fig. 5c and d). The probability values for the McFadden and Lowes (1981) test (Eqs. 3 and 4) are plotted as solid red curves in Fig. 5c and d, suggesting a 236–267 Ma confidence region for the age estimated using the APWP with the 20-Myr window (Fig. 5c) and a 233–270 Ma region for the estimate obtained with the 10-Myr-window APWP (Fig. 5d). The conservative estimates are 235–270 Ma and 230–270 Ma, respectively. Using similar analysis for the Tennessee and Wisconsin Zn–Pb mineralization poles (example 3) and the 20-Myr-window APWP (Fig. 5a and c), we arrive to the age estimates of 314 Ma (308–320 Ma nominal confidence interval, 305–320 Ma conservative confidence interval) and 308 Ma (307–313 Ma nominal confidence interval, 305–315 Ma conservative confidence interval), respectively. With the use of the 10-Myr-window APWP (Fig. 5d), the estimates become 312 Ma (306–319 Ma nominal confidence interval, 305–320 Ma conservative confidence interval) for the Tennessee pole and 305 Ma (302–311 Ma nominal confidence interval, 300–315 Ma conservative confidence interval) for the Wisconsin pole.

The examples considered here illustrate the sensitivity of the estimated ages and their precision to the choice of a reference APWP. In all examples, the ages estimated using the APWPs with the 20-Myr and 10-Myr averaging windows do not differ significantly (the differences are below the uncertainty limits). The reference poles in the 10-Myr-window APWP have larger uncertainties (A_{95}), producing slightly wider confidence intervals for the estimated ages. This result shows that there is no real advantage in using a reference path with an averaging window shorter than 20 Myr for obtaining a better constrained age (smaller confidence region). Hence, we recommend using APWPs constructed with a 20-Myr window for most applications of paleomagnetic dating technique.

Our examples also illustrate that the precision of paleomagnetic age estimates critically depends on the rate of polar motion (spacing of reference poles along the APWP). A 40-Myr-long confidence interval for the estimated age of the southern Illinois intrusions can be tracked back to a virtual standstill between ~245 and 265 Ma in both APWPs, whereas higher rates of polar motion over the 300–320 Ma period produce much tighter confidence intervals for the Zn–Pb mineralization poles from eastern Tennessee and Wisconsin (10–15 Ma). Thus, the temporal resolution of the reference APWP imposes a fundamental limitation on the precision of ages estimated using paleomagnetic data.

Summary and Conclusions

APWPs have proven invaluable as a means to succinctly communicate plate motions, as well as a convenient tool by which to study them. Well-defined APWPs may be used as a geochronological tool, capable of revealing the unknown age of a magnetization according to the position of the paleomagnetic pole derived from it on a reference APWP. The paleomagnetic dating method can be used to deduce the age of any geologic event which produces an attendant remanent magnetization, assuming there is a well-characterized APWP corresponding to the age and area (continent/terrane) of the event. We have presented several case studies which demonstrate the application of this method to the dating of intrusive rocks, faulting, ore mineralization, and regional remagnetization. We have also discussed a simple statistical technique that can be used to derive a best-fit estimate of the unknown age and constrain its 95 % confidence interval. It is important to note that random but persistent short-term variations in the geomagnetic field (paleosecular

variation), uncertainties of the reference APWP, and its temporal resolution (rate of polar motion) impose fundamental limitations on the geochronological resolution of this method. Even the most ideal paleomagnetic result would normally yield a paleomagnetic pole with an intrinsic uncertainty of $A_{95} \approx 5^\circ$, which would roughly correspond to an age error of approximately ± 11 Ma if the host continent had a N-S drift of 5 cm/year and its APWP was perfectly defined. A slower plate speed and/or a poorly defined APWP will see an increase in the age uncertainty. Finally, a word of caution: paleomagnetic results dated by this technique cannot subsequently be used in the construction of an APWP unless their age is verified independently, as the estimated age of the magnetization is derived from the path itself.

Magnetometer

Vicente Soler Javaloyes*

Estación Volcanológica de Canarias, IPNA-CSIC, La Laguna, Spain

Definition

An instrument used to measure the intensity and direction of the remanent magnetization of specimens.

In the middle of the last century, the astatic magnetometer was widely used in paleomagnetic laboratories for the measurement of the natural remanent magnetization (NRM). It is based on a magnet pair that is equally and oppositely magnetized, and this magnet system twists in response to the direction and intensity of magnetization of the specimen beneath it. The measurement limit of these instruments was about 10^{-3} amperes per meter (Am^{-1}), for a standard 2.5×2.1 cm cylinder (Collinson 1983).

Today, the most common instruments used for the measurement of the NRM are spinner and cryogenic magnetometer, like those manufactured by Agico, 2G Enterprises, and Cryogenic Limited, among others.

Many different spinner magnetometers have been developed, but they all involve spinning a rock specimen within or adjacent to a magnetic field sensor (typically a conductive pickup coil or fluxgate element). This rapid rotation places significant demands on the physical competence of specimens. The models available commercially can measure magnetizations less than 10^{-5} Am^{-1} (McElhinny and McFadden 2000).

Cryogenic magnetometers use a detector called a SQUID (superconducting quantum interference device) that is maintained at liquid helium temperatures and are based on the properties of a superconducting ring. This instrument has greater sensitivity and speed of measurement than spinner magnetometers and can measure magnetizations of 10^{-6} Am^{-1} .

Pass-through cryogenic magnetometers are now available that can be used to measure “U-channels” and either whole cores or split half-cores, without the necessity of physically sampling the cores.

The main disadvantage of cryogenic magnetometers is the requirement of having to keep the sensing coil superconductive, since this normally requires immersion in liquid helium.

Recently, 4.2 K cryocoolers have been used without the need of liquid helium. High-temperature SQUIDs are able to operate at liquid nitrogen temperatures, but the increased thermal noise prevents them from attaining the sensitivities available for conventional SQUIDs (Williams 2007).

A new magnetometer is now under development, the spin-exchange relaxation-free (SERF) atomic magnetometer, based on the precession of the spins of alkali atoms in the vapor phase. It is anticipated that SERF atomic magnetometers could achieve sensitivities exceeding those of SQUID devices (Shah et al. 2007).

Definition

The 35-km-long by up to 4-km-wide Isua supracrustal belt (ISB) lying within the Isukasia terrane, southern West Greenland (Fig. 1), consists of ca. 3,700 and 3,800 million years old (Ma) volcanic and sedimentary rocks that are among the oldest on the Earth. The ISB is the most significant and highly studied region for understanding early Earth chemistry and environments. This is because of its great antiquity and excellent exposures of a diverse range of rock types, including pillow basalts and banded iron formations (BIF).

Introduction

The ISB belt has been recognized for more than 40 years to be a significant resource for revealing early Earth history, as it contains the most extensive and least deformed sequences of Eoarchean (>3,600 Ma) ancient rocks deposited on Earth's surface. Although all rocks >3,600 Ma have undergone some degree of heating (metamorphism) and deformation due to later tectonic events, portions of the ISB rocks contain the world's least heated and least deformed oldest rocks and therefore more faithfully record their early history and processes of formation. The ISB is dominated by meta-volcanic amphibolites of island arc tholeiite and picrite geochemical affinity, some preserving pillow structures with lesser amounts of clastic and chemical sediments including quartz-magnetite banded iron formation, metachert, dolomites, and some felsic schists and pelites of volcano-sedimentary origin. The ISB lies within a larger complex of Eoarchean rocks composed mainly of quartzo-feldspathic orthogneisses derived from granitic rocks (Fig. 1).

The term *Isua* or *Isua supracrustal belt* is sometimes generically (and incorrectly) applied to all Eoarchean (>3,600 Ma) rocks from the >3,000 km² ancient terranes of West Greenland; however, these terms should only be reserved for this specific region and the term *Itsaq gneiss complex* (*Itsaq* is the Greenlandic word for ancient) as defined in Nutman et al. (1996), used when referring to the entire assemblage of >3,600 Ma rocks in the region.

Fig. 1 Summary geological map of the Isua area, Nuuk region, West Greenland. The arcuate Isua supracrustal belt is composed of two temporally distinct terranes, both containing a range of volcanic and metasedimentary rocks. The northern terrane has rocks with ages of ca. 3,700 million years old and the southern terrane with rock ages of ca. 3,800 million years old (constrained by >30 zircon U/Pb age determinations – see Nutman and Friend 2009). The legend lists the rock types present in each terrane

History of Geochronology

The first mapping of the Isua region in 1967 was done by geologists employed by prospecting companies, with the first visit by academic geologists (S. Moorbath and V. McGregor) in 1971. Following this visit Moorbath and coworkers at Oxford University produced the first radiometric age determination (Moorbath et al. 1972; ~3,695 Ma banded iron formation indicated on Fig. 1) for the ISB using the whole rock *rubidium-strontium* isochron dating method. This early work established an age for the ISB of $\geq 3,700$ Ma, making these the oldest volcanic and sedimentary rocks then known. However, owing to the limitations of the method, this age had large uncertainties (>100 myr). Other attempts to date the age of the ISB using *Pb-Pb*, *rubidium-strontium*, and *samarium-neodymium isochrons* also confirmed the great antiquity of these rocks, but again with large uncertainties (a detailed review of the history of the investigation of the ISB is provided in Nutman and Friend 2009). *U-Pb zircon* geochronology (Baadsgaard 1976; Michard-Vitrac et al. 1977; first zircon dating site indicated on Fig. 1) also confirmed the great antiquity of the rocks, but with much improved precision. Because variations in the ages of adjacent rock units could not be resolved with this level of precision, the whole of the ISB was regarded until the mid-1990s as a single assemblage formed at more or less the same time.

A breakthrough in geochronology, particularly for determining the ages of Archean rocks arrived in mid-1980s, with the first development of in situ methods for U-Pb dating of zircon crystals using the Sensitive High Resolution Ion MicroProbe (*SHRIMP*), designed and built at the Australian National University. With this instrument 25- μm -wide sites in single zircon crystals, extracted from rocks, could be individually dated with a precision on the $^{207}\text{Pb}/^{206}\text{Pb}$ age commonly better than 10 Ma. The first SHRIMP U-Pb zircon dating at Isua (Compston et al. 1986) used the same sample as Baadsgaard and achieved a far superior pooled precision of ± 2 Myr (2σ) for the entire dated zircon population. As detailed U-Pb SHRIMP geochronology became increasingly available for ISB rocks (e.g., Nutman et al. 1997), it could be demonstrated that the ISB contained two unrelated packages of volcanic rocks differing in age by about 100 Ma. Combined with detailed mapping (available now as 1:20,000 scale maps in Nutman and Friend 2009), this showed that the ISB contains two unrelated sequences of rocks. The northern supracrustal terrane has ages of ca. 3,700 Ma and the southern terrane has ages of ca. 3,800 Ma (summarized in Fig. 1). The juxtaposition of these two separate regions occurred by 3,660 Ma, as determined by the age of the oldest unit common to both terranes.

Intensive U-Pb dating efforts by various groups using both solution single zircon crystal (e.g., Crowley 2003) and in situ large ion probe methods, with now more than 30 ages available for the ISB as compiled in Nutman and Friend (2009), have confirmed the earlier findings and extended to $>3,900$ Ma the ages of individual detrital zircon crystals within sediments. However, despite intensive searches, so far there is no U-Pb zircon evidence for $>3,900$ Ma rocks in the ISB or surrounding areas.

Current Investigations

After more than 40 years of investigation, the ISB is still the prime natural resource for the study of Earth's early history and is visited regularly by teams of researchers from institutions worldwide. Examples of past work have included using the presence of basalts with pillow structures and the identification of water-deposited chemical sediments to demonstrate the presence of liquid water on the surface of the Earth at 3,800 Ma. The geochemical characteristics of the least altered volcanic rocks in both the northern and southern ISB terranes have chemical affinities with those of younger

subduction-related rocks. This has been used to argue for the formation of ancient crust in convergent margin, plate tectonic processes on the early Earth (see review of chemistry of Isua volcanic rocks in Polat et al. 2011). Ongoing research by various groups is focused on using a range of chemical and isotopic signatures preserved in these oldest sediments and volcanic rocks to reveal the chemistry of the early ocean and atmospheres, to trace the chemical development of the continental crust and mantle reservoirs, and to search for evidence of early life.

Magnetic polarity stratigraphy; Magnetostratigraphy

Definitions

Geomagnetic north/south poles: the points where the axis of the geocentric magnetic dipole that best fits the geomagnetic field intersects the surface of the earth. The south (north) pole of the best fitting dipole is actually in the northern (southern) hemisphere during Normal polarity, and is, by convention, called the north (south) geomagnetic pole.

Virtual geomagnetic poles (VGP's): the geomagnetic poles corresponding to the geocentric dipole that would produce an observed palaeomagnetic direction. VGP's are calculated from the declination and inclination of a paleomagnetic measurement and the latitude and longitude of the site from which the measurement was obtained.

Magnetostratigraphy: *the application of the well-known principles of stratigraphy to the observed reversal pattern of the geomagnetic polarity recorded in rock sequences.*

Paleosecular variation: *the gradual changes in direction and intensity of the geomagnetic field observed at all locations on the Earth's surface on timescales of years to millennia.*

Introduction

Paleomagnetism has become a standard discipline in dating the terrestrial record as it can be used to date and correlate sedimentary successions from all over the globe. It uses the well-documented variations in polarity, direction, and intensity of the Earth's magnetic field that have been independently dated by radiometric, astronomical, or other dating techniques. The geomagnetic polarity timescale (GPTS) is a "bar code" of alternating normal and reversed polarity intervals with characteristic lengths (Fig. 1). Sedimentary successions can be magnetostratigraphically dated by correlating their individual polarity patterns to the GPTS, with each recognized reversal providing an age tie point. The duration of individual polarity intervals varies from 20,000 years to several Myr, so that this technique will mainly work for long (>1 Myr) and continuous successions. The most recent polarity reversal (Brunhes/Matuyama) took place ~780,000 years ago. Since then several "excursions," thought to be failed or aborted reversals, have been recorded against a background of continuous low amplitude changes in direction and intensity, known as the geomagnetic secular variation. The combination of continuous records from sedimentary cores

Fig. 1 Schematic representation of the geomagnetic field of a geocentric axial dipole (“bar magnet”). During normal polarity of the field, the average magnetic north pole is at the geographic north pole, and a compass points northwards. During normal polarity, the inclination is positive (*downward directed*) in the northern hemisphere and negative (*upward directed*) in the southern hemisphere. Conversely, during reversed polarity, a compass needle points to the south; the inclination is negative in the northern hemisphere and positive in the southern hemisphere. In the GPTS, periods of normal and reversed polarity are represented by *black*- and *white*-colored intervals, respectively

with data from archaeomagnetic studies has resulted in the construction of regional secular variation master curves and models. Holocene lake sediments can be dated by correlating their direction and, in some cases, their intensity records to these secular variation master curves. Terrestrial sediments are generally more difficult to date than marine sediments because the continuity of the depositional record is more easily disrupted by erosional or nondepositional processes and because biostratigraphic information (the fossil record) is often scarce.

The Paleomagnetic Signal of Terrestrial Sediments

The magnetic field at any point on the Earth’s surface is a vector that is described by three parameters: its strength (F), declination (D) – the angle, measured eastwards, between geographical north and the horizontal component of the field – and inclination (I), the angle of the field below the horizontal (Fig. 2). Ferrimagnetic grains that are deposited by wind and water experience a torque and tend to align with the ambient magnetic field as long as they are in the water column or in the soft water-saturated topmost layer of the sediment (Fig. 3). These grains will become mechanically locked by dewatering and compaction and will preserve the ambient magnetic field direction as depositional remanent magnetization (DRM). Compactional processes, however, may also affect the orientation of elongated magnetic grains and result in a shallowing of the inclination (e.g., Tauxe 2010). The paleomagnetic signal of terrestrial sediments may also be affected by secondary components of magnetization. Secondary magnetic minerals may grow chemically within the sediment, and their magnetization will become locked when they grow through a critical grain size, after which their remanence may be stable over billions of years as chemical remanent magnetization (CRM). These geochemical processes may result in the (partial) removal of the original paleomagnetic signal and in a secondary component that may be significantly younger than the deposition of the sediment. Such processes may offset the position of a reversal boundary by a time of up to tens of thousands of years. In most sediments, however, the offset is small and the paleomagnetic signal may be considered as reliable and near-depositional. Inclination shallowing does not occur in CRM because chemical growth continues after dewatering.

Fig. 2 (a) The magnetic field at any point on the Earth's surface is a vector (F) which possesses a component in the horizontal plane called the horizontal component (H) which makes an angle (D) with the geographical meridian. The declination (D) is an angle from north measured eastward ranging from 0° to 360° . The inclination (I) is the angle made by the magnetic vector with the horizontal. By convention, it is positive if the magnetic field vector points below the horizontal and negative if it points above. (b) and (c) The standard method for presentation and analysis of paleomagnetic demagnetization results is called the Zijderveld diagram (Zijderveld 1967). The endpoint of the vector measured after each demagnetization step is projected both onto the horizontal plane (closed symbols) and onto the vertical plane (open symbols). Difference vectors (lines between data points) then show the magnetization removed between steps

Fig. 3 Illustration of how rocks acquire a depositional remanent magnetization. When magnetic particles are eroded from a source rock and are deposited as a sediment, the particles can align with the geomagnetic field to give rise to a depositional remanent magnetization (DRM). If the sediment is remobilized (e.g., by bioturbation), high water contents can allow the magnetic particles to realign with the geomagnetic field via the torque exerted on such particles by the field (From Roberts and Turner (2013), after Tauxe and Yamazaki (2007))

In terrestrial sediments, early diagenesis is widespread and occurs in virtually every sedimentary environment. Depending on the role of organic matter, existing magnetic minerals may dissolve, iron may be mobilized, and it may precipitate elsewhere. Suitable environments for paleomagnetic dating are generally those with a sufficiently high sedimentation rate, a significant detrital input, and a predominantly oxic environment. Sediments that are deposited under oxic conditions typically contain the iron oxides magnetite (Fe_3O_4) and/or hematite ($\alpha\text{-Fe}_2\text{O}_3$) that are both magnetically stable, especially if they are fine-grained. These conditions are common in many alluvial, fluvial, and deltaic depositional environments. Sediments that are deposited under anoxic

or dysoxic conditions may contain iron sulfides like greigite (Fe_3S_4) and pyrrhotite (Fe_7S_8). Pyrrhotite is generally considered to form during late diagenesis and therefore not suitable for paleomagnetic studies. Greigite can form authigenically any time after deposition, which complicates the interpretation of its paleomagnetic records (Roberts et al. 2011). Recent studies, however, show that two particular populations of greigite may provide reliable records of the ancient geomagnetic field variations, biogenic components of primary origin generated by magnetotactic bacteria living near the sediment/water interface, and authigenic components of secondary origin that formed by early diagenetic processes (Vasiliev et al. 2008). Greigite is especially common in restricted lacustrine and brackish water (e.g., Black Sea) environments.

The paleomagnetic signal in terrestrial sediments is extremely small compared to that of volcanic rocks and lavas and strongly depends on the magnetic carriers. Magnetite-bearing sediments usually yield a much stronger paleomagnetic signal than hematite- or greigite-bearing sediments. Rocks with relatively fine grain sizes (clay, marls, silts, fine sands) usually provide the best results, because smaller magnetic particles are generally more stable.

Sampling and Laboratory Techniques for Magnetostratigraphy

Paleomagnetic samples of rocks and consolidated sedimentary outcrops are commonly collected in the field using a portable electrical or gasoline-powered drill with a water-cooled diamond drill bit. Rocks can also be drilled with compressed air, e.g., if the cooling water dissolves the unconsolidated rocks (e.g., Dupont-Nivet and Krijgsman 2012). The drilling direction (azimuth and dip) of the cores is measured (and marked) in the field by a magnetic compass and a clinometer before extraction from the outcrop. Alternatively, samples can be collected as oriented blocks which need to be drilled in the laboratory later. Standard paleomagnetic cores have a diameter of ~ 2.5 cm and are at least 2 cm long. For unlithified deposits, oriented samples are often obtained by pushing PVC sample boxes into the soft sediment and orienting them before extraction.

Ideally, the ancient geomagnetic field can be reconstructed from its record in rocks during the geological past. The primary paleomagnetic signal, i.e., originating from near the time of deposition, however, is often contaminated with chemical overprints and “viscous” remanent components, referred to as VRM. Such a VRM may result from partial realignment of “soft” magnetic domains in the present-day field or from low-temperature oxidation of magnetic minerals. Weathered rocks will most certainly yield a paleomagnetic signal overprinted in the present-day field. Overprints can generally be removed through magnetic “cleaning” by demagnetization techniques.

The standard demagnetization procedure is to progressively remove the remanence of the samples by applying stepwise increasing temperatures or alternating fields (AF) in a magnetically shielded environment. After each demagnetization step, the remaining remanence is measured on either a spinner or a cryogenic magnetometer. Most rocks contain several components of magnetization, which are demagnetized within different temperature (or AF) ranges. If these components are formed at different times, they often have recorded the paleomagnetic field with a different direction. In the ideal case, the decay of the remanence will be linear within separate demagnetization ranges, so that direction and intensity of individual components can be reliably determined. The stepwise demagnetization results are commonly displayed in so-called Zijderveld diagrams or Z-plots (Fig. 2b, c). Their advantage over stereographic projections is that they enable resolution of the relative intensity and directions of the various linear components. The direction is usually determined by principal component analysis and is documented by declination, inclination, and maximum angular deviation (MAD).

Magnetostratigraphic Dating of Terrestrial Sediments

There are several prerequisites for the successful application of magnetostratigraphy as a dating technique for terrestrial sedimentary sequences (Opdyke and Channell 1996; Langereis et al. 2010). First, the originally recorded geomagnetic field has to be retrieved with sufficient accuracy and resolution to enable the successive intervals of normal and reversed polarity to be faithfully determined. Second, one needs to have some approximate (biostratigraphic or radiometric) age control. Finally, the studied sequences must represent a sufficiently long period to reveal a characteristic pattern of polarity intervals (generally >1 Myr during the Cenozoic) that can be unambiguously correlated to the standard GPTS. Naturally, hiatuses and major changes in sedimentation rate may obscure this “barcode” pattern, requiring careful field observations, while sampling resolution must ideally be several times higher than the shortest duration of (sub)chrons (20–30 kyr). Sampling of multiple sections, covering the same stratigraphic interval, increases the reliability of the age determination.

Often, these prerequisites are met, enabling magnetostratigraphy to be used as a high-resolution age control, which has several fundamental advantages above other dating techniques (Opdyke and Channell 1996; Langereis et al. 2010). Unlike most biostratigraphic events, reversals of the geomagnetic field are globally synchronous events, within sampling resolution, allowing precise correlations between different parts of the world and between different environments. A successful correlation of the recorded polarity pattern to the GPTS provides accurate ages of every recognized reversal boundary, allowing estimation of rates and rates of change (Fig. 4). This enables, for example, detailed continental-marine correlations and hence the determination of synchrony or diachrony of regional or even global paleoclimatic or tectonic events. Magnetostratigraphy can also be used to study the paleogeographic evolution and paleoclimatic history of different regions over long periods.

The latest development in dating the terrestrial record comes from orbital tuning of observed sedimentary cycles to cyclic changes in Earth’s orbit around the Sun and its axial tilt. In the “astronomically tuned polarity timescale,” each reversal boundary – or any other geological boundary for that matter, e.g., biostratigraphic datum levels or stage and epoch boundaries – is dated individually. The astronomical polarity timescale (APTS) has provided a breakthrough in dating of the geological record (Hilgen et al. 1997) and has significantly increased our understanding of, for example, the (paleo)climate system, since astronomical tuning relies on deciphering and understanding environmental changes driven by climate change which in turn is orbitally forced. Some parts of the geological timescale – e.g., the Late Triassic and the Middle Miocene – are largely based on astronomically tuned polarity reversals documented in terrestrial sediments (Kent and Olsen 1999; Abdul Aziz et al. 2000).

Geomagnetic Excursions

There is growing evidence from dynamo theory and the paleomagnetic record that for every successful polarity reversal, there have been a number of unsuccessful attempts of the geodynamo to reverse. Theory suggests that this is due to the longer magnetic time constant of the inner core: a reversal is initiated in the liquid outer core, but the inner core often fails to reverse before the initiating anomaly has reverted to the original polarity. In the paleomagnetic record, an excursion is seen as a significant deviation of the direction of magnetization – the virtual geomagnetic pole moving more than 45° from the rotation axis and a drop in intensity to maybe 20 % or 30 % of its

Fig. 4 Cyclostratigraphic and magnetostratigraphic correlations between subsections and correlation of the terrestrial Orera composite section (*OCS*) to the GPTS. The *OCS* is located in the continental Calatayud Basin of NE Spain. Solid lines between *OCS* and GPTS connect (interpretative) concomitant polarity boundaries. The inset diagram illustrates the changes in accumulation rates through time (After Abdul Aziz et al. (2000))

value during steady polarity. Many excursions are observed worldwide and therefore make good global stratigraphic markers. In the Brunhes these include the Mono Lake (33 ka), Laschamp (41 ka), Blake (120 ka), Iceland Basin (180 ka), Pringle Falls (210 ka), Big Lost (570 ka), and Stage 17/Delta (670 ka) (e.g., Roberts and Turner 2013).

Paleosecular Variation Curves of Holocene Lake Sediments

Secular variation refers to the gradual changes in the geomagnetic field that occur at all locations on the globe on timescales of years to millennia and are due to changes in the internal geodynamo. At any given location, the direction may vary by several tens of degrees and the intensity by a factor of two or more over a few centuries. In general the variations are not regular but consist of characteristic time-varying signals in each of the three components. Spherical harmonic analysis of historical observations made over the past 400 years shows that all the Gauss coefficients vary with time indicating that both the dipole and non-dipole field contribute to the secular variation (Jackson et al. 2000).

Several prerequisites are of crucial importance for paleosecular variation studies. Sediments should be fine-grained and contain single-domain detrital or biogenic magnetic minerals in sufficient concentration to yield a stable magnetization that can be measured with accuracy. They should have accumulated in a quiet environment, free from currents that might otherwise upset the alignment of magnetized grains as they fall, settle, and are locked into position in the sediment (Fig. 3). In many cases, the direction of such a detrital remanent magnetization (DRM) is an accurate record of the paleomagnetic field direction; however, sometimes the inclination appears to be shallowed during the depositional process, resulting in erroneously low average inclinations. Techniques are available for detecting and estimating a correction for such inclination error (e.g., Tauxe 2010).

Lake and shallow marine sediments typically accumulate at rates of between 0.5 and 5 m per millennium, and so the DRM of such sediment sequences can, in favorable circumstances, provide a continuous high-resolution record of prehistoric (or paleo-) secular variation (Tauxe 2010). The intensity of a DRM depends on the intensity of the paleomagnetic field and a complex function of the properties of the magnetic grains carrying the remanence. In order to obtain an estimate of paleointensity, a normalizing factor must be found that gives an empirical estimate of this function. In principle this should be a laboratory-grown remanence that affects the same spectrum of magnetic grains as the DRM, that is, it has a similar magnitude and coercivity spectrum. In practice normalization using anhysteritic remanent magnetization (ARM) is often found to yield a good proxy for relative paleointensity in sequences where there is little variation in magnetic mineralogy or grain size (Levi and Banerjee 1976; Tauxe and Yamazaki 2007).

Coring and Sampling for Secular Variation Studies

When coring unconsolidated subaqueous sediments for paleomagnetism, the most important considerations are to core vertically, to avoid rotation of the core barrel which might upset the declination record, and to avoid disturbance of the sediment due to compaction or vibration. Piston corers, operated from boats or small ships, are the usual choice. The Mackereth corer (Mackereth 1958), made of nonmagnetic materials, is operated pneumatically from cylinders of compressed air and collects 6, 9, or even 12 m long cores in a single drive. Once cut into 1.0 or 1.5 m sections and split into halves, cores are sampled either in discrete, typically 2.0–2.5 cm plastic cubes, or in continuous U-channels of 2 × 2 cm cross-section and up to 1.5 m in length. Many laboratories now employ pass-through cryogenic magnetometers to measure the NRM of U-channel samples continuously; some also have in-line automated alternating field demagnetization instrumentation (Turner et al. 2007). A downside of such automation, however, is that the measured signal is a convolution of the magnetization and the sampling profile of the sensors and deconvolution

should be performed (e.g., Jackson et al. 2010). Measurement of discrete samples is more time-consuming but circumvents the convolution problem. Clearly there is a trade-off between time and resolution: with very long marine cores, the efficiency of automated measurements on U-channels wins, but with Holocene secular variation records from perhaps 6 m long cores, the extra resolution often makes discrete samples preferable.

Secular variation “master curves” are now available covering the Holocene period in several parts of the world. Typically these have been compiled by correlating and combining the records of replicate cores within lakes and then combining such records from different lakes. Where lakes are more than about 100 km apart, the directional records are reduced to a common location, usually via a virtual geomagnetic pole transformation (e.g., Roberts and Turner 2013). Age control is typically provided by radiocarbon dating, pollen assemblages, tephra identification, etc. The stacking of several records also allows the estimation of statistical confidence in the records. An example is the UK master curve of declination and inclination of Turner and Thompson (1981, 1982) and later European records in which many of the same features are recognizable, modified increasingly with distance from the United Kingdom.

Confidence in such lake sediment records is enhanced by their correlation with archaeomagnetic records from the same region (Fig. 5). Archaeomagnetic data derived from the thermoremanent magnetization (TRM) imparted to an artifact (pottery, brick, fireplace, cooking stone, etc.) the last time it cooled through the Curie temperature of its constituent magnetic minerals. Age control may be available directly from the historical context or may be provided by radiocarbon dating of associated organic material. Although archaeomagnetic records lack the continuity of sedimentary ones, the TRM process leads to a stronger remanence. Further, there is little or no smoothing or averaging in either the magnetization or measurement process, so confidence in the direction is usually very good, and in addition an estimate of absolute paleointensity can often be made from a TRM.

Databases, Models, and Dating Tools

Various compilations of lake sediment and archaeomagnetic secular variation data are available, many in online databases. Most of these have been compiled with the aim of producing mathematical models of the geomagnetic field, and the datasets included all fulfill agreed quality criteria. The overall distribution of available data is heavily biased towards the northern and Atlantic hemispheres, and relatively few archaeomagnetic data are older than 3 ka.

Various models have been constructed using these data. The CALS suite of models (e.g., Korte et al. 2011) are continuous time-varying models of the global field based on spherical harmonic expansion of the magnetic potential in space and cubic B-splines in time. The most recent of these, CALS10k, covers the entire Holocene to degree and order 10. As is to be expected, such models are most reliable where the data coverage is best, for example, Europe and North America. In such regions, they are useful dating tools: a model master curve can be calculated for any given location (latitude and longitude) and observed declination, inclination, and/or intensity matched, either by eye or using formal statistical procedures. In other regions, where data are currently sparse, the reliability of global models and their potential for dating is poorer and will improve as more data accumulate.

An alternative approach is to model the high-density data at the regional level: to produce regional models, using only a restricted dataset. Whereas spherical harmonic analysis is a well-validated technique for use in a spherical reference frame such as the Earth, methods for producing

Fig. 5 Paleomagnetic secular variation records from Europe for the past 4,000 years. Declination and inclination: *black data points* with error bars are archaeomagnetic data averaged over 160-year windows, calculated at 50-year intervals, with 95 % confidence intervals, from Bucur (1994) and Gallet et al. (2002). *Red curves* are the UK lake sediment records of Turner and Thompson (1981, 1982), transformed to the latitude and longitude of Paris. Paleointensity: archaeomagnetic intensities from Spain, France, Norway, and Denmark, referred to the latitude of Paris from Gómez-Paccard et al. (2008). The *red curve* and *shading* represent the mean and 95 % confidence. In all three plots, the *blue* and *yellow curves* are calculated from the regional and global models, SCHA3k and CALS3k of Pavón-Carrasco et al. (2009) and Korte et al. (2009), respectively (After Roberts and Turner (2013))

models on restricted areas of the globe are less well developed. One method is spherical cap harmonic analysis (Haines 1985; Thébaud et al. 2006), which has been used to produce models for Europe, SCHA.DIF.3k and SCHA.DIF.8k (Pavón-Carrasco et al. 2010). Although the method is still controversial, these European models reproduce the data as well as or better than existing global models based on spherical harmonic analysis (Fig. 6).

Pavon-Carassco et al. (2011) have gone one step further – they have produced a Matlab dating tool, whereby input of a paleomagnetic declination, inclination, and ideally intensity, together with sampling location, results in an estimate of age, based on comparison with a PSV master curve for the location that is calculated from regional and global models. The next decade will almost certainly see both improvements in global models and the appearance of PSV-based dating tools for many more regions of the globe.

Fig. 6 *Black*: Paleomagnetic secular variation “master curve” for the United Kingdom, compiled from ten 6 m long sediment core records (four from Loch Lomond, three from Windermere, three from Llyn Geirionydd) with age control provided by suites of radiocarbon dates on three of the cores (From Turner and Thompson (1981, 1982)). *Red*: Modeled declination and inclination variations at the latitude and longitude of Loch Lomond calculated from the CALS10k model, which is based on spherical harmonic analysis of globally distributed secular variation records (Korte et al. 2011). *Green*: Modeled declination and inclination variations at the location of Loch Lomond calculated from the SCHA3k and SCHA8k models, which are based on spherical cap harmonic analysis of European secular variation records (Pavón-Carrasco et al. 2009, 2010). In each case, the uncertainty bars and bands signify 95 % confidence limits

Summary/Outlook

Paleomagnetic records of polarity reversals and secular variation can provide valuable age control for geological and archaeological materials, particularly sedimentary sequences. The geomagnetic polarity timescale is applicable worldwide. Secular variation is coherent over regions of continental scale. The use of regional master curves of declination, inclination, and sometimes intensity is gradually being supplanted by mathematical models at regional and global scale from which dating tools can be created. The current GPTS offers high-resolution age control for the past 160 Ma, where it is constructed from seafloor magnetic anomaly profiles, complemented by astronomical and radiometric ($^{40}\text{Ar}/^{39}\text{Ar}$; U-Pb) dating of terrestrial rocks. Research is now focused on excursions and older parts of the GPTS. Secular variation models will be improved as more data is obtained to fill in the gaps, particularly in the southern hemisphere and Pacific regions.

$^{207}\text{Pb}/^{206}\text{Pb}$ dating; Pb-isotopic dating; Pb-Pb dating; U-Pb dating of meteorites

Definition

Determination of ages of meteorites and their components using decay of radioactive isotopes ^{238}U and ^{235}U and accumulation of their decay products (daughter isotopes) ^{206}Pb and ^{207}Pb .

Introduction

Meteorites contain trace amounts of uranium, and their ages can be calculated from the quantities of accumulated radiogenic isotopes of Pb. Two long-lived isotopes of uranium ^{235}U (0.7205 %, half-life 4.468×10^9 year) and ^{238}U (99.2736 %, half-life 0.704×10^9 year; isotopic abundances based on the data of Brennecka and Wadhwa 2012, half-lives from Jaffey et al. 1971) decay to stable isotopes of lead ^{207}Pb and ^{206}Pb . The dual nature of the U–Pb decay scheme has two important implications for geochronology (Ludwig 1998; Amelin 2006; Schoene 2014). First, consistency of the dates calculated from two parent-daughter pairs, ^{238}U – $^{206}\text{Pb}^*$ and ^{235}U – $^{207}\text{Pb}^*$ (the asterisk indicates radiogenic Pb), can be checked using concordia diagrams (Wetherill 1956; Tera and Wasserburg 1972), and their consistency provides evidence that the U–Pb-isotopic system remained closed since formation of the rock. Second, the two decay schemes can be combined, and the date can be calculated from the ratio of radiogenic isotopes $^{207}\text{Pb}^*$ and $^{206}\text{Pb}^*$. The $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ dates are insensitive to recent migration of U or recent loss of radiogenic Pb, so it may be possible to get accurate ages even from meteorites affected by recent impacts, terrestrial weathering, and laboratory treatment that is usually necessary for removal of non-radiogenic Pb. Modern U–Pb chronology of meteorites is based on $^{207}\text{Pb}^*/^{206}\text{Pb}^*$, whereas $^{206}\text{Pb}^*/^{238}\text{U}$ and $^{207}\text{Pb}^*/^{235}\text{U}$ provide supporting information.

Concentration and Distribution of Uranium in Meteorites

Modern “terrestrial” U–Pb geochronology mainly relies on dating minerals such as zircon, baddeleyite, and monazite that usually contain 10–1,000 ppm or more U and negligible quantities of non-radiogenic Pb. In contrast, minerals with U content greater than several ppm are very rare in chondrites and their components and in achondrites of asteroidal origin. Uranium concentrations in various types of meteorites are summarized in Table 1. Because of low U concentration, several milligrams of bulk meteorite, or a chondrule or CAI material, are required for a single analysis, compared to microgram or

*Email: yuri.amelin@anu.edu.au

Table 1 Examples of uranium concentration (in parts per million) in meteorite classes, selected meteorites, and their components

Meteorite class	Meteorite group	Component or mineral	Uranium concentration, ppm, range, and (median)
<i>Bulk meteorites and their major components</i>			
Ordinary chondrites	H	Bulk meteorite	0.009–0.135 (0.022)
Ordinary chondrites	L and LL	Bulk meteorite	0.007–0.027 (0.012)
Estatite chondrites	EH	Bulk meteorite	0.006–0.008
Carbonaceous chondrites	CI, CM, CV, CR, ungrouped	Bulk meteorite and chondrules	0.012–0.491 (0.026)
Carbonaceous chondrites	CV	Bulk Ca-Al-rich refractory inclusions (CAIs)	0.041–0.192 (0.113)
Eucrites		Bulk meteorite	0.008–0.305 (0.100)
Angrites	Quenched and plutonic	Bulk meteorite	0.030–0.302 (0.128)
<i>Rare high-U minerals in meteorites of asteroidal (non-planetary) origin</i>			
Carbonaceous chondrites	CV	Perovskite in CAIs	3–23
Chondrites and achondrites		Zircon	30–133
Angrites	Plutonic	Silica-rich apatite	11–22

Data from Kaltenbach et al. (2012) and Amelin et al. (2009) and references therein

smaller quantities of zircon and other U-rich minerals commonly analyzed in “terrestrial” U–Pb geochronology. Some meteorites contain very rare minerals with 10 ppm or more of uranium: perovskite in some CAIs in CV chondrites, silica-rich apatite in plutonic angrites, and small grains of zircon on some chondrites and eucrites. Despite the advantage provided by higher U concentrations and the evidence for usually concordant isotopic systems in these minerals, their use in meteorite U–Pb chronology has been limited because of their extreme rare occurrence. The mainstream meteorite U–Pb chronology still relies on representative fractions of whole meteorites, bulk chondrules, and CAIs and on rock-forming minerals such as pyroxene, all of which contain well below 1 ppm of uranium.

From Isotopic Ratio to the Age of a Meteorite in Five Steps

Obtaining a meaningful Pb-isotopic age of a meteorite from precise Pb-isotopic measurements involves five steps (Amelin et al. 2009, including their Electronic Annex EA-1). First, the Pb-isotopic ratios are corrected for all sources of analytical biases, such as mass fractionation, interferences, and matrix effects. Second, laboratory blank is subtracted, resulting in accurate isotopic composition of the Pb that was isolated from the sample. Third, radiogenic $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ratio is calculated or inferred from blank-corrected isotopic ratios that may include initial Pb, radiogenic Pb, and terrestrial contaminant Pb using an isochron (preferably) or a model date approach. Fourth, the $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ratio is converted to a date – a measure of time, using known values of uranium decay constants and isotopic composition. Finally, the meaning of the date as marking the timing of a real, natural event is established, and the nature of this event is identified. Systematic uncertainties possibly leading to inaccuracy in $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ages of meteorites can be

introduced at all five steps, and their sources have to be carefully examined. Below we discuss two of the most important sources of potential inaccuracy in meteorite ages.

Removal of Non-radiogenic Pb

Along with radiogenic Pb, meteorites contain several components of non-radiogenic Pb: initial Pb of primordial composition, Pb mobilized from the target and projectile rocks by impacts in the parent asteroid and implanted into surrounding rocks, and terrestrial Pb introduced by weathering and handling. In U-Pb dating of meteorites containing as little as 10–200 ppb of U (and similar concentrations of radiogenic ^{206}Pb), we have to work with larger samples and rely on laboratory treatments, such as multistep acid leaching, to separate radiogenic Pb from several components of non-radiogenic Pb. Modern multistep leaching schemes produce radiogenic Pb with reasonably high $^{206}\text{Pb}/^{204}\text{Pb}$ (up to several thousands in favorable cases) from most refractory inclusions and igneous meteorites and are usable even if less efficient for chondrules. However, most radiogenic Pb is lost in the earlier leaching steps along with non-radiogenic Pb, so that the final, usually the purest, leaching steps typically contain only 5–10 % of the total radiogenic Pb. This is a serious disadvantage in dating materials of limited size or quantity, such as individual chondrules, or low-U mineral phases from CAIs and achondrites. Furthermore, acid leaching can fractionate radiogenic Pb from its parent U, thus rendering a concordance test of closed system behavior invalid. A search for alternative treatments, such as nonacidic selective dissolution of minerals and volatility-driven separation of Pb components by evaporation under controlled conditions, can bring about more efficient methods for extraction of radiogenic Pb from meteorites.

Isotopic Composition of Uranium

The $^{238}\text{U}/^{235}\text{U}$ ratio was considered constant and equal to 137.88 until recently, but several studies published since 2010 show that it is variable. Uranium isotopic variations among the CAIs, ranging from 137.409 ± 0.039 to 137.885 ± 0.009 (Brennecka et al. 2010), are most prominent. Most recent data from bulk chondrites and achondrites suggest uniform $^{238}\text{U}/^{235}\text{U}$ ratio (Bouvier et al. 2011; Brennecka and Wadhwa 2012; Connelly et al. 2012), but it is unclear whether variations at a smaller scale observed in these and ongoing studies are significant and whether the meteorite and terrestrial U isotopic compositions are significantly offset from each other. Considering possible variability, the U isotope ratios should be determined for every meteorite that is being precisely dated with the $^{207}\text{Pb}/^{206}\text{Pb}$ method. These determinations are, however, performed at the limit of analytical sensitivity of modern multicollector inductively coupled plasma mass spectrometry (MC-ICPMS) and typically require several times larger quantities of material than Pb-isotopic analyses by ionization in thermal ionization mass spectrometry (TIMS). Development of a more sensitive method for precise (0.01 % or better) measurement of the $^{238}\text{U}/^{235}\text{U}$ ratios is one of the most desperately needed analytical advancements in U–Pb dating of meteorites. As the analytical uncertainties of U–Pb dating decrease, methods of non-radiogenic Pb removal improve, understanding of chemical and isotopic systematics of meteorite progresses, and correction for variable $^{238}\text{U}/^{235}\text{U}$ becomes one of the dominant components in the total uncertainty of meteorite U–Pb dates. Reducing this uncertainty will require thorough understanding of U isotopic variation in meteorites, along with improvements in analytical sensitivity and precision.

Precision of Pb-Isotopic Dates of Meteorites

Fast decay of ^{235}U and its high relative abundance at the time of the solar system formation make the change of radiogenic $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ over time strongly nonlinear and initially very rapid, so that the relative uncertainty of the $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ dates for the oldest minerals and rocks ($>4,500$ Ma) is 3.2 times smaller than the relative uncertainty of the $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ratio. Together with the modern advancements in techniques of isotopic analysis, this makes the $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ratio an exceptionally precise chronometer for ancient rocks and minerals. Precision of 0.2–0.5 Ma is now common in dating early meteoritic solids such as refractory inclusions, chondrules, and differentiated asteroidal materials (Amelin 2008; Wadhwa et al. 2009; Connelly et al. 2012). This precision is similar to that obtained with the popular extinct radionuclide systems ^{182}Hf – ^{182}W and ^{53}Mn – ^{53}Cr . In the most favorable cases, the uncertainty of the $^{207}\text{Pb}/^{206}\text{Pb}$ can be as low as 0.1 Ma, rivaling precision of the state-of-the-art ^{26}Al – ^{26}Mg dating. Similar precision levels form a strong basis for building a coherent timescale of the early solar system processes with a combination of Pb-isotopic and extinct radionuclide chronometers.

The Prospect of Further Improvement of Precision in Pb-Isotopic Dating of Meteorites

Even the most precise Pb-isotopic dates reported so far have 30–100 times larger uncertainties than the ultimate precision level based on counting statistics and the number of atoms of ^{207}Pb and ^{206}Pb consumed during analysis: about 0.11 Ma for 1 pg of radiogenic Pb and a mere 3,400 years for 1 ng of radiogenic Pb. The main sources of additional analytical uncertainties are incomplete conversion of Pb atoms in the sample to the ions that reach the detectors and noise and distortions in the ion beam registration. The efficiency of Pb ionization in TIMS using the best existing emitters is about 5–10 %, and this alone increases the counting statistics-related uncertainty by 3–4.5 times compared to the hypothetical 100 % ionization and extraction. In MC-ICPMS, another technique commonly used in meteorite U–Pb chronology, the ionization efficiency for Pb, is close to 100 %, but the limited ion extraction efficiency makes the total ion yield of even the most sensitive instrument configurations (2–3.5 %) lower than in TIMS. The detector systems also add substantial uncertainties to the isotope ratio measurements. The noise of the Faraday cup arrays with amplifiers in the current mode, which is used in modern commercial mass spectrometers, is limited by the thermal noise of the feedback resistors. This source of noise can be greatly reduced by using amplifiers with high input impedance in charge mode. Ion counting with an array of multipliers is an alternative solution for measuring very low ion beams, but it also requires many improvements in linearity, cross-calibration, gain stability, and other parameters.

Summary

The $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ form of the U–Pb method is the only extant radionuclide dating method with sufficient precision for resolving individual events in accretion of the solar protoplanetary disk and for cross-calibration with extinct radionuclide chronometers. It allows dating refractory inclusions, chondrules, and achondrites with precision of 0.1–0.5 Ma using samples of several milligrams to tens of milligrams. Accuracy of the dates is similar, if we do not consider uncertainty in the decay constants of uranium isotopes, which is only relevant in comparisons to other long-lived

radionuclide chronometers. Multistep isotope leaching can efficiently separate radiogenic Pb. Pb isotope dating must be accompanied by measurements of U isotopic ratios because of their known variability. Further substantial improvement of precision and reduction in sample sizes is likely to be achieved in the future by improvements of analytical sensitivity and reduction of all components of instrument noise and laboratory contamination.

Ujaraaluk Unit (Nuvvuagittuq greenstone belt)

Jonathan O'Neil*

Department of Earth Sciences, University of Ottawa, Ottawa, Canada

The Ujaraaluk unit is the dominant lithological unit in the Nuvvuagittuq greenstone belt (formerly called Porpoise Cove greenstone belt) in Northeastern Canada. It is interpreted to be as old as 4.39 Ga, which would make it the oldest vestige of crust preserved on Earth (O'Neil et al. 2008, 2012). The Ujaraaluk unit is an amphibolite composed of variable proportions of cummingtonite – plagioclase – biotite $\pm$ quartz $\pm$ garnet $\pm$ anthophyllite (O'Neil et al. 2011). The abundance of cummingtonite gives the Ujaraaluk unit an unusual light beige color compared to most other dark green to black hornblende-dominated greenstone belts in the Northeastern Superior Province. The Ujaraaluk unit was formerly named “Faux-amphibolite” due to this unusual aspect (O'Neil et al. 2007).

The Ujaraaluk is mafic in composition ranging from basaltic to basaltic andesite. It is divided into three distinct geochemical groups following a chemostratigraphy within the Nuvvuagittuq greenstone belt (O'Neil et al. 2011). The Ujaraaluk at the base of the sequence is characterized by high Ti content and exhibits tholeiitic affinities with relatively flat incompatible trace element profiles. The top of the sequence consists of rocks with lower Ti concentrations. This low-Ti group is further subdivided in two subgroups with distinct rare earth element profiles. The Ujaraaluk directly above the high-Ti group displays U-shaped rare earth element profiles similar to modern boninites, whereas the rocks at the very top of the sequence are enriched in light rare earth elements and follow calc-alkaline differentiation trends. The Ujaraaluk unit also includes ultramafic bodies that can be divided into the same three geochemical groups. The ultramafic rocks are interpreted to be co-genetic olivine and orthopyroxene cumulates that fractionated from the mafic Ujaraaluk unit.

The age of the Ujaraaluk unit has been debated. Thin intrusive trondhjemitic bands are dated by U-Pb in zircon at $\sim$ 3.8 Ga (e.g., Cates and Mojzsis 2007; David et al. 2009) and provide a minimum age for the Ujaraaluk unit. Cates et al. (2013) proposed a maximum age of 3.78 Ga based on the oldest $^{207}\text{Pb}/^{206}\text{Pb}$ age on zircon from a fuchsitic quartz-rich horizon they interpreted as a detrital sediment. Darling et al. (2013) however suggested that these fuchsitic quartzites represent metasomatically altered intrusive felsic orthogneiss. Rocks from the Ujaraaluk unit and co-genetic ultramafic cumulates are characterized by $\sim$ 26 ppm variation in $^{142}\text{Nd}/^{144}\text{Nd}$ ratios that correlate with Sm/Nd ratios, with a significant number of samples displaying deficits in ^{142}Nd compared to terrestrial standard (O'Neil et al. 2012). Because of the short half-life of ^{146}Sm (68 Myr; Kinoshita et al. 2012), deviations in $^{142}\text{Nd}/^{144}\text{Nd}$ from the terrestrial standard can only have occurred while ^{146}Sm was still extant, i.e., before 4.1 Ga. O'Neil et al. (2008, 2012) interpreted the $^{142}\text{Nd}/^{144}\text{Nd}$ vs. Sm/Nd correlation to be an isochron and evidence that the rocks formed at $\sim$ 4.39 Ga. Massive gabbro sills intruding the Ujaraaluk unit yielded a ^{147}Sm - ^{143}Nd isochron age of $4,115 \pm 100$ Ma, consistent with an Hadean age for the Ujaraaluk unit (O'Neil et al. 2012).

Method for chemical separation

Definition

Chromatography is a general term describing chemical procedures for the separation of mixtures of elements or compounds. Chromatographic methods are used for both preparation and analysis of samples. A fundamental principle of chromatography is that components of a mixture will have different *distribution* or *partition* compound between a *mobile* and *stationary* phase. Distribution coefficients are a measure of a compound “preference” for either the mobile or the stationary phase. A solution containing compounds to be separated is usually dissolved in the mobile phase, which then is allowed to flow through a stationary phase. The dissolved components *elute* at different times in this flow system, the times being determined by the distribution coefficients – those that are preferentially retained by the stationary phase appear later in the *chromatogram*, which is the graphical output of the chromatographic separation.

Preparative chromatography is part of the purification of a sample prior to more advanced instrumental analysis. Many early advances in chromatography involved the extraction and separation of natural pigments found on biological samples and sediments. Examples of preparative chromatographic techniques used on geochronology include the separation of individual compounds (amino acids, lignins, chlorophyll) for radiocarbon analysis (Hatte et al. 2008; Marom et al. 2012) and separation of elements from solute mixtures for isotope ratio geochronology (Sanna et al. 2010; Isnard et al. 2012; Souders et al. 2012; Rotenberg et al. 2012). Analytical methods that follow these preparative steps often involve high-resolution, sensitive instrumental analytical chromatographic methods.

Analytical chromatographic procedures in geochronology include high-performance liquid chromatography (HPLC), gas chromatography (GC), size-exclusion chromatography, and various combinations of liquid or gas chromatography with instrumental mass spectrometric analysis. HPLC methods involve a liquid containing the mixture to be analyzed flowing under high pressure through a small diameter column containing the stationary phase. A range of HPLC methods exist, each tailored to the specific analysis to be conducted. Some involve ion-exchange chromatography (IEC), where the stationary phase is charged and interacts with solute ions as they flow through the column. Adjusting the pH of the solute during the analytical run will change the affinity of the solutes for the stationary phase. IEC is a common tool in amino acid racemization geochronology. Other forms of HPLC rely upon different polarities of the stationary and mobile phases, reverse

*Email: jwehm@udel.edu

phase chromatography (RPC – where the mobile phase is more polar than the stationary phase) now being a common procedure for analysis of amino acid enantiomers (D/L values) (Kaufman and Manley 1998; Penkman et al. 2013). GC methods involve a gas as the mobile phase and a thin liquid coating on a narrow-bore capillary column as the stationary phase. The mixture to be analyzed is vaporized in the injection port of a gas chromatograph, being carried through the liquid column by a carrier gas. Elution order is determined by the affinity of compounds for the solid phase. Flow rate and overall elution times are influenced by carrier gas pressure and column temperature. GC methods have also been traditional in amino acid racemization geochronology (Wehmiller and Miller 2000; Wehmiller 2013). Size-exclusion chromatography is a preparative chromatographic method useful for separation of compounds based on their molecular weight, an important step in the further analysis of individual compounds or mixtures found in geological samples. Mass spectrometric analyses often are focused on isotope ratio determinations (often with geochronological applications) and many examples exist where gas- or liquid-chromatographic systems are coupled with mass spectrometric systems to separate complex mixtures prior to the final mass spectrometric analysis.

Amino Acid Racemization, Fluvial and Lacustrine Sediments (AAR)

John Wehmiller*

Department of Geological Sciences, University of Delaware, Newark, DE, USA

Synonyms

[Climate history](#); [Fossils](#); [Geochronology](#); [Lakes](#); [Rivers](#)

Definition

Amino acid racemization. The phenomenon of conversion of “left-handed” (L or “levo”) amino acids to their “right-handed” (D or “dextro”) form. In most living systems, 100 % of the amino acids are of the L form, and the conversion results in an equal mixture of D and L when the racemization reaction is complete.

Fluvial sediments, lacustrine sediments. Sedimentary material that accumulates and is preserved in river, stream, or lake environments. These can include sediments dominated by biological material (shells) and those dominated by inorganic material that may form by cementation or evaporation, such as carbonates or evaporates and mud or clay. Sediments range in age (time since deposition) from days to millions of years and are found in a variety of terrestrial sedimentary environments.

Introduction

Amino acid racemization (AAR) studies of fluvial and lacustrine deposits usually require the analysis of a biogenic mineral (e.g., bivalve, gastropod, ostracode, or egg shell) or organic material associated with these environments. These terrestrial deposits include river terrace and delta sediments, glacial and pluvial lake sediments, and eolian sediments derived from combined glacial and fluvial sources. In some cases fluvial deposits merge with coastal deposits in areas influenced by sea level change, providing an opportunity to link global ice volume (sea level) history with local fluvial stratigraphy. Archaeological studies that include AAR often involve samples associated with one or more of these terrestrial depositional processes (Johnson and Miller 1997). In many situations the geochronological study of these environments provides an opportunity for comparison of multiple dating methods (Oches et al. 1996; Owen et al. 2007; Bright et al. 2010). Additionally, when suitably calibrated, AAR results yield insights into local or regional temperature histories for the late Pleistocene (Goodfriend and Mitterer 1993; Miller et al. 1997). Examples of AAR applications in each of these depositional systems are reviewed in the following sections.

Shallow (<2 m) ground temperatures can vary significantly because of exposure and moisture conditions (Wehmiller et al. 2000). Consequently, the interpretation of AAR data from many

*Email: jwehm@udel.edu

fluvial, eolian, colluvial, or archaeological deposits must account for possible differences in burial temperature histories. This issue is particularly important for any sample that has experienced a large portion of its history either exposed at the land surface, heated by fire, or buried just a few cm below land surface. Lacustrine and marine samples are less vulnerable to this effect because their initial burial environment is usually under water. Many AAR studies demonstrate the effect of shallow burial heating (Wehmiller 1977; Goodfriend 1987; Miller and Brigham-Grette 1989; Ellis et al. 1996; Wehmiller et al. 2000; Owen et al. 2007), and many others indicate the potential thermal effects on relative age interpretations (Miller and Brigham-Grette 1989; Johnson and Miller 1997; Miller et al. 1997).

Fluvial and Lacustrine Deposits, Western United States

During Pleistocene glacial intervals, a series of large lakes existed in the Western United States where present-day precipitation is quite low (Reheis et al. 2012 and references therein). The modern remnants of these large lakes include Great Salt Lake (Utah), and Pyramid and Walker Lakes (Nevada). The hydrologic balance of these lake regions was vastly different from the present, involving a major increase in the ratio of precipitation to evaporation during glacial times. AAR is one of the many chronological tools applied to the development of a regional chronology for lake level fluctuation during the Quaternary, using either deposits created in the deeper portions of the lake (Oviatt et al. 1999) or shoreline deposits created around the high stand lake margins (McCoy 1987).

Lake Bonneville is the name given to the large lake that occupied what now is most of the state of Utah. AAR analyses of gastropods from various shallow-water deposits of Lake Bonneville identified five aminozones, each representing different phases of deposition during the middle and late Pleistocene (McCoy 1987; Oviatt et al. 1987). Numerical ages of these deposits are estimated using associated radiocarbon (C14) and U-Th data and volcanic ash deposits that are found in association with the oldest aminozone. Available geochronological data suggest that Lake Bonneville reached peak volumes at the end of marine isotope stages 4 and 2, roughly 60 and 12 ka, respectively (Kaufman et al. 2001), as well as at earlier times that are less well constrained. The ages of the shallow-water deposits constrain the times of maximum lake levels (deepest lake); samples from cores from near the center of the Bonneville Basin provide information on the transitional phases when lake levels may have been at low or intermediate levels (Oviatt et al. 1999; Kaufman 2003a). AAR results from these cores, also combined with volcanic ash chronology, demonstrate a long and discontinuous record of lacustrine deposition over the last ~700 ka.

Paleoclimatologic Information from Calibrated Lake Bonneville AAR Data

AAR data can be used to infer effective temperatures if the analyzed samples have been independently dated (see section “[Cross-Reference](#)” list). AAR analyses of well-dated ostracodes from late Pleistocene sediments in the Lake Bonneville record imply that full glacial (MIS 2) temperatures in the basin were approximately 10 °C colder than present (Kaufman 2003b). Effective temperatures for older units were not as cold (Kaufman 2003b). Ostracode AAR results from Summer Lake, a smaller pluvial lake in Oregon, imply unrealistically cold effective temperatures when compared with the Bonneville results, suggesting that other factors besides temperature may influence AAR kinetics in this sample type (Bright and Kaufman 2011; Reichert et al. 2011).

Western North America River Systems

The Pleistocene history of the Colorado River includes phases when large lakes were created upstream of large lava dams (see Kaufman et al. 2002). Deposits created by these large lakes are quite rare, and the ages of some potential lacustrine deposits in the Grand Canyon have been debated. AAR and ^{14}C results from mollusks and ostracodes indicate that lacustrine deposits found in the eastern Grand Canyon were formed <45 ka BP in small travertine-dammed ponds rather than in the large deep lakes that would have been formed in association with the much older (>100 ka to ~ 2 Ma) lava-dammed lakes (Kaufman et al. 2002).

At the downstream end of the Colorado River, the river's delta has changed dramatically during the past century in response to upstream water diversions. Part of this change has been documented using ^{14}C -calibrated AAR results for mollusks from beach ridges within the delta system. Nearly all the analyzed shells formed prior to 1930 and since ~ 1000 AD, indicating a decline in benthic productivity in the delta region corresponding to the time of diversion of water flow in the river (Kowalewski et al. 2000).

Fluvial terraces of the Chama/Rio Grande River system in the Espanola Basin of northern New Mexico record the downcutting of the rivers during the middle and late Pleistocene (Dethier and McCoy 1993). AAR data from gastropods found in slack-water deposits preserved on these terraces identify five aminozones with increasing D/L values found at increasing elevations above the modern river. Rapid deposition of shells and limited surface exposure are inferred, thereby minimizing shallow thermal effects on the results. The oldest of these zones is ~ 620 ka based on volcanic ash chronology (ash of the same age is used for calibration of aminostratigraphy in the Lake Bonneville sequence – see above), younger ones being estimated to represent ~ 310 , 170, 95, and <19 ka, respectively (Dethier and McCoy 1993).

Bright et al. (2010) used AAR data, along with associated ^{14}C and IRSL results, to revise the chronology of a bison-bearing fluvial deposit in northern Mexico. Previous $\text{Ar}^{40}/\text{Ar}^{39}$ ages on associated lava flows suggested an age of 440 ± 130 ka for this deposit, far older than expected for the presence of Bison in this region. The revised interpretation of the combined geochronological data indicates a late Pleistocene (<40 ka) age.

Fluvial and Lacustrine Deposits, Eastern United States and Southeastern Canada

AAR data from this region are helpful in understanding the geochronology of deposits formed during advances or retreats of the Laurentide Ice Sheet, a major influence on the climate and environment of eastern North America during the Quaternary. Ostracodes, gastropods, and bivalves are intermittently preserved in some of the classic stratigraphic sections from this region, ranging from the Mississippi River Valley to the St. Lawrence Valley. AAR data for gastropods from a broad range of sites, mostly in loess, from the Mississippi River Valley (Clark et al. 1989; Miller et al. 1993; Oches et al. 1996) define at least four phases of eolian (loess) deposition over the past ~ 750 ka, the most recent phase corresponding to the late Pleistocene Wisconsinan (MIS 4-3-2) glacial advance into the region. Elsewhere, portions of this regional aminostratigraphic record are preserved at isolated sites both within the Laurentide Ice Sheet margin (Karrow et al. 1997; Karrow 2004) and near the ice sheet margin in southeastern Indiana (Miller et al. 1993) and in the St. Lawrence River Valley (Occhietti et al. 1996). See “► [Amino Acid Racemization, Loess and](#)

[Glacial Sediments \(AAR\)](#)” for more discussion of Mississippi River Valley and also Eurasian Loess-AAR studies.

Fluvial, Lacustrine, and Glacial Deposits, United Kingdom

An extensive and detailed record of glacial, fluvial, and lacustrine sedimentation in the British Isles has provided an opportunity for many geochronological studies involving AAR analysis of nonmarine (and some marine) samples (Bowen et al. [1989](#); Bowen [2000](#); Penkman et al. [2013](#)). Many samples have been collected from interglacial stratotypes with associated faunal, floral, or archaeological information, including many with independent chronological data. The AAR studies of UK sites likely represent the most intense coverage of AAR data of any region of the world, as numerous investigations (most within an area $3^{\circ} \times 3^{\circ}$), involving many laboratories and collections have occurred over nearly 40 years. The advent of sensitive instrumentation and new strategies to isolate and analyze the most robust amino acid component now provides a regional aminostratigraphic framework for the British Quaternary record, a complex of glacial, non-glacial, fluvial, and marine sequences (Penkman et al. [2011](#), [2013](#)). Because of the relatively low effective temperatures for the region and the slow racemization rate during glacial intervals, the difference in D/L values for samples from one interglacial and the next can be small, but when these results are considered within lithostratigraphic or fluvial terrace relative age sequences, meaningful age estimates and correlations with the global marine isotopic record can be established (Penkman et al. [2011](#), [2013](#)). Aminozones corresponding to interglacial stages 11, 9, 7, and 5 are evident (Bowen [2000](#); Penkman et al. [2011](#), [2013](#)). Aminozones representing corresponding phases of deposition are recognized in the coastal-marine records of the southern North Sea (Meijer and Cleveringa [2009](#)).

The Nile River Delta

Sediments of the eastern Nile River Delta (Egypt) contain late Holocene marine bivalves and gastropods for which radiocarbon-calibrated AAR results have been obtained (Goodfriend and Stanley [1996](#), [1999](#)). As with other studies, the relative ease and inexpensive cost of AAR analyses allow for large numbers of analyses to be conducted, far more than could be done using radiocarbon alone. Calibrated AAR kinetics indicate the extent of mixing of older Holocene samples into younger deposits (Goodfriend and Stanley [1996](#)) and also indicate that this portion of the Nile Delta underwent rapid strand-plain accumulation in the ninth century A.D., likely leading to relocation of major port cities (Goodfriend and Stanley [1999](#)).

Fluvial and Travertine Deposits, Iberian Peninsula

In Central Spain, tufa deposits are found within fluvial terraces in small tributaries of the Tagus River, a region of karst terrain. AAR data for ostracodes from these terrace deposits, combined with racemization kinetic modeling for the region (Ortiz et al. [2004](#)), suggest phases of tufa deposition that correspond with most interglacial warm phases since ~400 ka (Torres et al. [2005](#); Ortiz et al. [2009](#)).

Lake Eyre Australia: Lacustrine Chronology and Paleoclimatology

As with the combined stratigraphic and paleoclimatic studies of the pluvial lakes of the Western United States, a similar record occurs in the Madigan Gulf region of Lake Eyre, South Australia, a region influenced by monsoonal precipitation (Magee et al. 1995). This playa lake has been episodically flooded during the late Quaternary, and a combination of radiocarbon, uranium-series, luminescence, and racemization data indicates that the lake reached a maximum depth of ~25 m during the early part of MIS 5. A Holocene high lake interval did not reach this same depth, and intervening phases of variable moisture and deflation during dry lakes dominated the regional history.

AAR studies of ostrich eggshell (OES) from the Lake Eyre region yield insights into the magnitude of cooling during the late Pleistocene (Miller et al. 1997). Combined ^{14}C , AAR, and luminescence data document the extent of racemization for samples with ages from last interglacial to the present, and the contrast in rates for samples <20 ka compared with those between 60 and 20 ka implies a glacial temperature reduction of approximately 8°C (Miller et al. 1997). See also the entries “► [Amino Acid Racemization, Paleoclimate](#)”; “► [Amino Acid Racemization, Egg Shell](#)”.

Summary

AAR study of terrestrial (fluvial, lacustrine, eolian, or archaeological) deposits has often been conducted in association with other dating methods that provide either calibration for AAR or insights into other processes affecting the physical record. Many AAR terrestrial studies focus on issues of correlation of local records with regional terrestrial records or global ice volume records, in order to understand the climatic links between local processes and the global record. Many of these terrestrial records demonstrate discontinuous or episodic deposition, in phase with either interglacial or glacial stages, depending on the physical process being dated. Volcanic ash or paleomagnetic geochronology establishes a calibration for the older parts of many records. Advances in instrumental technology have allowed large numbers of small samples (ostracodes, land snails, etc.) to be analyzed, thereby establishing a firm statistical basis for chronostratigraphic interpretations. The use of calibrated AAR results to infer late Pleistocene temperature histories is demonstrated by examples from the Western United States, the United Kingdom, Australia, and Jamaica.

Magnetostratigraphic Dating

Miguel Garces*

University of Barcelona, Barcelona, Spain

Definition

Magnetostratigraphy relies on the ability of sedimentary rocks to acquire a remanent magnetization when they form, which parallels the direction of the Earth's ambient magnetic field. Since the geomagnetic field has undergone multiple nonperiodic reversals through Earth history, a magnetic zonation of sedimentary sequences is feasible according to the polarity of the rock magnetization. A magnetostratigraphic zonation allows dividing the stratigraphic record into time slices which can be correlated worldwide. Magnetostratigraphic dating refers to the identification in the stratigraphic record of magnetozones, which can be correlated to age-equivalent geomagnetic chrons. The compiled absolute ages of geomagnetic chrons form the basis for the geomagnetic polarity time scale (GPTS), which is routinely revised with new radiometric or astronomic calibrations (Fig. 1).

Essential Concepts

The Magnetization of Sedimentary Rocks

Some minerals in nature can behave as magnets, that is, they exhibit spontaneous magnetization. They rarely represent a significant volume in sedimentary rocks, with abundances typically below detection limits of X-ray diffraction and grain size too small to be spotted by optical microscopy. Their magnetization, however, can be normally measured in the laboratory using a state-of-the-art rock magnetometer. Most common magnetic minerals in sedimentary rocks belong to the group of iron oxides and sulfides (Table 1).

The magnetization of an assemblage of magnetic particles (M) decays with geologic time (t) according to the following equation:

$$M(t) = M_0 e^{(-t/\tau)}, \quad (1)$$

where M_0 is the initial magnetization and τ (relaxation time) is the time elapsed to decay to $1/e$ of the initial magnetization. Following the Néel theory, relaxation time is defined as

$$\tau = \frac{1}{C} e^{[Kv]/[kT]}, \quad (2)$$

where C is a frequency constant ($\sim 10^{10} \text{ s}^{-1}$) and K is the magnetic anisotropy factor (Tauxe 1998). From this equation, it is derived that relaxation time is dependent on particle size (volume, v) and the thermal energy (kT). In the case of equidimensional pure magnetite with size range of $0.1\text{--}0.08 \text{ }\mu\text{m}$, relaxation time is greater than the age of the Earth, but it sharply decreases to seconds for particle sizes lower than $0.06 \text{ }\mu\text{m}$. On the other hand, magnetite particles larger than $1 \text{ }\mu\text{m}$ gradually reduce

Table 1 Common magnetic minerals of application in paleomagnetism. *Ms* Saturation magnetization, *T_c* Curie temperature, *H_c_{max}* maximum coercivity (Evans and Heller 2003; Lowrie 1990; Tauxe 1998)

Mineral	Formula	Ms(kA/m)	<i>T_c</i> (°C)	<i>H_c_{max}</i> (T)
Magnetite	Fe ₃ O ₄	480	580	0.3
Hematite	α-Fe ₂ O ₃	~2.5	675	>5
Maghemite	γ-Fe ₂ O ₃	380	590–675	0.3
Goethite	α-FeOOH	~2	120	>5
Pyrrhotite	Fe ₇ S ₈	~80	320	>0.1
Greigite	Fe ₃ S ₄	~125	~330	>0.1

their relaxation time as their internal magnetic ordering shifts from a stable single domain to a multi-domain state. Thus, to be useful for paleomagnetic studies, magnetic minerals must occur in the appropriate size range, so that magnetic remanence remains stable over time scales comparable to the age of the rocks.

The Natural Remanent Magnetization (NRM) of rocks typically results from the addition of different magnetic components acquired since the time of rock formation. Primary magnetic components record the polarity of the geomagnetic field at the time of rock formation and thus provide the basic information for a magnetostratigraphic zonation. Secondary magnetizations acquired in later stage during geological history have no stratigraphic relevance and need to be identified and clearly separated from primary magnetizations.

The NRM signal in sedimentary rocks comprises three main types: Detrital Remanent Magnetization (DRM), Chemical Remanent Magnetization (CRM), and Thermal Remanent Magnetization (TRM). A DRM is carried by magnetic minerals incorporated into the sedimentary rock as detrital particles, either as part of the terrigenous fraction or from biogenic sources within the water column. If the magnetic grains are sufficiently small, their magnetic moments counterbalance the gravitational torques, producing a statistical particle alignment with the ambient field. A Detrital Remanent Magnetization (DRM) is blocked as early compaction reduces porosity and prevents further mechanical rotation of magnetic particles. The lock-in depth at which a DRM is fixed varies from millimeter to meter scale and depends on both magnetic mineralogy, rock type, and the sedimentary environment. In pelagic sediments, a reasonable estimate of the lock-in depth is 10–20 cm below the sediment-water interface (Opdyke and Channell 1996). If the time elapsed between sedimentation and DRM acquisition is considered of relevance, the term post-Depositional Remanent Magnetization (pDRM) may be used. Sediment bioturbation of different kinds may influence DRM, either allowing reorientation of magnetic particles giving rise to a new delayed pDRM or causing randomization of magnetic particles and erasing a preexisting DRM. Common carriers of DRM are the iron oxides magnetite and hematite, which resist chemical alteration as they are transported along the sediment transfer system. Once a DRM is locked-in, its preservation in sediments is determined by burial conditions: reducing environments that are associated with the presence of abundant organic matter can cause the dissolution of preexisting magnetic particles. Despite the lock-in depth uncertainty, DRM is taken as a reliable recorder of the geomagnetic field at the time of rock formation for most magnetostratigraphic purposes.

A Chemical Remanent Magnetization (CRM) is acquired due to authigenic formation of magnetic minerals, with the magnetic moment being blocked when the crystal grows through a critical size. Processes leading to a CRM acquisition can occur in an early post-depositional stage, but also in later stages of the rock history. A CRM is suitable for magnetostratigraphy as long as the acquisition takes place in an early post-depositional stage. A typical CRM carrier in terrestrial environments is hematite, which occurs as very fine-grained cement filling the porosity of siliciclastic sediments

(redbeds). In marine environments, authigenic magnetite may form as a product of oxidation of iron sulfides, giving rise to a stable CRM which is relatively frequent in environments influenced by changing redox conditions. Finally, an early CRM carried by authigenic iron sulfides can occur under specific burial conditions (Vasiliev et al. 2005), but their occurrence in the geological record is rare because these minerals easily undergo later oxidation.

A Thermal Remanent Magnetization (TRM) is acquired when magnetic minerals cool below their Curie temperature (Table 1), the temperature at which magnetic minerals change from paramagnetic into ferromagnetic (s.l.) behavior. Magnetization is then free to align with the ambient field until the minerals cool through their blocking temperature, representing the temperature transition at which relaxation time sharply increases from seconds to millions of years, efficiently locking magnetic moments. The TRM is typically carried by volcanic rocks forming the ocean crust, as well as stratified lava flows. The net magnetic moment of rocks carrying a TRM is several orders of magnitude greater than sediments having a DRM. Most common carriers of TRM in igneous rocks belong to the titanomagnetite solid solution series.

A time dependence exist for unblocking temperatures such that a thermoviscous magnetization may be acquired by rocks subjected to moderate temperatures over millions of years. Occurrence of a thermoviscous remanent magnetization is not uncommon if long-term deep burial occurs after sedimentation, particularly in regions of elevated geothermal gradients. A partial to total resetting of earlier (primary) magnetizations can result from thermoviscous magnetization processes.

As shown above, common processes of rock magnetization in nature are not uniquely related to the time of rock formation. Therefore, the NRM of rocks is an aggregate of multiple components of different age, each carried by a characteristic population of magnetic particles. Identification of the different NRM components is crucial for all paleomagnetic studies, and this is achieved by means of diverse stepwise demagnetization techniques (Langereis et al. 1989). Stepwise demagnetization is based on the assumption that each component is carried by a magnetic phase which has its own thermal stability and/or coercivity spectra (Table 1). Ideally, the stability fields of magnetic components do not overlap completely, so that the direction of every component can be determined. A wide overlap between components may lead to errors in the interpretation of paleomagnetic directional data.

The Geomagnetic Polarity Time Scale

The fact that the Earth's magnetic field has undergone reversals does not rely on direct observations. When Bernard Brunhes first discovered in 1906 the existence of reversely magnetized volcanic rocks, the finding was interpreted as a self-reversal artifact related to the thermoremanence acquisition process. It was Motonori Matuyama who later observed that a stratigraphic ordering existed in the magnetic polarity of successive lava flows, such as age dependence supporting the existence of past geomagnetic reversals. The parallel development of the radioisotope dating techniques allowed the birth of a first K–Ar calibrated geomagnetic polarity time scale (GPTS) back to 4 Ma (Cox et al. 1964). This first time scale was based on pairs of radiometric ages and magnetic polarity of lava flows distributed globally, a method that could not be extended to older ages because at that time the dating error exceeded the duration of chrons. The use of biostratigraphic correlation in deep sea cores allowed the construction of composite magnetostratigraphic sequences and further extension of the time scale to older ages (Opdyke et al. 1966). But, it was the discovery of seafloor magnetic anomalies which provided the unprecedented record of datable geomagnetic reversals back to Late Jurassic (Cande and Kent 1992, 1995; Gee and Kent 2007; Heirtzler et al. 1968).

The transformation of seafloor magnetic anomaly profiles into absolute ages relies on age interpolation from a selected number of radiometric dates (Fig. 1). Cande and Kent (1992) used

Fig. 1 Development of the geomagnetic polarity time scale of the last 12 Ma since marine magnetic anomaly patterns was first studied (Heirtzler et al. 1968). The convention is that periods of normal polarity are represented in black and reversed in white. *Short lines* to the right of the Cande and Kent (1995) polarity column correspond to cryptochrons. Event names are J (Jaramillo), CB (Cobb Mountain), R (Reunion), K (Kaena), M (Mammoth), C (Cochiti), N (Nunivak), S (Sidufjall), T (Thvera)

nine tie points for age calibration of the GPTS for the Late Cretaceous and Cenozoic. More recent calibrations have included astronomical ages of geomagnetic reversals of the Pliocene (Cande and Kent 1995), the Neogene (Gradstein et al. 2004), and Paleogene (Gradstein et al. 2012) (Fig. 2). It is expected that future developments of the GPTS will include astrochronological information of progressively older ages (Hinnov and Ogg 2007). In order to improve on both accuracy and precision of age calibration, important efforts for synchronization of the radiometric and astronomic time are needed (Kuiper et al. 2008).

Seafloor magnetic anomalies provide a quasi-continuous record of geomagnetic reversals. However, in the deconvolution of the magnetic anomaly signal into a polarity sequence, a resolution limit exists which depends on the depth and thickness of the magnetized layer in the oceanic crust. In general terms, geomagnetic chrons of 10^5 kyr duration are well represented in anomaly profiles

acquired from the sea surface. But even better resolution may be achieved in high-resolution profiles from fast-spreading ridges (>90 km/Myr), where short polarity intervals of few 10^4 year duration can be recognized (Gee and Kent 2007). Cande and Kent (1992) coined the term “cryptochron” to refer to magnetic anomalies which are too short to be unequivocally interpreted as true reversals. Further evidence for short chrons not yet present in the time scale can be obtained from high-resolution magnetostratigraphic records (Channell et al. 2003; Krijgsman and Kent 2004). At present, stability of the GPTS is not reached at this level of resolution, and it is expected that more cryptochrons will be elevated in the future to the category of new subchrons.

Fig. 2 Geomagnetic polarity chron zonation included in the last version of the geological time scale of Gradstein et al. (2012) and detailed nomenclature adopted from Cande and Kent (1992)

The occurrence of geomagnetic reversals follows a random pattern with no signs of periodicity. This indicates that geomagnetic reversal is essentially a process free of memory. And it is precisely the random and global character of geomagnetic reversal which makes magnetostratigraphic zonations useful for long-distance correlations. The age resolution of magnetostratigraphy depends on the average frequency of geomagnetic reversals, which has not remained stable through geological time (Gee and Kent 2007). The best resolution is achievable for the last 30 Ma, when the mean duration of geomagnetic chrons was 0.25 Ma, increasing to 0.75 Ma for ages between 30 and 80 Ma. On the other hand, magnetostratigraphy is inadequate for some quiet long periods when no reversals occurred, or one polarity dominated, such as the Cretaceous Normal Superchron (121–83 Ma) and the Carboniferous-Permian Reversed Superchron (310–265 Ma) (Langereis et al. 2010).

The Local Magnetostratigraphy

Sampling

A magnetostratigraphic study requires that suitable lithologies are sampled at approximately regular intervals. In principle, clay/silty sediments are best candidates to carry a primary remanence because stable magnetization is carried by small magnetic particles within the sub- μm size range. Coarser sandy sediments may yield good results as long as they contain significant amounts of clay matrix. Low-permeability fine-grained sediments are also preferred because they are less affected by later fluid flow and related remagnetization processes. As rock alteration processes can add secondary spurious magnetizations, fresh outcrops are highly recommended for paleomagnetic sampling. Some lithologies, such as organic-rich soft sediments, are prone to undergo alteration after sampling. In these cases, sample refrigeration may help preservation of their magnetic properties.

Paleomagnetic samples are taken in the field using either a water/air cooled portable drill or a hand sample. In soft sediments, the use of a hand pick is often required to dig down to fresh material. Drilling cores in situ is recommended because it is faster and simplifies sample preparation work in the laboratory. Electric-, rather than gasoline, powered drills are more appropriate for sampling unconsolidated soft sediments. In all cases, samples must be oriented before they are removed from the outcrop in order to calculate directions in geographic coordinates. In the case of tilted strata, bedding orientation data is needed in order to restore paleomagnetic vectors into tilt-corrected coordinates.

An optimal sampling resolution for magnetostratigraphy is such that allows recovery of all geomagnetic reversals recorded in the rock sequence. Available age constraints help constraining the most appropriate sampling density, although other factors such as field logistics, outcrop accessibility, and availability of suitable lithologies determine the sampling resolution finally achieved. Special care must be taken at this stage, since an incomplete sampling may give a polarity zonation that is unrepresentative of the true pattern of reversals.

Drill cores from marine and lacustrine unconsolidated sediments often provide unaltered material suitable for paleomagnetic measurements. Leading technologies used in scientific drilling have made possible full core recovery in soft sediments, providing the best material for very detailed magnetostratigraphic studies, where the resolution limit is marked by the sample size (7 cm^3) or, for continuous core measurements, the width of the response function of the magnetometer pick-up coils. In addition, advanced tools exist that provide azimuthal orientation to core samples, thus allowing full correction of paleomagnetic vectors into geographic coordinates.

Laboratory Processing

The NRM of samples is measured in the laboratory with rock magnetometers specially designed for paleomagnetic applications. Superconducting rock magnetometers are best suited for magnetostratigraphy because of their adaptability to standard paleomagnetic samples, cores, and U-channel samples. They provide the highest sensitivity and best performance with in-line automated measuring routines. An alternative instrument is the inexpensive spinner magnetometer, which has sufficient sensitivity to measure many sedimentary rocks, but requires more careful sample preparation and handling.

Treatment of paleomagnetic samples in the laboratory is oriented at identifying the different components contributing to the NRM. Widely applied techniques include stepwise thermal (TH) and alternating field (AF) demagnetization (Butler 1992; Langereis et al. 1989). Sample demagnetization is achieved by keeping the samples in a low-field environment, typically less than 10 nTesla, while subjected to TH or AF treatment. Complete thermal demagnetization is accomplished after exposure to a number of increasing temperature steps, until the maximum unblocking temperature of magnetic carriers is reached. Assuming that every NRM component is carried by a different population of magnetic grains, an effective isolation of components is achieved if their unblocking temperature spectra do not overlap significantly. TH demagnetization is optimal for removing secondary components carried by hydroxides such as goethite, because of its low unblocking temperature (Table 1). Thermal separation of fine-grained hematite and magnetite components needs closely spaced temperature steps because of the overlap of their stability fields. Alternatively, AF demagnetization successfully isolates magnetite from hematite components because they exhibit a large contrast in coercivity. Ideally, a set of pilot samples of representative lithologies is both TH and AF demagnetized, so that a specific demagnetization protocol can be designed for each case study.

Among the NRM components isolated after stepwise demagnetization, the most stable and consistent component is referred to as the Characteristic Remanent Magnetization (ChRM). Principal component analysis (Kirschvink 1980) is used to calculate the orientation of the ChRM, which is expressed with their values of declination (azimuth) and inclination (dip). By application of the geocentric axial dipole hypothesis, and given a site location on the Earth's surface and the orientation of a paleomagnetic component, the latitude of the corresponding virtual geomagnetic pole (VGP) can be calculated (Butler 1992; Tauxe 1998). Northern hemisphere VGP latitudes (positive) correspond to normal polarity and southern hemisphere latitudes (negative) to reversed polarity. A local magnetic polarity stratigraphy can be constructed after plotting VGP latitudes as a function of stratigraphic position of samples (Fig. 3).

Paleomagnetic data from drill cores not azimuthally oriented can be used for magnetostratigraphic purposes as long as the drill hole is perpendicular to bedding. Information of magnetic polarity is then given by the vertical component (Z) of magnetization. In this case, special attention must be given to the latitude at which the sediments originated; the Z component tends to zero at equatorial latitudes, and its sign is no longer a good indicator of polarity. At low latitudes, azimuthal orientation of cores is needed because information of magnetic polarity is best extracted from the paleomagnetic declination.

The reliability of a given magnetostratigraphy relies on, first, the demonstrable primary nature of the ChRM and, second, the completeness of the polarity sequence. To assess the age of the magnetization, some stability tests (fold test, conglomerate test, consistency test, and reversal test) can be carried out (Butler 1992; Opdyke and Channell 1996; Tauxe 1998). The fold test provides information on the timing of magnetization relative to folding. A fold test is positive if paleomagnetic directions from opposing flanks of a fold converge after tilt correction. A positive fold test

Fig. 3 Magnetostratigraphy of the Librilla section, Fortuna basin, Spain (Garcés et al. 2001). A polarity sequence is determined from the Virtual Geomagnetic Pole latitude, positive VGP latitudes represent normal polarity, and negative VGP latitudes reverse polarity

indicates that remanence predates folding, but does not strictly demonstrate a primary (syndimentary) origin as required for magnetostratigraphy. Only in cases of early syndimentary folding, or slumped sediments, a positive fold test provides greater confidence on the primary origin of the magnetization. The conglomerate test assesses the stability of the magnetization measured from intraformational clasts. Random paleomagnetic directions from different clasts indicate that the magnetization has not been reset since the clasts were reworked from its original strata, thus yielding a positive test. The consistency test is applied for multiple overlapping magnetostratigraphic sections. A sequence of reversals that can be traced laterally, and cross-checked with lithostratigraphy, gives the strongest evidence of a primary magnetization. The reversal test is used to check for antipodality of the average normal and reversed paleomagnetic directions. A failed reversal test

Fig. 4 Magnetostratigraphic jackknife of the Librilla section. A J value between 0 and -0.5 indicates that the probability of missing magnetic reversals due to sampling resolution is low

indicates that stepwise demagnetization has not succeeded in fully isolating discrete magnetic components. Passing the reversal test is critical for studies in which the angular deviation from a reference paleomagnetic direction is used to interpret tectonic rotation of rock units. On the other hand, the reversal test is not so crucial for magnetostratigraphy since the magnetic polarity can be often assessed from partially overlapped paleomagnetic directions.

Assessing Completeness of Local Magnetostratigraphy

A magnetostratigraphic section is considered complete when the sampling density is enough to support that no geomagnetic reversals are missed between sampled horizons. Note that, in this sense, magnetostratigraphic completeness is different from stratigraphic completeness, the latter referring to the occurrence and duration of sedimentary (=time) gaps. Completeness of local magnetostratigraphy can be statistically assessed by different means. The dependence of a given magnetic polarity sequence on sampling strategy was investigated by Johnson and McGee (1983), who concluded that polarity sequences yielding an average of 8 sites/magnetozones are insignificantly affected by sampling bias. Tauxe and Gallet (1991) proposed a statistical jackknife in order to test magnetostratigraphic completeness. The sensitivity to sample resolution is described by a parameter J , which represents the slope relating the percentage of magnetozones missed after a random and progressive deletion of samples up to 20 % of the total number of samples (Fig. 4). These authors recommend J ranges between 0 and -0.5 , lower values indicating that the section was insufficiently sampled.

Magnetostratigraphic Correlation

The random character of geomagnetic reversals originates a distinctive polarity sequence when a sufficient length of time is observed, which depends on the average frequency of reversals. For Neogene times, it can be estimated that a stratigraphic sequence spanning about 3 Myr will reveal a magnetic polarity sequence of 10–15 reversals, an adequate number to assess a correlation. A correlation with the geomagnetic polarity time scale (GPTS) is achieved if the pattern of magnetozones finds a positive match with a sequence of reversals in the GPTS. In achieving this,

absolute ages of geomagnetic reversals can be assigned to every magnetozone boundary in the local stratigraphy.

Magnetostratigraphic correlation with the GPTS is often assisted by absolute age constraints, for example, radiometric ages from interstratified ash layers or lava flows, or biostratigraphic data which may provide chronostratigraphic information at stage level or better. But attention must be paid to the diverse sources of error associated to external age constraints. In the case of radioisotopic dating, only the analytical precision (often less than 0.5 %) is propagated into the error reported (Renne 1998). Radioisotope decay constant uncertainties and other sources of systematic errors, which are often unnoticed by non specialists, are particularly problematic when different isotopic systems are combined, as occurs in the calibration of the GPTS. A recommended practice is that best correlation is searched within a time range only approximated by external age constraints, but not forced by a single tie point of presumed high accuracy. A correlation which is not supported by a positive match of the magnetostratigraphic pattern and is solely substantiated on an external age constraint must be taken with caution.

Achieving a robust correlation between a local magnetostratigraphy and the GPTS requires that sedimentation rates do not change significantly at the time scale of geomagnetic chrons, so that the relative thickness of magnetozone maintains proportionality with the duration of corresponding geomagnetic chrons. From a sedimentological perspective, sedimentation steadiness may appear as severe restriction for magnetostratigraphic correlation, particularly in continental settings dominated by alluvial/fluvial processes of clearly episodic nature. A compilation by Sadler (1981) showed that for typical durations of chrons (10^4 – 10^6 year), average accumulation rates of fluvial sediments may vary by three orders of magnitude. The scattering, however, partially responds to the diverse geologic (tectonic, paleogeographic, climatic) settings from which the database was constructed. Observations restricted to a specific setting and location result in sedimentation rates which cluster to within an order of magnitude (Fig. 5a), as already observed by (Johnson et al. 1985) in the Siwaliks Himalayan foredeep. More important for correlation purposes is the relative change of sedimentation rate between adjacent magnetozone. Observations from the alluvial sequences of the Ebro Basin shows that sedimentation rates rarely change by a factor greater than 2 between two adjacent chrons, while the relative duration of adjacent chrons of the GPTS varies over an order of magnitude

Fig. 5 (a) Average sedimentation rates in continental sediments as a function of time span of observation (duration of chron) (Data from magnetostratigraphic studies in Cenozoic basins of Spain). Note that sedimentation rates cluster to an order of magnitude when data from a single basin is considered. (b) Ratio of duration of adjacent chrons in the Cenozoic compared to ratios of sedimentation rates of adjacent chrons (Data from the Ebro Basin)

(Fig. 5b). These observations lead to the conclusion that changes in sedimentation rate rarely originate an excessive mismatch between the local magnetostratigraphy and its equivalent reversal sequence in the GPTS (Fig. 6).

In the long term ($>10^7$ year), average accumulation rates are fundamentally constrained by basin forming mechanisms and the resulting balance between sediment yield and accommodation space. At this scale, significant changes of the tectonic, paleogeographic, and/or paleoclimatic setting may lead to gradual or even abrupt changes in the sedimentation trends. Fortunately, periods of sedimentary reorganization, which impact on a specific site location, are few compared to times of stability. The result is that evolution of basin infill often reveals long periods of steady sedimentation, these being interrupted by short periods of change (Fig. 7). Under these circumstances, unambiguous magnetostratigraphic correlation with the GPTS, independent of external age controls, is still an achievable goal.

Assessing Overall Reliability

Assessment of the overall reliability of magnetostratigraphic dating was addressed by others (Talling and Burbank 1993), who analyzed all sources of error associated with absolute ages derived from magnetostratigraphy and quantified error magnitudes related to the accuracy of the GPTS and the completeness of the local magnetostratigraphy. But, uncertainties involved in nonunique correlations could only be qualitatively treated. In this respect, it is recommended that an explicit discrimination is made between correlations based on an external (biostratigraphic or radiometric) age control and those based on the smoothest-derived sediment-accumulation rates. There are cases that a best-fit magnetostratigraphic correlation does not meet other external age constraints (Fig. 6). At this point, magnetostratigraphic correlation becomes a multidisciplinary approach which involves a proper analysis of all sources of uncertainty.

A reliability index for magnetostratigraphic data was put forward by Opdyke and Channell (1996) based on criteria listed below, with the recommendation that ratings of 5 (out of 10) should be achieved:

1. Biostratigraphic data provides an age control at the level of stage.
2. Sampling localities placed in a measured stratigraphic section.
3. Complete stepwise NRM demagnetization of all samples.
4. Paleomagnetic directions determined by least-square analysis.
5. Numerical data fully documented with plots of VGP latitude against stratigraphic position (or declination and inclination).
6. Determination of magnetic mineralogy.
7. Use of field tests (fold test, conglomerate test) to determine the stability and age of the magnetization.
8. Reversal test, to check for the overlap with secondary magnetizations.
9. Radiometric ages are available for the section and fully documented with their associated errors.
10. Consistency test, to check for the stratigraphic control of polarity reversals, and the primary nature of the magnetization.

Among these, criteria 2, 3, 4, 5, and 6 are standardized procedures in modern magnetostratigraphic studies and should be mandatory for proper publication of results. Other criteria, such as availability of external age controls (1 and 9) and stability tests (7, 8, and 10), are case dependent and cannot always be met.

Fig. 6 A magnetochronology of the Fortuna basin infill based on multiple magnetostratigraphic sections (Garcés et al. 2001). Basin scale correlations are guided by both lithostratigraphic boundaries (diachrony allowed) and biostratigraphic markers (MN12, MN13, MN14 correspond to European mammal zones). A magnetostratigraphic correlation between overlapping sections yields a positive consistency test, supporting a primary magnetization. The resulting composite magnetostratigraphy is made of 19 magnetozones (10 Normal, 9 Reverse), with a pattern of reversals which allows unambiguous and independent correlation with the GPTS. Note that some external (biostratigraphic and radiometric) age constraints do not match with the proposed correlation. In particular, K/Ar data of the Barqueros volcanism (Bellon et al. 1983) and calcareous nanoplankton from the Rio Chicamo (Lancis et al. 2010) suggest an age >1Myr younger for the lower marine units. On the other hand, the Ar/Ar dating of the Cabezos Negros

Fig. 7 Sedimentation rates in the Fortuna basin derived from magnetostratigraphic correlation (Fig. 6). The basin underwent a complex evolution, with a paleogeography which rapidly changed from open marine to a restricted elongated gulf and, finally, continental environments eventually altered by the sea level drop of the Mediterranean during the MSC. Despite this unfavorable scenario, periods of steady sedimentation in the Fortuna basin are long enough to support a preferred magnetostratigraphic correlation

Conclusions

Magnetostratigraphy is challenging among the different dating methods of sedimentary rocks, because the outcome is not as simple as determining a numerical age with its associated error. A correlation is established between a local magnetic polarity zonation and the globally isochronous geomagnetic reversals of the GPTS, whose age calibration relies on absolute chronometers, such as radioactive dating and astrochronology. Thus, a recommended practice is that magnetostratigraphic ages are not only expressed with its derived numerical value but as a correspondence with geomagnetic chron boundaries. Popularity of magnetostratigraphy as a dating tool relies on the fact that many sedimentary rocks are faithful recorders of the ancient magnetic field and that modern magnetometers are capable of measuring very weakly magnetized samples. On the other hand, the inadequacy of magnetostratigraphy to be applied to discontinuous or very short sedimentary records remains as the fundamental limitation. A full comprehension of the regional stratigraphic context and accessibility to long and continuous sedimentary sequences is crucial for magnetostratigraphy to contribute robust and independent age constraints.

Fig. 6 (continued) volcanism (Kuiper et al. 2006) supports the proposed magnetostratigraphic correlation. The Tortonian Salinity Crisis (TSC) corresponds to a tectonic-driven basin restriction event which caused the precipitation of evaporates in the Fortuna and Lorca basins (Krijgsman et al. 2000). The Messinian Salinity Crisis (MSC) of the Mediterranean culminated with a base level drop which caused erosion of the Mediterranean peripheral margins. The MSC in the Fortuna basin caused fluvial incision which was later flooded during the Pliocene transgression (Garcés et al. 2001)

Research School of Earth Sciences, The Australian National University, Acton, ACT, Australia

Synonyms

[Rb–Sr geochronology](#)

Definition

Parent–daughter ratio: The ratio of rubidium (Rb) to strontium (Sr). The ratio is commonly expressed as $^{87}\text{Rb}/^{86}\text{Sr}$, where the unstable Rb-87 isotope is referred to as the parent nuclide, being approximately 27 % of all rubidium. The daughter nuclide (Sr-87) is represented by Sr-86, which is stable and not subject to radiogenic ingrowth and constitutes approximately 9.9 % of all strontium.

Nicolaysen diagram: A diagram of Rb-87 (abscissa) versus Sr-87 (ordinate), both normalized to Sr-86 (expressed as $^{87}\text{Rb}/^{86}\text{Sr}$ and $^{87}\text{Sr}/^{86}\text{Sr}$) illustrating the effect of age on the radiogenic decay of Rb-87 to Sr-87.

Initial isotope equilibrium: The assumption that at the time of formation of a rock, all phases therein share the same Sr isotope composition; a prerequisite for an isochron.

Isochron: A best-fit line of three or more phases in a Nicolaysen diagram with its slope corresponding to an age of phases that are in initial isotope equilibrium. Two-point isochrons may be used and can have geologic significance but do not allow constraints on their reliability.

Errorchron: A median through three or more phases in a Nicolaysen diagram that do not plot on a single regression line within the limits of their uncertainty. An age corresponding to the slope of this median may have geologic relevance but cannot be treated as an actual geologic event.

Isochron initial: Common expression of the intercept of the isochron with the ordinate in a Nicolaysen diagram that marks the strontium isotope composition at the time of formation which, by definition, is that of all phases contributing to the isochron.

MSWD: Mean square of weighted deviates; a value describing the degree of correlation of individual points on an isochron with an ideal value of 1.

Historical Background

The Rb–Sr dating technique is among the most widely used and most powerful dating tools available in Earth sciences. It is an effective means of dating igneous rocks or metamorphic events and, under special circumstances, can be applied to sedimentary sequences, ore deposits, and past volcanic eruptions or to date fluid events in the deep crust. The natural radioactivity of Rb-87 was discovered by Campbell and Wood (1906) and first described as a dating technique by radiochemist pioneer

*Email: oliver.nebel@anu.edu.au

Table 1 Relative abundances of the stable isotopes of Sr (average atomic mass of 87.62 ± 1) and Rb (average atomic mass of 85.4678 ± 3) and the radioactive isotope Rb-87 (De Laeter et al. 2003). Note that relative abundances of Sr are variable in individual reservoirs due to the radiogenic ingrowth of Sr-87. All uncertainties refer to the last significant digit

Strontium (Sr)		Rubidium (Rb)	
Sr-84	0.0056 ± 1		
—		Rb-85	0.7217 ± 2
Sr-86	0.0986 ± 1		
Sr-87	0.0700 ± 1	Rb-87	0.2783 ± 2
Sr-88	0.8258 ± 1		

Otto Hahn (Hahn et al. 1943; Hahn and Walling 1938). Subsequent improvements in precision and accuracy have contributed significantly to a better understanding of Earth's history.

With the advent and distribution of mass spectrometers, the Rb–Sr technique has become the most important tool in dating igneous rocks throughout Earth's history and to the infant stages of the solar system. It has been used to date meteorites (e.g., Minster and Allègre 1976; Minster et al. 1982; Misawa et al. 1993), was among the first dating techniques applied to lunar samples returned from the Apollo missions (e.g., Murthy et al. 1971; Papanastassiou and Wasserburg 1970; Papanastassiou et al. 1970), and has identified the oldest rocks of Earth (e.g., De Laeter et al. 1985; Hurst et al. 1975; Moorbath et al. 1977a, b). Hence, Rb–Sr dating has greatly contributed to developing an emerging idea of our environment: an evolving and ever changing planet.

In recent years, the Rb–Sr dating technique has lost some of its popularity to other dating tools. Other chronometers, such as U–Pb in zircon, can, in principle, date similar events to higher precision and, in the case of high-temperature igneous emplacement events, higher accuracy. Nonetheless, taking the properties of alkali and alkaline earth elements into account, and refinements in analytical techniques for Rb–Sr, it remains a powerful tool to date rocks and metamorphic assemblages and is re-establishing its place among the top dating techniques.

The Concept of Rb–Sr Dating

Rb–Sr dating is based on the radioactive decay of the isotope Rb-87 (that today accounts for ~28 % of all rubidium) to Sr-87 (~7 % of all strontium, Table 1) by beta decay, i.e., the emission of an electron. Rb-87 decays to Sr-87 with a half-life of approximately 49 billion years. This makes the Rb–Sr dating technique, in principle, suitable to date samples from the infant stages of the solar system to very recent igneous events, i.e., a few million years before present.

For dating with the Rb–Sr technique, at least two phases (either whole rocks or minerals) with different Rb–Sr ratios are required. To directly compare Sr isotope compositions of these phases, irrespective of their absolute amount of Rb and Sr, all Sr-87 values are reported relative to a stable Sr isotope (Sr-86) that is not subject to radiogenic ingrowth. Thus, all Sr isotope compositions are reported as $^{87}\text{Sr}/^{86}\text{Sr}$; $^{87}\text{Rb}/^{86}\text{Sr}$ ratios are reported accordingly as $^{87}\text{Rb}/^{86}\text{Sr}$ following the equation:

$$\frac{A(\text{Rb-87}) \times M(\text{Rb}) \times [\text{ppm Rb}]}{A(\text{Sr-86}) \times M(\text{Sr}) \times [\text{ppm Sr}]} \quad (1)$$

where A is the relative abundance, M the atomic mass, and [ppm] the concentration of a species, usually given in parts per million. The amount of radiogenic ingrowth of Sr-87 in at least two phases with different Rb–Sr corresponds to the amount of decayed Rb-87. With knowledge of the exact decay rate (the Rb decay constant, $\lambda^{87}\text{Rb}$), this enables the calculation of radiogenic ingrowth and

Fig. 1 (a) $^{87}\text{Rb}/^{86}\text{Sr}$ isochron diagram (Nicolaysen 1961); showing the time-dependent evolution of three different phases, (A–C) with variable $^{87}\text{Rb}/^{86}\text{Sr}$ that formed in initial isotopic equilibrium and thus have the same initial Sr isotope composition. Points A'–C' reflect the present-day isotope composition of phases A–C, as measured by mass spectrometry. (b) The same isotope evolution in an Sr isotope versus time plot with the relative evolution of the three different phases as a consequence of their variable $^{87}\text{Rb}/^{86}\text{Sr}$

ultimately, by integrating both phases, the time required for this decay. This relationship is displayed in Fig. 1, where three phases with different $^{87}\text{Rb}/^{86}\text{Sr}$ (A, B, and C) start with the same Sr isotope composition and with time evolve to different $^{87}\text{Sr}/^{86}\text{Sr}$ (A', B', and C'), based on their $^{87}\text{Rb}/^{86}\text{Sr}$. Today, these phases plot on a regression line (within analytical uncertainty), which is usually highlighted by an MSWD ~ 1 .

The isotope composition of a sample after a given time t is expressed by the decay equation:

$$\frac{^{87}\text{Sr}}{^{86}\text{Sr}}(t) = \frac{^{87}\text{Sr}}{^{86}\text{Sr}}(t_0) + \frac{^{87}\text{Rb}}{^{86}\text{Sr}}(e^{\lambda t} - 1) \quad (2)$$

where $^{87}\text{Sr}/^{86}\text{Sr}(t_0)$ is the initial isotope composition at a time t_0 . If two or more Sr isotope compositions and their $^{87}\text{Rb}/^{86}\text{Sr}$ are known, a time interval Δt ($t_1 - t_0$) and the Sr isotope composition at t_0 can be calculated using a Nicolaysen diagram (Nicolaysen 1961), where the age difference Δt (or simply t) corresponds to the slope of the regression line through those samples. Ideally more than two samples are used for this concept to ensure that the regression line indeed reflects an age; the more samples that are used in a Nicolaysen diagram plot, the more likely it is that the regression is geologically meaningful. Obviously, for two samples a regression can be calculated, even though both samples may not be related to each other, rendering any calculated age (or initial isotope composition) of such “two-point” isochrons potentially dubious without any independent age indicators.

Analytical Techniques and Limitations

The precision of an age derived from an isochron is controlled by (i) the number of points used to obtain a regression line, (ii) the spread in $^{87}\text{Rb}/^{86}\text{Sr}$, (iii) the degree to which the phases involved formed in isotope equilibrium, and (iv) the errors on each individual analysis of $^{87}\text{Rb}/^{86}\text{Sr}$ and Sr isotope composition. Where the first three parameters are defined by the sample, the latter is a matter of analytical capability. Strontium isotope compositions ($^{87}\text{Sr}/^{86}\text{Sr}$) vary from subtle variations among whole rocks or mineral phases in the fifth decimal place (i.e., 0.0000X) to large variations, especially in older samples. The $^{87}\text{Sr}/^{86}\text{Sr}$ can be routinely analyzed with high precision and accuracy in samples with >50 ng Sr by thermal ionization mass spectrometry (TIMS) to within 40 ppm. Modern TIMS instruments can achieve precisions that are far better (up to 5 ppm); however,

other sources of error usually result in poorer accuracy and higher external reproducibility, i.e., the variability in isotope compositions of a single sample from multiple analyses (including sample digestion). Error sources can include procedural contaminants (commonly referred to as “blank”) or isotope tracer calibrations. The procedural blank can be minimized to insignificant levels by the use of ultraclean reagents (e.g., distilled acids, de-ionised water, or purified chromatographic extraction resin) and by chemical purifications in a clean room environment, and modern laboratories generally fulfill this requirement.

The second parameter required for age determinations is the $^{87}\text{Rb}/^{86}\text{Sr}$, which is commonly determined by isotope dilution using an isotope tracer. To ensure accurate results for isochron relationships, the Rb–Sr of a sample should directly be determined in the same sample cut as the one used for Sr isotope analysis so that the amount of Rb directly corresponds to the radiogenic ingrowth of Sr. The method of isotope dilution is currently the most precise and accurate way to obtain this ratio in conjunction with Sr isotope analyses; a precision of ~0.1–0.2 % on $^{87}\text{Rb}/^{86}\text{Sr}$ values can be obtained. Alternative methods, e.g., using single-collector mass spectrometry with inductively coupled plasma source (ICP-MS), can be used, but currently yield much poorer precision (~3–5 %) on the elemental ratio. For isotope dilution, both Sr and Rb (resident in the same material) are doped with a mixed isotope tracer artificially enriched in one Sr and one Rb isotope, preferably a low natural abundance isotope. This “spike” is added to the sample prior to digestion to ensure full spike-sample equilibrium. Knowledge of the concentrations and isotopic compositions of the spike, coupled with accurate weights of sample and spike, can be used to calculate Rb and Sr concentrations. Spiked Sr isotopes are simultaneously analyzed with the radiogenic isotope composition; spiked Rb isotopes are analyzed individually. For this, both Rb and Sr must be separated from the rock matrix and from each other to avoid matrix effects during the isotope analyses and, more importantly, isobaric interferences of Sr-87 and Rb-87, which will both be detected as mass 87. The common method for this separation is chromatographic extraction of dissolved (and spiked) sample material.

The calibration of the isotope tracer, a prerequisite to ensure accurate determinations of $^{87}\text{Rb}/^{86}\text{Sr}$, is not straightforward for both Rb and Sr. Whereas for other radiogenic systems, such as U–Pb or Sm–Nd, metals can be weighed very accurately and used to prepare a well-characterized standard solution, Rb metal is highly reactive in the atmosphere and does not permit this approach. Alternatives are Rb salts, which must be dried prior to analyses (due to their hygroscopic nature) and stoichiometry must be assumed. A good example of a modern calibration of a Rb–Sr spike using different salts for cross-calibration is given in Nebel et al. (2011). A way to avoid interlaboratory bias due to different spike calibrations is through analyses of a Rb–Sr isotope standard. Unfortunately, there are currently not many well-characterized standards available. The most commonly used standard is the NIST-607 K-feldspar standard. There are several problems associated with K-feldspar (see below); however, Nebel and Mezger (2006) presented a possible solution using this standard to cross-calibrate isotope tracer solutions. To obtain the most accurate result and to eliminate error magnification by mixing disproportional spike-sample ratios, general knowledge of sample concentrations for both, Rb and Sr, is desirable and often different spikes with variable $^{87}\text{Rb}/^{86}\text{Sr}$ are used for high or low Rb–Sr phases, respectively.

The conventional method for Rb isotope dilution analysis is by thermal ionization mass spectrometry (TIMS). Mass spectrometric-induced isotope fractionation on a TIMS instrument can only be controlled to within 0.5–1 % for elements with only two stable isotopes, such as Rb, and for decades this has been a limiting factor in Rb–Sr chronology. Recent developments in multi-collector ICP-MS have enabled analyses of Rb isotopes to <0.1 % (Nebel et al. 2005; Waight et al. 2002a), which enables the determination of $^{87}\text{Rb}/^{86}\text{Sr}$ to a precision of ~0.2 % (Nebel and Mezger 2006;

Fig. 2 Compilation of reported decay constants with details on the methods of determination (Modified after Nebel et al. (2011)). Gray dotted lines are recalculated values as reported in Begemann et al. (2001) (Data sources: Amelin and Zaitsev 2002; Davis et al. 1977; Kossert 2003; Minster et al. 1982; Neumann and Huster 1976; Rotenberg et al. 2012; Shih et al. 1985; Steiger and Jäger 1977; Williams et al. 1982)

Waight et al. 2002a), which corresponds to precisions achieved for other dating tools, as, e.g., Sm–Nd or Lu–Hf. In contrast to other dating methods, a major disadvantage for Rb–Sr dating is that no *in-situ* dating can be performed. To date, ion microprobe and laser ablation ICP–MS analyses, common *in-situ* techniques applied to date high U/Pb minerals, do not yield precise and accurate combined Sr isotope ratios and parent–daughter ratios in high $^{87}\text{Rb}/^{86}\text{Sr}$ phases required to obtain geologically significant ages (Vroon et al. 2008; Waight et al. 2002b). The major reason for this is the inability to adequately correct for the isobaric interference of Rb-87 on Sr-87.

The last key parameter to accurately date rocks and mineral assemblages with Rb–Sr is the decay constant ($\lambda^{87}\text{Rb}$). By successfully addressing all of the abovementioned parameters, a precision in Rb–Sr ages can be achieved that is comparable to other dating techniques. However, a systematic bias can be introduced by insufficient knowledge of the Rb decay constant (Begemann et al. 2001), i.e., the rate at which Rb decays. Recent efforts to refine $\lambda^{87}\text{Rb}$ have improved the precision and accuracy of the constant to $\pm 0.1\text{--}0.2\%$ (Nebel et al. 2011; Rotenberg et al. 2012); an error in the order of the analytical precision of the measurements (see Fig. 2 for a compilation of reported Rb-87 decay constants and their precisions). Accordingly, all ages in this article have been recalculated using an Rb-87 decay constant of $\lambda^{87}\text{Rb} = 1.393 \times 10^{-11}$ (Nebel et al. 2011). The value of $\lambda^{87}\text{Rb} = 1.42 \times 10^{-11}$, which was commonly used before this revision, was proposed in 1977 by an international commission on geochronology (Steiger and Jäger 1977). The revision of this value implies that all previously reported Rb–Sr ages are ca. 2 % older than previously thought.

Dating of Igneous Rocks (Including Volcanic Ash)

The most widely used application of the Rb–Sr dating technique is in determining the age of crystallization of igneous rocks. For this, either multiple whole rocks (with a genetic, often comagmatic relationship) or mineral separates from a single rock that formed contemporaneously are used to date the emplacement event. This implies that all species used for the dating share an

Fig. 3 Isochron diagram of whole rocks from a late Archean granite complex in Greenland (Moorbath et al. 1981). Rb–Sr and Pb–Pb yield identical results, and all rocks are presumably non-altered, indicating coherence of the isotope systems and an emplacement event at 2.58 ± 0.03 Ga

identical Sr isotope composition at the time of formation. Rock suites and minerals need to be carefully evaluated to fulfill this criterion, which is often not the case (Field and Raheim 1979), or to assess subsequent alteration by secondary processes. Examples of such cases are detailed below. However, in the ideal case of isotope coherence between samples and further textural or petrogenetic evidence for an igneous origin of a rock, an age for a suite of samples can be calculated. For this, in the isochron diagram of Fig. 1a, the dashed lines correspond to a family of lines leading from A to A', B to B', and so on, with the equation

$$y = mx + n \quad (3)$$

where all x–y coordinates in a Nicolaysen diagram plot as points on a straight line: the isochron. In this diagram the following parameters define the age: $x = {}^{87}\text{Rb}/{}^{86}\text{Sr}$ and $y = {}^{87}\text{Sr}/{}^{86}\text{Sr}(t)$ for any given sample, and $n = {}^{87}\text{Sr}/{}^{86}\text{Sr}(t_0)$ or initial ${}^{87}\text{Sr}/{}^{86}\text{Sr}$ is common to all samples. The age t (in years) of the suite of samples then corresponds to the slope m of this isochron with

$$m = e^{\lambda t} - 1 \quad (4)$$

The initial ratio n is the intercept of the isochron with the ordinate; λ is the Rb-87 decay constant. Obviously, two or more co-genetic species are required for this dating method. An example for one of the first dating attempts of a suite of Archean igneous whole rocks from the Qorqut igneous complex in Greenland (Moorbath et al. 1981) is presented in Fig. 3. These samples, assumed to be in initial isotope equilibrium, correspond to a calculated age that is similar to the Pb–Pb age of the same samples, noting that the MSWD of this example indicates some isotope disturbance and thereby technically is an errorchron (MSWD ~ 13).

Other samples that are seemingly in isotope equilibrium (assuming no post-emplacement disturbance) are volcanic ash horizons. These represent important time markers in the Phanerozoic era because of (i) mineral species that allow precise dating and (ii) their widespread spatial distribution that allow correlations of stratigraphic horizons. Although U–Pb in zircon is the most precise and commonly used method to date these events with extremely precise resolution on timescales of thousands of years in Quaternary eruptions (Crowley et al. 2007), Rb–Sr is, in principle, applicable

to dating of volcanic ash (Lanphere and Baadsgaard 2001). Ash often contains apatite, K-feldspar, and biotite, which, in combination, share a large spread in $^{87}\text{Rb}/^{86}\text{Sr}$ and are thus ideally suited for Rb–Sr dating. However, in agreement with high-precision U–Pb analyses of zircon and titanite from tuff (Schmitz and Bowring 2001), Rb–Sr on single grains from the Fish Canyon Tuff, an enormous volcanic eruption approximately 28 Ma ago and often used as a dating standard in $^{40}\text{Ar}/^{39}\text{Ar}$ chronology, has revealed that Rb–Sr systematics can yield different age information. This difference may reflect crystal residence times in the underlying magma chamber prior to eruption or that some crystals are xenocrysts, i.e., assimilated from other sources, and are thereby not in isotope equilibrium with the host melt (Charlier et al. 2007), as is so often observed for U–Pb in zircon. In young volcanic systems where timescales of magma storage contribute more substantially to the absolute age, this can be problematic and needs to be carefully evaluated to obtain precise and accurate times of eruption. This is of particular importance for cross-calibration of geochronologic tools. However, in older systems, a pristine sample suite provided, precise and accurate Rb–Sr ages on bentonites are a useful alternative to U–Pb or $^{40}\text{Ar}/^{39}\text{Ar}$ dating in obtaining absolute ages of key stratigraphic horizons in Earth's history (Baadsgaard et al. 1988; Williams et al. 1982). This can be expected to be more important in future studies, especially in light of recent analytical improvements of Rb–Sr dating of mica as an alternative to $^{40}\text{Ar}/^{39}\text{Ar}$ dating (Willigers et al. 2004).

Isotope Mixing Versus Isochron Relationship

A potential complication for accurate age determinations of igneous rocks with the Rb–Sr technique may result from the mixing of two isotopically distinct magmatic reservoirs at or close to the time of emplacement, where isotope equilibrium is not achieved prior to crystallization. Isotope mixing between two reservoirs cannot easily be identified in a magmatic suite without additional age constraints or other petrologic genetic information. Mixing of the two end-members produces a straight line in an isotope evolution diagram, because both abscissa and ordinate are normalized to the same isotope ($\text{Sr}-86$). Mixing thus mimics isochron relationships and indicates an age that is older than the actual igneous-rock-forming event. This is particularly important for bulk rock analyses where geochemical heterogeneity can be preserved more easily than for mineral species derived from a single sample. This effect is illustrated in Fig. 4a for a granitic suite from southern Germany (Siebel 1994). The slope of the isochron using whole rocks calculated to the time of emplacement of ~ 325 Ma indicates a pseudo-chron age of ~ 100 Ma (with a typical, almost ideal $\text{MSWD} = 1.4$), which is superimposed on the actual age. Because mixing between two different reservoirs on a whole rock scale is not a perfect process on a larger scale (kilometers), the correlation may exhibit an $\text{MSWD} > 1$ resulting in an errorchron relationship. Mixing may be identified in a 3-dimensional plot of $^{87}\text{Rb}/^{86}\text{Sr}$ versus $^{87}\text{Sr}/^{86}\text{Sr}$ versus $1/\text{Sr}$ [ppm] (Wendt 1993), as shown in Fig. 4b.

Isotopic Closure and “Cooling Ages”

Isotope dating requires all phases, whole rocks or minerals, to be in isotopic equilibrium at the time of formation. However, for large igneous bodies, cooling of magma and the mineral phases that crystallized from it do not occur instantly and contemporaneously. Because conductive heat transfer in igneous rocks is an inefficient process, the thermal gradient between the intrusive magma and the ambient rocks may persist for a long time, often for millions of years. Minerals in the igneous body

Fig. 4 (a) Pseudo-isochron produced by a two-component mixing between isotopically distinct reservoirs preserved in granites from Southern Germany (Data from Siebel 1994). The data are age corrected to the time of formation at 320 Ma, as deduced independently by $^{40}\text{Ar}/^{39}\text{Ar}$ isotope dating. (b) The reciprocals of the Sr concentration show a straight line correlation with isotopic composition that indicates mixing of two components with variable Sr concentrations (Wendt 1993). The combined pseudo-chron and isochron slopes yield an apparent, yet meaningless “age” of 423 ± 41 Ma ($MSWD = 1.7$; $n = 7$; (Siebel 1994)

remain open systems with exchange of parent–daughter isotopes by volume diffusion. Only when a certain temperature is reached are minerals considered “closed” for an isotope system. This temperature is called the closure temperature, T_C (Dodson 1973). Alternative scenarios are possible, in which a system is closed rather quickly after emplacement but is subject to interdiffusion of elements between minerals (Jenkin et al. 2001, 1995). For phases with high $^{87}\text{Rb}/^{86}\text{Sr}$, such as phengite, biotite, or K-feldspar, relative T_C has been empirically determined (e.g., Von Blanckenburg et al. 1989). They vary between 500 °C and 300 °C and may be dependent on grain size, chemistry, pressure, or fluid content (Villa 1998). The T_C for Rb–Sr is lower than for most other isotope systems including K–Ar or $^{40}\text{Ar}/^{39}\text{Ar}$. This effect has long been known (Armstrong et al. 1966; Delmoro et al. 1982; Verschure et al. 1980) and used to calculate cooling paths for igneous and metamorphic systems (e.g., Von Blanckenburg et al. 1989).

Rb–Sr analyses of different mineral phases can still yield coherent ages with a well-defined isochron relationship among different phases, even if all phases closed long after the actual emplacement event. This dates the time of cooling through isotope closure. Although initially considered a matter of grain size and diffusional processes (Dodson 1973), element exchange between coexisting phases may be equally important for Rb–Sr (Jenkin et al. 2001). Thus, Rb–Sr analyses of different grain fractions should not be used to determine cooling paths by Rb–Sr dating alone and are better accompanied by analyses of other phases with other isotope systems, which, in turn, have other closure temperatures. A cooling path may then be determined in a temperature–time diagram. Additional complications may, however, arise, due to diffusion below the T_C . Detailed micro-drill investigations (on a sub-crystal scale) in K-feldspar grains from a slowly cooled plutonic body indicate Sr isotope heterogeneity, likely induced by diffusion (Siebel et al. 2005), which can compromise bulk mineral analyses.

Timescales of isotope closure vary considerably and, as noted, depend on a number of parameters. A good example is cooling of the Great Dyke, a layered mafic intrusion in the Zimbabwe Craton. This massive mantle-derived igneous body is an extreme case of a magmatic body that intruded into presumably hot country rock, such that the thermal gradient between the intrusion and the ambient country rocks was small. Accordingly, the intrusion cooled very slowly, and reported Rb–Sr ages are

Fig. 5 (a) Rb–Sr age for the Great Dyke, Zimbabwe. (b) Cooling path of the intrusion by comparison with other chronometers (Modified after (Nebel and Mezger 2008))

~23 Myr younger than ages determined for the same rocks using systems with higher closure temperatures (e.g., U–Pb in zircon or sphene) (Nebel and Mezger 2008; Fig. 5). The age deduced from ortho- and clinopyroxenes is identical to the age calculated from combined pyroxene–biotite, which indicates a similar T_C for both minerals. Summing information from the available literature then allows a relative T_C for Rb–Sr that is phengite > K-fsp > biotite $\pm$ clinopyroxene.

Dating Metamorphic Rocks

For the dating of rocks, it is required that, after the time of its formation (termed t_0), a system remains undisturbed with respect to Rb–Sr systematics, i.e., that both Rb and Sr elemental and isotope abundances remain a closed system. That means that the amount of the parent nuclide Rb-87 must not be altered (by removal or addition) by exchange with the surrounding environment and that the daughter product Sr-87 must correspond to the amount of Rb responsible for the ingrowth. If a rock is subject to metamorphism, i.e., physical and/or chemical processes that lead to a change in its texture and mineralogical and/or chemical composition, this requirement may be compromised.

Metamorphic conditions can reach temperatures far exceeding T_C for Rb–Sr so that a system can “reset.” Metamorphism and the associated formation of minerals at the expense of existing ones often also include the release of fluids or involve fluids from outside the rock (metasomatism), which promote the diffusion of ions and/or the mobility of elements. This is especially the case for the classical “mobile” large ion lithophile elements (LILE) that include most alkali and alkaline earth elements (including Rb and Sr), and often the Rb and Sr budget in such rock associations can be significantly altered. Isotope systems are very sensitive to these processes, even without an apparent (i.e., visible) metamorphic overprint, and they may even affect a rock below the igneous T_C for an isotope system, e.g., because of dislocation effects in the crystal lattice that occur during the radioactive decay and isotope ingrowth, up to the point when a crystal becomes metamict. This susceptibility is often reflected in age relationships of old rocks that yield younger Rb–Sr ages than their presumed emplacement age (deduced from other chronometers) or no age information at all (isotope scatter that does not permit construction of an isochron). With the already relatively low T_C for Rb–Sr in most minerals (300–500 °C) compared to temperatures in metamorphic reactions that can easily exceed these values, this feature can have considerable impact on many rock assemblages

Fig. 6 (a, b) Modified after Faure (1986). (a) Concept of isotope resetting. Whole rocks 1, 2, and 3 preserve an isochron of the original igneous event with the age t_0 , whereas minerals of whole rock 2 give the metamorphic age t_m . Half-open symbols are metamorphic assemblages; open symbols are the reset assemblages of WR2 at the time t_m . At this time WR2 is internally homogenized with an initial $^{87}\text{Sr}/^{86}\text{Sr}$ of Sr_{I-m} . B: isotope evolution of various minerals of a whole rock during a metamorphic event. All phases evolve as a function of their $^{87}\text{Rb}/^{86}\text{Sr}$. At the time t_m , all phases are reunited and homogenized in their Sr isotope composition with a new initial Sr isotope composition Sr_{I-m} . The whole rock remains a closed system and is not affected by this event. Corrections of metamorphic phases to an incorrect age can yield false initials ($\text{Sr}_{I-\text{false}}$); reciprocally, an incorrect initial Sr isotope assumption will provide a biased model age (t_{mica} , $t_{\text{K-fsp}}$)

in old crustal terranes and has been a long-standing problem in Rb–Sr dating (Fairbairn et al. 1961; Riley and Compston 1962).

However, this seemingly strong limitation of the Rb–Sr chronometer can, in turn, be used advantageously to date “secondary events,” i.e., the time of metamorphic resetting, hereafter termed t_m . Internal mineral isochrons for individual whole rocks can yield age information on the thermal event, whereas on a whole rock scale the original emplacement age of an igneous rock can be preserved. For this to occur, the system is closed on a bulk rock scale and preserves its amount of accumulated Sr-87 and Rb concentration, and only a redistribution between mineral phases took place. This can be the case if little or no fluids are involved in the metamorphic reactions, as fluids often act as a transport medium for Rb and Sr beyond the scales of bulk rock samples. The combination of igneous whole rock and metamorphic mineral isochrons is illustrated in Fig. 6a, where whole rocks 1, 2, and 3 yield the original emplacement age (t_0), whereas the constituent

minerals of whole rock 2 in combination with the bulk rock yield the time of metamorphic reset (t_m). At t_m , minerals achieve isotope equilibrium with $^{87}\text{Sr}/^{86}\text{Sr}$ similar to that of their respective whole rock, and radiogenic ingrowth then starts anew as a function of the Rb–Sr in each mineral. This ideal case scenario of metamorphic reset on a mineral scale and preservation of primary age information on a whole rock scale has been observed in the Carn Chuinneag Intrusion in Scotland (Long 1964; Pidgeon and Johnson 1974). Unfortunately, in most cases the cooling of metamorphic terranes can be very slow such that individual mineral phases do not close contemporaneously, so that their isotopic clock does not start ticking at the same time. This is then reflected in an errorchron relationship that, at best, only allows the broad determination of cooling paths or an approximation of t_m that often fails modern requirements on precision.

The concept of isotope resetting is illustrated in Fig. 6b (redrawn after Faure (1986) and following the concept of Riley and Compston (1962)), where the isotopic evolution over time of different mineral phases with variable $^{87}\text{Rb}/^{86}\text{Sr}$ is shown. It is important to note that some phases reset earlier than others (or may solely be affected by the metamorphic events), all of which are a function of their individual metamorphic T_C (which as stated earlier can also include isotope diffusion) (Ganguly and Ruiz 1987). In most cases, Rb–Sr isotope systematics yield errorchron ages that may be geologically meaningless. However, in the worst case (often if only two or three data points are employed or they have a relatively small spread in $^{87}\text{Rb}/^{86}\text{Sr}$), Rb–Sr data do not allow distinctions between a true isochron or meaningless mixing age populations (Riley and Compston 1962). This can be the case if whole rocks are reset at different times or elemental and isotope exchange beyond whole rock scales occurred, but data coincidentally plot on a straight line within their analytical uncertainty. In the absence of other petrologic or isotopic parameters, the determination of model ages of, for example, K-feldspar and mica (t_{mica} , $t_{\text{K-fsp}}$) can assist in clarification of the geologic history of a sample, as, for a given initial Sr isotope composition, these ages should be identical. These model ages then should correspond to the correct igneous age. However, the initial $^{87}\text{Sr}/^{86}\text{Sr}$ for this calculation is often unknown, and iterative approaches by multiple phase analyses are often too imprecise to yield useful age information.

In many cases, one (or more) metamorphic event(s) results in a complete redistribution and homogenization of Rb–Sr systematics in all phases and on whole rock scales for very large metamorphic terranes. This has been shown by many early Rb–Sr studies on Archean metamorphic terranes in old cratons (e.g., Hurst et al. 1975; Kalsbeek 1981; Moorbath et al. 1977a, b). A complete reset is also possible during the metamorphic crystallization of sediments, so that metamorphic Rb–Sr ages t_m can be determined for para- and orthogneisses alike.

Obviously, without additional constraints it is not possible to predict to which extent isotopic exchange and homogenization occurred, and the possibility of isotope “inheritance” has been reported even for isotope systems with very high T_C , such as the Sm–Nd system (Roth et al. 2013). On the other hand, isotope systems with a high closure temperature may not yield metamorphic ages as they may only be partially reset, whereas Rb–Sr may have been fully re-equilibrated. Such a case is reported for the Yilgarn block in Western Australia (Fig. 7), where Rb–Sr systematics give a precise timing of metamorphic resetting (McCulloch et al. 1983). Sm–Nd data, however, preserved its isotope character during this metamorphic event and can be used to reconstruct the history of the precursor of the metamorphic terrane. Therefore, if placed in a geologic context, the Rb–Sr systematics of metamorphic rocks have the potential to yield precise and accurate age information and may otherwise simply be used to test the extent of isotope equilibrium (for a given age) by correction for radiogenic ingrowth to the respective initial ratios.

Fig. 7 Rb–Sr whole rock isochron for metamorphic gneisses from the Yilgarn Craton in Western Australia yields a precise metamorphic age, whereas Sm–Nd isotope systematics do not permit tight age constraints (2800 ± 150 Ma). When age corrected to the Rb–Sr age, the Nd isotope data is interpreted to reflect variable juvenile protoliths of the gneiss (McCulloch et al. 1983)

Dating Fluid Events and Ore Deposition

The fluid mobility of LILE implies that Rb and subsequently Sr can be mobilized in crustal fluids during low- to high-grade metamorphic events. Whereas this is often considered a problem for igneous rocks (they do not stay as a closed isotope system), there is a potential for dating such events with the Rb–Sr technique. In addition, mobilization of elements is often related to the formation of ores, and knowledge of the timing of ore formation is of great importance in economic geology or in regional geologic investigations. The Rb–Sr technique has long been exploited in dating base metal sulfide deposits, such as Mississippi Valley-type deposits (Brannon et al. 1992; Christensen et al. 1995; Nakai et al. 1990, 1993), which are associated with large-scale brine migrations under low temperatures (i.e., $<200^\circ\text{C}$; Nakai et al. 1993), or lode gold deposits that are either porphyritic or epithermal in nature (Yang and Zhou 2001). These ores often contain mineral assemblages with parent–daughter ratios that are unsuitable for dating, which makes age determinations of the mineralization notoriously difficult.

Sphalerite and pyrite are common sulfides formed during mineralization events and appear to contain a reasonable spread in Rb–Sr and enough material to obtain isotope results on mineral separates of reasonable size and quantity. This is of particular importance as sample heterogeneity (in $^{87}\text{Sr}/^{86}\text{Sr}$) can be significant (i.e., outside analytical reproducibility) in crystals that grow in the presence of fluids as fluid sources and compositions can vary in these systems. Hence, variations in $^{87}\text{Rb}/^{86}\text{Sr}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ may occur between neighboring samples or within growth domains of single samples. In the latter case, full isotope equilibrium of all domains is required, which, under hydrothermal conditions, is not always the case. However, some fluid systems can be deposited on timescales of minutes (e.g., Weatherly and Hanley 2013) so that isotope equilibrium can likely be assumed in these systems.

An example of such an application is shown in Fig. 8 that shows pyrite-only isochrons for a lode gold deposit from China (Yang and Zhou 2001), where the spread in $^{87}\text{Rb}/^{86}\text{Sr}$ within individual crystals and/or batches of crystals is used as an advantage for dating. Pyrite separates from two individual veins yield two well-defined isochrons with a mean age of 125.2 ± 0.9 Ma. Both individual determinations give confidence that gold deposition from fluids in the veins occurred at

Fig. 8 Rb–Sr isochron for two individual veins from a gold deposit in China (Yang and Zhou 2001). Both isochrons indicate an identical age of deposition, yet display variations in their initial Sr isotope composition, indicative of distinct fluid sources. If combined, both veins would display an errorchron relationship

this time. However, as illustrated in the figure, the source of the fluids is distinguished by their initial isotope compositions, so that a joint-age determination would inevitably result in an errorchron.

Dating Extraterrestrial Material

The Rb–Sr technique was widely applied to meteorite and lunar research, predominantly in the 1970s and 1980s, with a wide number of applications (e.g., Allègre et al. 1975; Birck and Allègre 1978; Birck et al. 1975; Minster and Allègre 1976; Minster et al. 1982; Misawa et al. 1993; Nyquist et al. 1986; Papanastassiou and Wasserburg 1970; Papanastassiou et al. 1970; Shih et al. 1992). Even though extraterrestrial whole rock samples and mineral species have limited spread in $^{87}\text{Rb}/^{86}\text{Sr}$, their extreme age makes them suitable for dating with this technique. However, the use of Rb–Sr in cosmo-chronology has become less popular in recent years. The reason for this is the improvement in other dating methods and intense isotope tracing of reservoirs that has led to a much more refined chronology of early solar system events and the identification of multiple processes and events. This renders most whole rock dating approaches incorrect as they would lead to comparison of mixed populations of rocks producing geologically meaningless ages (Field and Raheim 1979). First analyses of a series of bulk meteorites yielded a good correlation among different groups of meteorites. Whereas absolute age determinations were hindered by the issue of decay constant uncertainties, these authors used the data to calculate an Rb decay constant of $1.402 \times 10^{-11} \text{ year}^{-1}$ (Minster et al. 1982), a value that is close to the recently refined value (Nebel et al. 2011; Rotenberg et al. 2012). However, it is now clear that, while this approach yielded important information at the time, replicate analyses using modern Rb–Sr methods would most certainly reveal isotope disequilibrium among these samples, as decades of meteorite research has revealed substantial isotope heterogeneity among early solar system reservoirs (cf. Hans et al. 2013).

A second serious problem for Rb–Sr dating of extraterrestrial samples is that of terrestrial alteration in most meteorites (if not reported as “falls”). Rb–Sr dating of such material should be accompanied by other chronometers, intense evaluation of trace element abundances that allow identification of primary igneous processes or secondary alteration, and/or careful treatment of samples (such as leaching). If these conditions are met, modern Rb–Sr dating can provide very precise and accurate information on the history of solar system material (Rankenburg et al. 2007). In

Fig. 9 Whole rock–mineral isochron (including a melt vein but excluding a leachate fraction) from lunar meteorite LAP02205 (Data taken from Rankenburg et al. (2007)). The Rb–Sr isochron yields an almost ideal MSWD of 1.07 indicating isotope equilibrium. **(b)** Comparison of the Rb–Sr age with other age data for the same meteorite; the Rb–Sr age is the most precise and likely indicates the time of formation of the rock. $^{40}\text{Ar}/^{39}\text{Ar}$ ages (Fernandes et al. (2009)), Sm–Nd age (Rankenburg et al. (2007)), U–Pb age (Anand et al. (2006))

addition, if an isochron relationship can be established, the initial Sr isotope ratio of this isochron can provide invaluable information on the time-integrated evolution of the greater source domain, such as the Moon (Papanastassiou and Wasserburg 1970; Papanastassiou et al. 1970). In addition, despite the difference in age and origin for many meteorites, isotopic closure also applies to metamorphic events in space, and similar to terrestrial analogues, the Rb–Sr technique is capable of obtaining ages for high-temperature collision events, for example, on Mars (Nyquist et al. 1979), or meteorites that have been subject to metamorphic overprinting (e.g., Birck and Allègre 1978).

A good example of modern Rb–Sr dating of extraterrestrial material is the lunar meteorite La Paz Icefield 02205 (LAP02205). Rankenburg et al. (2007) analyzed bulk rocks, pyroxene, and feldspar separates (and additional phases) and obtained a Rb–Sr age of 3010 ± 14 Ma (illustrated in Fig. 9a). This age agrees with, but is more precise than, the corresponding U–Pb age of 2.93 ± 0.15 Ga (Anand et al. 2006) or the Sm–Nd age of 2992 ± 85 Ma (Rankenburg et al. 2007) on the same sample (Fig. 9b). The latter system has also been subject to disturbance in phosphates so that Rb–Sr appears to be more robust with respect to the nonsilicates that often occur in meteorites. Notably, $^{40}\text{Ar}/^{39}\text{Ar}$ results of 2985 ± 16 Ma and 2874 ± 56 Ma (Fernandes et al. 2009) on this meteorite appear to be somewhat younger, which at least in the first instance may be related to inaccuracies in the Ar decay constants (Begemann et al. 2001). Irrespective of the cause of difference in absolute

ages using various chronometers, it seems apparent that Rb–Sr can provide accurate and very precise age information that cannot otherwise be determined.

Conclusion

The Rb–Sr dating technique is a widely used technique in obtaining ages of igneous or metamorphic events and may be applied to dating volcanic sequences, ore deposition, or fluid-related events. In comparison with other dating techniques, there are several disadvantages, for example, its relatively low closure temperature and consequent susceptibility to isotope disturbance. However, if applied in a petrogenetic context or on samples that allow other means of identifying (hydro-)thermal overprints, it is a useful and reliable dating tool. In addition, it can also be used to date low-temperature events or the prolonged cooling history of igneous bodies or greater crustal terranes. The advent of modern analytical instrumentation now enables determination of high-precision Rb–Sr ages that are comparable in precision and accuracy with other dating techniques. Limitations such as poorly constrained thermal histories of samples and the necessity of species (mineral or rock) with a considerable spread in Rb–Sr ratios remain.

Sedimentary Rocks (Rb-Sr Geochronology)

Tod Waight*

Department of Geosciences and Natural Resource Management, Geology Section, University of Copenhagen, Copenhagen K, Denmark

Synonyms

Clay dating; Glauconite dating; Rb-Sr dating; Shale chronology; Sr dating; Sr geochronology

Definition

Application of the radioactive decay of ^{87}Rb to ^{87}Sr to determining the age of deposition of sedimentary rocks.

Characteristics

Absolute dating of sedimentary rocks is of interest to obtain depositional ages and to provide a quantitative link between the relative ages provided by fossil successions (biostratigraphy) and the geological time scale, and improve our understanding of the evolution of life through the fossil record. However, application of the Rb-Sr system to dating of sedimentary rocks has had variable results and has often proved to be problematic.

The Rb-Sr geochronological system is based on the beta decay of ^{87}Rb to ^{87}Sr with a half-life of 48.8 Ga, corresponding to a decay constant (λ) of $1.42 \times 10^{-11} \text{ a}^{-1}$, making the decay system potentially able to provide absolute age information for geological events throughout most of the Earth's history. The general decay formula for the Sr isotope system is

$$\frac{{}^{87}\text{Sr}}{{}^{86}\text{Sr}_{(0)}} = \frac{{}^{87}\text{Sr}}{{}^{86}\text{Sr}_{(i)}} + \frac{{}^{87}\text{Rb}}{{}^{86}\text{Sr}} e^{\lambda t} - 1$$

where the subscripts (0) and (i) refer to the measured present-day and initial Sr isotope composition, respectively. Age determination with the Rb-Sr system typically involves construction of an isochron using minerals or rocks with as wide a range in Rb-Sr ratios as possible. Rb and Sr have chemical characteristics similar to K and Ca, respectively; therefore, Rb will tend to be concentrated in K-rich minerals and Sr will be concentrated in Ca-rich minerals. Examples of minerals in sedimentary systems with high-K contents and therefore high Rb-Sr are micas, alkali feldspar, and various clay minerals, whereas minerals such as carbonates and phosphates (e.g., calcite and apatite) are Ca-rich and therefore have low Rb-Sr. With time the ^{87}Rb in the minerals will decay to ^{87}Sr , such that high Rb-Sr minerals will become progressively more radiogenic (higher $^{87}\text{Sr}/^{86}\text{Sr}$) with time, whereas the amount of ingrowth of ^{87}Sr in the Rb-poor minerals will be

*Email: todw@ign.ku.dk

lower or, in the case of Rb-free minerals, absent. The measured $^{87}\text{Sr}/^{86}\text{Sr}$ of the different minerals or rocks phases will then define a line, an isochron, with a slope that is proportional to the age of the rock. The intersection of the isochron with the Y-axis, or alternatively analysis of a Rb-free phase or an assumption of an initial isotopic composition, provides the initial Sr isotopic composition of the system $^{87}\text{Sr}/^{86}\text{Sr}_{(i)}$.

The age of the rock can then be calculated using the equation:

$$t = \frac{1}{\lambda} \ln(1 + \text{slope})$$

In order to obtain meaningful age information from an isochron, three fundamental assumptions must be fulfilled:

- (a) The minerals/rocks must have all formed in equilibrium with each other.
- (b) The minerals/rocks must have all formed from a reservoir of homogeneous isotopic composition ($^{87}\text{Sr}/^{86}\text{Sr}_{(i)}$).
- (c) The minerals/rocks have been a closed system (i.e., not been subject to thermal or chemical disturbance) subsequent to formation.

There are three main groups of sedimentary rocks: clastic (transported), carbonate (biological), and chemical. Chemical sediments form by precipitation of minerals out of water (e.g., evaporates, carbonates, phosphates, and travertine in caves). Biological carbonate sediments (peat and coal are also biological) are formed from the accumulation of skeletal remains of organisms. The minerals formed in chemical sediments and in shells and skeletons are normally calcium-rich (e.g., calcite, apatite) and show a limited range in Rb-Sr. Thus, they are not suitable for Rb-Sr geochronology, although some can be dated using the U-series dating method, and will not be discussed further here. Siliciclastic sediments such as sandstones and mudstones form at relatively low temperatures at the Earth's surface as a consequence of erosion, transportation, and deposition of fragments and minerals from preexisting rocks dominated by silicate minerals. These sediments then undergo burial and diagenesis to become cemented into sedimentary rocks. Minerals that are unstable at surficial pressures and temperatures will tend to progressively break down during sedimentary processes to form new mineral phases, for example, feldspars will undergo hydrolysis to form clays (e.g., illite, smectite, kaolinite), many of which are K-rich and thus theoretically provide potential for dating using Rb-Sr.

The main difficulties encountered when applying the Rb-Sr system to dating of sedimentary rocks reflect uncertainties in the assumption that the sedimentary components had homogeneous isotopic compositions at the time of deposition and that the system has remained closed since. Most sandstones and clays consist of some mix of detrital phases and new authigenic minerals. Detrital minerals are derived from the eroding source region and have been transported unchanged or partially modified, and these grains will retain a Sr isotope signature reflecting the amount of ingrowth of ^{87}Sr from the decay of ^{87}Rb since their source region cooled through the closure temperature for the mineral in question. As the source regions for any particular region can comprise many different rock types of different ages and origins, this detrital component is potentially heterogeneous. Authigenic minerals grow during weathering, transport, or deposition and may therefore be in isotopic equilibrium with their transport medium (e.g., water). Because sedimentary processes take place at low temperatures, significantly below the closure temperatures for Sr isotope diffusion in the constituent minerals, the isotopic systematics are not reset to

equilibrium. Therefore, the fundamental assumption that all minerals in a sediment at the time of deposition or early diagenesis formed in equilibrium with each other and from a reservoir of homogenous isotopic composition ($^{87}\text{Sr}/^{86}\text{Sr}_{(i)}$) is unlikely to hold true.

Rb-Sr Dating of Clays

To avoid these complications, workers trying to date siliciclastic sediments have focused on fine-grained authigenic minerals such as clays that grow during deposition and early diagenesis and are so fine grained that they can equilibrate with the surrounding water. The assumption is then that these phases form in isotopic equilibrium and thus fulfill the criteria for creating an isochron. Subsequent variations in Sr isotopic composition in various clay fractions reflect their variations in Rb-Sr and ingrowth with time and can theoretically be used to construct an isochron. Two point isochrons may also be constructed if constraints on the initial Sr isotopic composition of the sediment can be made using the Sr isotope evolution curve for seawater, i.e. if an approximate age of the sediment is known beforehand or from analyses of interbedded carbonate or calcareous fossils.

Complications in the use of fine-grained clays for Rb-Sr geochronology exist because detrital components (including some clays) may be present even in the finest grain size fraction of sediments, and not all clays equilibrate with the surrounding water. Therefore, detailed X-ray diffraction studies of the clays are necessary to discriminate between detrital components and authigenic clays that have grown during diagenesis and low-temperature metamorphism. Furthermore, the ability of the clay minerals to equilibrate with the surrounding water also makes them susceptible to later disturbances by post-diagenetic interaction with pore waters which violates the remaining fundamental premise of isochron geochronology; that the minerals have remained a closed system since formation. It has also been shown that clay minerals can contain at least two different reservoirs of Sr with different origins and isotopic compositions, a loosely bound reservoir that can be released by leaching in acid or ammonium acetate and that represents the environment during deposition and clay crystallization, and a reservoir that is part of the crystal structure (e.g., Clauer et al. 1982).

The care and level of characterization that is required, and the complications involved, in obtaining geologically meaningful age data from clays in sediments are well illustrated in the study of Gorokhov et al. (1994). They separated the $<2\text{ }\mu\text{m}$ clay size fraction from a series of sediment samples from the Cambrian–Precambrian boundary in northern Estonia and Russia and then further separated these according to grain size. The samples were characterized by XRD to determine their illite crystallinity index by investigating the width of the (001) peak at half its height. A low index indicates a well-defined sharp peak and is indicative of well-crystallized illite which formed under relatively high-temperature conditions, whereas a high index indicates poorly ordered, less regular illite formed at lower temperatures (Dickin 2005). The clay fractions were then leached to produce 3-point isochrons (leachate, residue, and bulk) for each clay size fraction (Fig. 1).

The results from all clay samples and size fractions yielded a large scatter of ages but more importantly also revealed a trend of increasing age with increasing grain size (Fig. 2). In addition, the coarser-grained fractions were also characterized by XRD signatures that suggest crystallization at higher temperature, and thus, a significant detrital component was considered to be present in these fractions, subsequently resulting in older ages. Most of the other coarser-grained clay fractions were considered to be mixtures between detrital and authigenic components, and thus, the isochrons do not represent geologically meaningful ages but are instead mixing arrays. Nevertheless, when the data are combined in terms of grain size and crystallinity, some potentially

Fig. 1 Rb-Sr isochron for a representative clay sample from the Lontova claystones studied by Gorokhov et al. (1994) (sample 77NC80 < 0.1 μm fraction). Clays were leached with 1 N ammonium acetate, and a bulk sample, leachate, and residue were analyzed

Fig. 2 Compilation of apparent Rb-Sr ages for clay fractions from the Lontova claystones (see Fig. 1) against size of the clay fraction analyzed, showing a clear positive correlation between grain size and age (From Gorokhov et al. (1994))

meaningful age information can be obtained. The well-crystallized fine-grained (<0.2 μm) clays define an isochron with an age of 533 ± 8 Ma which Gorokhov et al. (1994) estimate to be the best estimate of the age of sedimentation, whereas fine-grained disordered clays yielded a younger age (430–480 Ma) that may be related to later disturbance and interactions with subsurface waters.

Rb-Sr Dating of Glauconite

A more promising approach to dating sediments using both the Rb-Sr and K-Ar systems has been to analyze authigenic glauconite, a distinctive green to black K-Fe mica that is a member of the glaucony family of minerals and forms at the sediment–water interface in shallow marine environments characterized by low energy and low rate of deposition. Sediments with high abundances of glauconite are commonly called greensands due to the characteristic color of the mineral. Glauconite originates as a result of biological activity such as ingestion and excretion of sediments. These fecal pellets, composed primarily of clay as well as potential detrital and organic material, become progressively dissolved and recrystallized on the seafloor and during burial in a process termed glauconitization. In order for glauconite to be of use in either Rb-Sr or K-Ar geochronology, it must be first assumed that it formed in equilibrium with a homogeneous reservoir (e.g., seawater)

Fig. 3 Compilation of model Rb-Sr ages calculated assuming initial $^{87}\text{Sr}/^{86}\text{Sr}$ = modern seawater against K_2O content for glauconites (*circles*) and coexisting clays (*triangles*) from modern sediment samples. The variation indicates that glauconites with <7 wt% K_2O contain a significant component of Sr derived from detrital sources (From Clauer et al. (1992))

and has remained a closed system since. Detailed studies on modern glauconite have provided important insights into the glauconization process and show that it occurs as the result of a relatively slow, two-stage process (Clauer et al. 1992; Stille and Clauer 1994). Clauer et al. (1992) investigated modern glauconites from the Guinea and California coasts. The investigated samples were leached in acid prior to analysis to remove contaminants such as detrital clays and silicates, and carbonates. Sr isotope analyses of these leachates are similar to modern seawater and indicate that the source of this Sr is mostly marine. The isotopic compositions of the leached glauconites were then used to create 2-point isochrons, using the composition of modern seawater ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7092$) as the initial composition. If there is no difference between the glauconite and seawater (i.e., an age of 0 Ma), then the glauconite is in equilibrium with seawater and could thus with burial and time yield meaningful geochronological information about the age of deposition. Strontium isotopic compositions of leached glauconite that are more radiogenic than seawater will result in positive present-day “ages” and suggest the presence of Sr in the glauconite inherited from detrital sources. These ages are of course geologically meaningless as the samples are effectively zero age. With burial and time, these rocks would develop isotopic compositions that would yield meaningless ages older than the age of deposition. Clauer et al. (1992) discovered a wide variation in apparent ages for the investigated glauconites and that the apparent age decreased with increasing K content, reaching a zero age at K contents in excess of 7 wt% (Fig. 3).

Clauer et al. (1992) therefore proposed that the initial stages of glauconite formation primarily involve recrystallization in equilibrium with progenitor materials and surrounding clays and are thus dominated by Sr inherited from the sedimentary source region. Isotopic analysis of these immature glauconites will not yield geologically meaningful ages. Later stages of glauconite growth are characterized by increasing K contents (>4 %) and involve chemical exchange with surrounding seawater. At equilibrium, this effectively resets the system to a homogeneous initial isotopic composition that is the same as that of the surrounding seawater. The glauconite then fulfills the first assumption of Rb-Sr geochronology as it formed from a homogeneous reservoir. With burial and isolation, it will begin to accumulate ^{87}Sr and thus potentially preserve the age of deposition and early diagenesis if there is sufficient spread in the Rb-Sr ratios of various glauconite fractions or when an assumed seawater composition or Rb-free phase such as apatite or calcite is used to constrain the initial composition. Careful chemical and mineralogical characterization of glauconite is therefore critical to ascertaining the validity of glauconite Rb-Sr ages.

Fig. 4 Rb-Sr isochron for glauconites (*circles*) separated from sandstones and siltstones from southeastern France. K-Ar analyses on the same material yield an identical isochron age of 97.3 ± 0.4 Ma, and the age is interpreted as representing the time of deposition (From Rousset et al. (2004))

An example of successful Rb-Sr glauconite dating is given by Rousset et al. (2004). Several carefully separated, cleaned, and well-characterized fractions of glauconite from Cretaceous sediments in France were investigated. The glauconites have K_2O ranging from 6.1 to 7.4 wt% suggesting they are mature and well equilibrated based on the studies of Clauer et al. (1992) described above and yield enough variation in Rb-Sr to define an isochron with an age of 97.9 ± 3.5 Ma (Fig. 4). The initial Sr isotope ratio of 0.70736 calculated from the isochron is in agreement with the composition of seawater at that time and calcareous fossils from the same sedimentary succession. A K-Ar age on the same material that is identical within error confirms the validity of the Rb-Sr age and indicates that no post-depositional alteration or recrystallization affected the sediments as this would likely have affected the two isotope systems differently.

Conclusions

Dating the age of deposition or early diagenesis of sedimentary rocks is highly problematic, but in certain instances, meaningful depositional ages can be determined. The constituent minerals in most chemical and biological sediments do not have enough range in Rb-Sr to produce measurable differences in $^{87}\text{Sr}/^{86}\text{Sr}$ with time. Clastic rocks on the other hand comprise a mixture of detrital grains with variable isotopic compositions inherited from their source regions and authigenic minerals that grew during burial and therefore cannot be assumed to have been in isotopic equilibrium at the time of deposition. To avoid these problems, age information can be derived from Rb-Sr isotopic analyses of authigenic minerals such as clays and glauconite. However, such studies are complex and require careful characterization of the material prior to analysis in order to assess the robustness and significance of the geochronological results. In particular, for clay analysis, detailed mineralogical analyses are required to identify different generations of clays developed during various diagenetic and post-diagenetic processes and to avoid detrital minerals that may still be present in the fine-grained clay fraction. Studies of modern glauconites have shown that only mature glauconites with high K_2O contents appear to be in equilibrium with the surrounding seawater and thus fulfill the requirement of having formed from a homogeneous isotopic source.

Noble Gas Mass Spectrometer

Leah E. Morgan*

Scottish Universities Environmental Research Centre, East Kilbride, UK

Noble gas mass spectrometry is a technique that allows for the measurement of isotopic ratios of small quantities of noble gases. Noble gases are typically extracted from samples in an extraction line, which connects directly to a mass spectrometer. Measurement of small quantities of gas is enabled by static-mode analysis, whereby gas is trapped in the mass spectrometer volume for the entirety of the measurement. Static mass spectrometric analyses were first considered by Aldrich and Nier (1948) and Nier (1981) and fully developed by Reynolds (1956).

Gas Extraction and Purification

Noble gas extraction and cleaning occur in an “extraction line” which has been pumped to ultrahigh vacuum (UHV) pressures of $<1 \times 10^{-9}$ mbar. Gas extraction from samples is typically achieved by furnace or laser heating. Gases thus released expand into the extraction line where they are purified to prevent isobaric interferences and source effects. Purification uses chemical traps (“getters”) made of metals that trap reactive gases and cryogenic traps, where regions of the line are held at temperatures below the vapor point of gases to be trapped. In some cases, different noble gases can be trapped and then later released for analysis, by varying the temperature of the cryogenic traps. Isotopic fractionation during extraction and purification is prevented by providing sufficient time for equilibration during gas expansions.

Mass Spectrometry

Purified noble gases are expanded into a mass spectrometer volume, which has typically been pumped to UHV until just prior to the inlet time. After allowing for isotopic equilibrium, the inlet valve is closed and analysis is initiated. Noble gas mass spectrometers contain a Nier-type electron impact ion source, which relies on a hot filament to create a beam of electrons that collide with and ionize gas atoms in the source. Ionized atoms are accelerated and analyzed as described in the entry on mass spectrometry elsewhere in this volume.

The isotopic composition of gas in the mass spectrometer evolves over the course of a measurement, due both to gas consumption and to outgassing from the walls of the mass spectrometer. Thus, each isotope is measured over a period of time, and the resultant data evolutions are fit with a line or curve that is extrapolated back to the time when gas was first expanded into the mass spectrometer. These “time-zero” fits for each isotope are assumed to represent the relative isotopic abundances of the samples.

Data must be corrected for background contamination and isotopic fractionation. Background corrections are made by replicating run conditions without heating the sample. Often blanks are run interspersed with samples, and a long-term fit of blank values is used to correct data. Isotopic

*Email: leah.morgan@glasgow.ac.uk

fractionation, or discrimination, is corrected via the measurement of a gas with a known isotopic ratio; for Ar this is most commonly the atmospheric $^{40}\text{Ar}/^{36}\text{Ar}$ value.

Geochronometers that rely on noble gas mass spectrometry include $^{40}\text{Ar}/^{39}\text{Ar}$, (U–Th)/He, $^4\text{He}/^3\text{He}$, tritium (by ^3He ingrowth), and cosmogenic radionuclides.

Amino Acid Racemization, Biostratigraphy

Matthew Kosnik*

Department of Biological Sciences, Macquarie University, NSW, Australia

Definition

Amino acid racemization biostratigraphy refers to using the ratio of right-handed (D) to left-handed (L) amino acids (D/L value) preserved in sediment or fossils to determine the age of sedimentary deposits including the duration of time recorded in sedimentary deposits. This can be done by direct comparison of D/L values to determine relative ages or by using calibrated D/L values to estimate ages in calendar years.

Characteristics

The age of sedimentary deposits is of fundamental importance to many topics in stratigraphy, sedimentology, evolutionary biology, and paleobiology. Amino acid racemization (AAR) provides a cost-effective way to directly date large numbers of fossils, and it has revolutionized the way paleontologists have been able to study the age of fossil deposits. AAR has made three key contributions to biostratigraphy. (1) AAR D/L values are one of many methods used to determine the relative age of sedimentary deposits (older deposits have higher D/L values). (2) AAR data are one of a few methods used to quantify the extent of mixing in sedimentary deposits. (3) Calibrated AAR data have enabled cost-effective studies of time-averaging (the amount of time recorded in a single deposit).

The use of AAR in biostratigraphy dates back to the 1960s (e.g., Hare and Mitterer 1967) and took hold in the 1970s (e.g., Bada et al. 1970; Bada and Protsch 1973). Because the rate of racemization increases with increasing temperature, the timespan over which AAR is useful depends on climactic conditions. AAR is useful over longer timespans in colder climates, stretching back over a million years in areas such as New Zealand (Bowen et al. 1998, and see ► [Amino Acid Racemization, Coastal Sediments](#)).

Post-deposition mixing and other factors impose fundamental limits on the resolution of fossil records. While D/L ratios can be used to demonstrate that two sediment layers have distinct age distributions (i.e., that one deposit is older than another), calibrated AAR enables the amount of time within a deposit and between deposits to be quantified. Calibrated AAR has been widely and primarily used to study sediment mixing processes in Holocene-aged sediments (e.g., Meldahl et al. 1997; Kowalewski et al. 1998, 2000; Carroll et al. 2003; Kidwell et al. 2005; Barbour-Wood et al. 2006; Kosnik et al. 2007, 2009, 2013; Krause et al. 2010; Simonson et al. 2013). The use of AAR as a cost-effective means of dating large numbers of shells has enabled these studies to date multiple shells per sedimentary deposit and quantify the amount of time recorded rather than

*Email: mkosnik@alumni.uchicago.edu

relying on a single age estimate. These datasets have enabled others to test mechanistic models of sediment mixing and fossil assemblage formation (e.g., Olszewski 2004).

In other cases, AAR has been used for recognition of taphonomic processes, such as shell preservation and transport (Murray-Wallace and Belperio 1994; Wehmiller et al. 1995; Martin et al. 1996). In these latter studies, it is often observed that samples of one or more Pleistocene-aged specimens can be found mixed into Holocene shell accumulations and that the source units for these reworked Pleistocene samples can also be identified in the region using AAR (Wehmiller et al. 1995; Martin et al. 1996).

A key advantage of AAR when dating fossil deposits, relative to other methods such as Pb-210 or OSL, is that AAR directly dates the fossils rather than the surrounding sediments. Directly dating the fossils avoids any biases associated with differential sediment mixing.

Luminescence, Earthquake, and Tectonic Activity

Morteza Fattahi*

Institute of Geophysics, University of Tehran, Tehran, Iran

Definition

- *Paleoearthquake*

An old, often prehistoric, earthquake.

- *Paleoseismology*

The study of paleoearthquakes, especially their geological expression, location, timing, and size.

- *Recurrence interval*

The repeat time of major earthquakes.

- *Slip rate*

The average velocity with which one side of the fault moves with respect to the other.

- *Earthquake catalogue*

A comprehensive earthquake database.

Introduction

On average, 15 earthquakes with a magnitude of 7 or greater occur on earth every year. Because of their devastating potential, much effort has been devoted to finding a reliable method for predicting the location and time of large earthquakes. So far these efforts have been unsuccessful. However, if the recurrence intervals for earthquakes of various magnitudes in the region of interest were known, it is possible to estimate the probability of an event in the future. Therefore, determining the average rate of recurrence of strong earthquakes on a fault is a key element in long-term hazard assessment.

Seismic Hazard Assessment

Seismic hazard assessment (see Kijko 2011) is based mainly on analysis of seismicity and knowledge of past earthquake activity in a region. Past earthquake records come in three categories: instrumental, historical, and prehistoric. Instrumental data (post 1890s) cover a too short period, and historical records are also short compared to the repeat times of large earthquakes on a fault. In most parts of the world, even in parts of old countries such as China, Japan, Iran, and the Mediterranean regions, historical information reaches back a maximum of a few thousands of years. However, the recurrence interval of large earthquakes on many important faults is several thousands of years (e.g., 7 ka in Xiyangfang, China (Yanchou et al. 2002); 3 ka in NE Iran (Fattahi et al. 2006)). Therefore, analysis of paleoearthquakes is required to complete the catalogue of earthquakes.

Fortunately, geologic sedimentary strata and geomorphic features preserve evidence of tectonic deformation and landscape changes caused by large earthquakes at or near the earth's surface. Geology and geomorphology identify and evaluate the location and extent of past fault displacements near surface folding and features related to coseismic deformation. Luminescence dating methods, among other geochronology techniques, determine the timing of these types of deformation. Paleoseismology uses these records to understand the faulting process (McCalpin 2009). The majority of paleoseismic studies have been undertaken to provide input for seismic hazard assessments (e.g., Gurpinar 2005). Paleoseismic data have been used for producing probabilistic seismic hazard maps (see Kijko 2011) which include information on fault location, geometry, dimensions, slip rates, and recurrence intervals (see Kijko 2011).

Recurrence Interval, Slip Rate, and Active Fault

There are two ways to estimate recurrence intervals. One method is direct dating of evidence of paleoearthquakes. The second method is to divide the average displacement per event by the long-term slip rate of the fault. Long-term average slip rate is calculated by dividing the cumulative displacement (net slip required to produce the observed deformation across the fault) by the total time over which this displacement occurred (the age of the deformation).

The deformation can be horizontal deformation of a geomorphic or man-made feature such as river or road or the vertical deformation of dated strata in the subsurface or geomorphic surfaces overlying the blind thrust (monoclines, anticlines). The vertical slip rate, the net slip rate, and the dip of the blind fault are trigonometrically related to each other. Therefore, if vertical slip rate and dip are known, the net slip rate can be calculated.

Slip rate is a key to understanding the relative importance of active faults in an area and the hazard those active faults present to local residents and developments. There are different definitions for "active fault" based on geologic or engineering purposes in different countries. However, a fault is commonly considered to be active if it has moved at least once, up to a certain time in the past, such as the last 10 ka, 35 ka, 50 ka, or 1.8 million years ago (e.g., Lee et al. 2006; USGS website <http://earthquake.usgs.gov/learn/glossary/term=activefault>). An active fault exhibits offsets and can therefore be identified by recognizing and dating tectonically deformed surface or material. Active faults, faulted land forms, and coseismic surface ruptures can be identified by different methods, including satellite images, aerial photographs (e.g., Lin et al. 2006; Fattahi et al. 2007), various geophysical techniques, airborne light detection and ranging (LIDAR), airborne laser swath, mapping, and field surveys (see Kijko 2011).

Evidence for Prehistoric Earthquakes

Earlier classifications of paleoseismic evidence are modified to 16 categories and 3 levels as primary or secondary, on-fault or off-fault, and stratigraphic or geomorphic (McCalpin 2009, Table 1.2). Primary evidence is formed by tectonic deformation and reflects seismic surface faulting or folding, whereas secondary evidence is produced by earthquake shaking or is a response to strong ground shaking. These evidences are either above a fault trace or away from a fault trace and are coseismic or postseismic features, which are preserved as stratigraphic or geomorphic evidence. This distinction often determines how to approach paleoseismic field investigations. The geomorphic method usually measures and dates the amount of landform deformation during paleoearthquakes. Fault scarps, fissures, folds, colluvial aprons, tilted surfaces, uplifted/subsided shorelines, and tectonic alluvial terraces are typical examples of primary geomorphic evidence. Landslides, sand blows, and rockfalls are examples of secondary paleoseismic geomorphic evidence.

The stratigraphic method usually measures and dates deformed strata in exposures (McCalpin 2009). Examples of stratigraphic paleoseismic evidences can be divided into primary and secondary evidence. Primary evidence include displaced or folded strata, unconformities, scarp-derived colluvial wedges, tsunami deposits, zones of sheared sediment, fissures, and uplifted, subsided, or tilted surfaces located some distance from the fault. Secondary evidence includes, for instance, sand dikes and other liquefaction features, filled craters, soft-sediment deformation structures, and turbidity current deposits.

Evidence of paleoearthquakes and old surface ruptures are often minimal directly on the earth's surface. Therefore, trenches are excavated to expose faults and young strata that record the evidence. In outcrops or trenches, corresponding stratigraphic evidence can be found. A trench log is used for defining and mapping the sequence of deformation, sedimentation, and weathering exposed at a site and for recording evidence of surface-rupturing earthquakes. These records (see Toda 2011, Fig. 4) can be preserved as direct fault exposure, such as upward fault termination, fissure fill, scarp-derived colluvial wedge, wrapping, folding, minor fracturing, and inferred offset, each of which is defined as an “event indicator” (see Toda 2011). Luminescence dosimeter minerals (quartz and feldspar) inside these event indicators are used to find the age of paleoearthquakes.

Luminescence Dating of Prehistoric Earthquakes and Faulting

Luminescence dating of earthquake-related deposits offers great potential for dating evidence of past earthquakes and faulting for a number of reasons (see Fattahi 2009). Daylight or friction temperature can reset the luminescence “clock” of sediments before burial due to earthquakes. Therefore, luminescence dating techniques can be applied for age determination of any of paleoearthquake evidence if the clock of quartz or feldspar inside that evidence is reset during, or just prior to, paleoearthquakes. They constrain timing of paleoearthquakes directly or indirectly by calculating ages of deformed stratigraphic units and underlying or overlying undeformed strata.

The most direct techniques for dating active faults and paleoearthquakes are dating fault scarp, fault-scarp colluvium, fault gouge, or liquefaction features such as injection dike and sand blows (deposition from the surface rupture of an injection dike). Although these techniques directly date the formation of coseismic features, age uncertainties can be relatively large.

Indirect dating methods involve bracketing the age of the paleoearthquake by luminescence dating of structures or deposits that predate and postdate the paleoseismic evidence. Maximum

ages are obtained from sediment deposited before the paleoearthquake. Minimum ages are obtained on material younger than the earthquake. The accuracy and precision of luminescence dating may be high, but the ages themselves may not provide close constraints on the age of faulting.

Fault-scarp and fault-collapse wedges have been identified as the most important records of the paleoearthquakes (Allen 1986). Fault-collapse wedges are a kind of colluvial deposit of sediments formed as wedge-shaped deposits on the foot slope. Colluvium is a term that describes sediments that are eroded from and transported along hill slopes by gravity. Reverse and normal faulting chronologies can be reconstructed from luminescence ages on fault-scarp colluvial wedge sediments (e.g., Fattahi et al. 2006; Porat et al. 2008). Colluvial wedges and fault planes are identified from exposures and trenches, while materials from buried soils within the faulted sediments are dated to obtain a fault-rupture chronology. A suitable exposure or trench exhibits multiple faulting events with clear displacements and consequent colluviation. For reverse faulting, the approach assumes that an overhanging fault scarp is produced coseismically and immediately following the earthquake, hanging-wall collapse to form an angle-of-repose debris slope. On the assumption that the production process of colluvial wedge is sufficiently slow for the sediments to have been exposed to sunlight long enough to reset the luminescence clock, direct dating of discrete fault-rupture events can be achieved by OSL dating of fault-scarp colluvium. For normal faulting, a vertical throw of some meters is not uncommon for the surface expression of faulting. Immediately following the earthquake, there would be a contour step, the low side of which would then become progressively filled with sediment. Normal faulting chronologies can be reconstructed from luminescence ages on colluvial wedge, slope-wash sediments, sag-pond deposit, and the soil horizons that underlie and overlie the wedge. The age of the event horizon decreases away from the fault due to the time taken for soil to pour laterally, accreting scarp-derived colluvium. The age of the event horizon might also be extrapolated from the age of several subsamples of the buried soil horizon. Luminescence surface-exposure dating recently introduced by Sohbati et al. (2012) theoretically has the potential to date fault scarp directly.

The usual approach to dating individual paleoearthquakes on strike-slip faults is to bracket the earthquake by dating the youngest datable stratum deformed by the quake and the oldest datable stratum that overlies the earthquake horizon (McCalpin 2009). However, for strike-slip fault, direct luminescence dating of a fissure fill can provide the age of the faulting event (e.g., Fattahi et al. 2010).

Fault gouge is formed by brittle fracturing of rocks as a result of slip along the faults during an earthquake. Luminescence dating of gouge to date neotectonic movements and past seismic events is based on the assumption that during the faulting event, the luminescence intensity of the gouge material is “zeroed” by either frictional heating or mechanical deformation or a combination of these. Even with agreement between TL and radiocarbon ages and despite consistent TL and IRSL data, there has been debate about the resetting of the luminescence signal in fault gouge. Some researchers propose a grain-size dependence with finest grains almost certainly reset, while others revealed no evidence for resetting of fault gouge (see Spencer et al. 2012 and references there in). It is suggested that luminescence emission from fault gouge samples has the potential to determine the age distribution of distinct deformation microstructures (Spencer et al. 2012). Such age determination could help constrain some of the proposed micromechanical models for shear localization in fault gouge, for example, identifying the relative effect of stress-driven mass transfer processes.

Injection dikes correspond to episodic pulses of an increasing hydraulic pressure generated mostly by seismic loading during earthquakes. These injection dikes (formed by liquefaction

during earthquakes) were used for reconstruction of paleo-epicenter locations (McCalpin 1996 and references therein) and have been under investigation to be dated by OSL in an attempt to directly date seismic events (e.g., Thomas et al. 2007).

Sand blows are lenticular sand bodies that were erupted onto paleo-ground surfaces and were fed by sand-filled dikes that were sourced from subjacent liquefied sand beds. Age constraint on the timing of liquefaction and seismic activity may be obtained by OSL dating of sand blows formed by the surface rupture of liquefaction features and injection dikes (e.g., Thomas et al. 2007).

Dating tsunami events is important in estimating the recurrence intervals of catastrophic events and hazard risk assessment. OSL measures the times elapsed since sedimentation, so direct dating of tsunamigenic sediments by luminescence is possible if signal resetting is complete. Usually, aeolian and fluvial resetting of the luminescence signal takes place during sediment transport. However, the process of sediment transport by tsunami is often rapid: maximum tens of minutes for each half wave with total sedimentation lasting several hours. The flow may be too muddy to expose all sediments to light and the tsunami may occur at night. Consequently, only limited resetting occurs during transport. The assumption for zeroed luminescence signals in tsunami-deposited sediments is that the source sediments are well bleached prior to tsunami entrainment. The source material is sediment from the coastal and near-shore zone that is constantly reworked by waves and tides. Intertidal sediments from various locations and beach-face sediments deposited by a combination of wind and wave action have been shown to have a near-zero residual luminescence signal. OSL dating of deposits of the 2004 Indian Ocean tsunami and paleotsunami sediments of known age proved the general applicability of the method for tsunamigenic sand sheets (see Brill et al. 2012; Prendergast et al. 2012 and references therein).

Luminescence Dating of Tectonic Movements

Terraces, alluvial fans, fluvial, and dry lake deposits are datable by OSL and can be important records of tectonic activity. Fault activity or fold deformation can uplift or subside land and change channel patterns near known structures (e.g., Thamó-Bozsó et al. 2010). Land uplift can block a river and make a lake or change the direction of rivers. River and marine terraces can be dated by OSL to determine the rate of uplift (e.g., Choi et al. 2003). Thick basin-fill sediments can be dated to determine subsidence rates (e.g., Chen et al. 2003). Late Quaternary landforms which are displaced by a fault can be used to determine the slip rate and average recurrence interval (e.g., Fattahi et al. 2007). OSL can provide dates of deformed and undeformed fluvial and aeolian sequences which can be used to find the timing of neotectonic activity (e.g., Thamó-Bozsó et al. 2010). IRSL dating of the inland fans/terminal fans (as the potential geomorphic markers) can be used to determine the shift of neotectonic activities in a region (Pati et al. 2012).

Luminescence dating has been used to assess tectonic activity by studying the fluvial geomorphic response of rivers to deformation (e.g., Rittenour 2008 and references therein). These include:

- Determining the timing of the switch from a highly sinuous channel to a straightened channel as a response to periodic clustering of seismic events and decreased gradient due to fault displacement
- Fold migration during the Holocene era due to fault length extension
- Examining the faulting and uplift history along a river and comparing the influence of tectonic uplift and climate for the formation of strath terraces
- Rates of active faulting during the late Quaternary fluvial terrace formation at a river

Conclusion

Luminescence dating is rapidly evolving into a very powerful tool for determining the depositional age of earthquake-related sediments. It can do this because of its versatility in directly sampling targeted features and deposits using the most common minerals on the earth: quartz and feldspar. Following the successful application of TL dating for paleoseismic reconstruction (reviewed by Fattahi 2009), a new approach using OSL was employed to date paleoearthquakes and related sediments that have been displaced and exposed to daylight by any physical phenomena associated with an earthquake (e.g., ground motion, ground failure, surface ruptures, liquefaction, and tsunami). These dates are also essential for estimating the activity of earthquake faults, understanding neotectonic processes and rates, determining fault slip rates, and establishing recurrence intervals of fault activities. These are only the most prominent uses.

Luminescence dating results can be used not only to resolve paleoseismological problems on their own but also to prove if a fault is active for engineering purposes. Ages of paleoearthquake features plus all possible background information (geomorphology, structural geology, sedimentology, various geophysical records, results from other investigations, etc.) make paleoseismological interpretation of the results possible, which provide useful new insights and information for earthquake hazard risk assessment.

Luminescence Dating, Instrumentation

Kristina Jørkov Thomsen*

Centre for Nuclear Technologies, DTU Nutech, Roskilde, Denmark

Definition

The basic instrumentation required to obtain a dose based on optically stimulated luminescence (OSL) signals consists of four main components: (i) a luminescence detection system, (ii) a stimulation light source, (iii) a heating system, and (iv) an irradiation facility. To obtain a thermoluminescence (TL) dose, a stimulation light source is not required.

Introduction

Luminescence dating is an absolute chronological technique widely used in archaeological and geological dating but also with applications in other areas of retrospective dosimetry such as environmental, accidental, medical, and forensic dosimetry. In dating applications an age is determined by measuring the dose absorbed by the target mineral, primarily quartz and feldspars, and dividing it by an independently determined dose rate in the media. This dose rate is mainly derived from the flux of ionizing radiation emitted from naturally occurring isotopes (from the thorium and uranium series as well as potassium-40) and from cosmic rays and is determined using methods such as gamma spectrometry, beta counting, alpha counting, inductively coupled plasma-mass spectrometry (ICP-MS), and neutron activation analysis. These measurement techniques and the associated instrumentation are described elsewhere. Here, the main emphasis is placed on the instrumentation required to determine the dose absorbed by the target mineral using luminescence techniques.

Luminescence Detection System

Many natural phosphors are only weakly luminescent making good light collection important. This requires a sensitive photon detector with a low noise (background) level to obtain a good signal-to-noise ratio. Luminescence is emitted in all directions, but the use of reflective metal sample holders helps to maximize the light emitted toward the detector. The distance between the photon detector and the sample should be as short as possible, since only a small increase in this distance will lead to a considerable loss in light collection efficiency. Alternatively, suitable optics can be used to improve the light detection.

The light detection system consists of two components: (i) a photon detector and (ii) detection filters.

*Email: krth@dtu.dk

Photon Detector

The most commonly used photon detector in luminescence dating is the photomultiplier tube (PMT), which converts photons into cascades of electrons. The quantum efficiency of PMTs is typically up to ~30 % (number of electron pulses per photon crossing the detection area) depending on the wavelength of the incident light. The bialkali EMI 9235QB PMT is widely used; this has a quantum efficiency of 25–30 % in the range from ~200 to ~450 nm making it suitable for detection of UV/blue luminescence from both quartz and feldspar (emitting mainly in the range 350–450 nm, e.g., Huntley et al. 1991). PMTs with an extended sensitivity in the red region (e.g., R943-02 Hamamatsu GaAs tube) are also used for red TL measurements of quartz and feldspar (e.g., Vandenberghe et al. 2009; Fattahi and Stokes 2000; Jain et al. 2005) or for IR-RF dating of feldspars (e.g., Krbetschek et al. 2000; Buylaert et al. 2012). Such PMTs need to be cooled to ~ -10 °C to reduce dark count.

PMTs do not provide any information on spatial variation of the emitted luminescence. Various imaging systems have been developed (see summary in Bøtter-Jensen et al. 2003) including the use of charged coupled devices (CCD). Recently, the use of EMCCD cameras has been suggested (Clark-Balzan and Schwenninger 2012; Richter et al. 2013).

Detection Filters

The main function of the detection filters is to define the spectral detection window, but they must also shield the photon detector from scattered stimulation light. The intensity of the emitted luminescence is $<10^{-15}$ times the intensity of the stimulation light, so for most applications it is very important to ensure that the spectral stimulation and detection windows are well separated. UV emissions (e.g., quartz, with stimulation with blue 470 nm light) are commonly detected through the broad band Hoya U340 glass filter, which has a peak transmission at 340 nm (full width at half maximum (FWHM) 80 nm). Blue emissions (e.g., feldspar, with stimulation with IR 870 nm light) are typically measured using a combination of BG3/Schott 7–59 and BG 39 glass filters, which has a peak transmission at ~380 nm (FWHM ~60 nm). This filter combination is also widely used for TL measurements, usually with the addition of heat-absorbing filters to reduce the contribution from blackbody radiation.

Stimulation Light Sources

In OSL, optical stimulation results in the eviction of trapped charge; subsequent recombination may lead to the emission of a luminescence signal. The probability of eviction and hence the luminescence signal intensity depends on the photoionization cross section of the target trap(s). This cross section is dependent on both the wavelength and the intensity (effective stimulation power) of the optical stimulation. In general, a brighter luminescence signal is obtained as the wavelength is decreased and the stimulation power is increased. Optical stimulation is usually achieved using a constant light intensity (CW mode), but the intensity can also be modulated to give a better visual insight into the number of traps contributing to the OSL signal (e.g., linearly modulated OSL, LM-OSL; Bulur 1996). In both CW and LM modes, the luminescence is recorded during stimulation. In pulsed OSL (POSL, e.g., McKeever et al. 1996; Denby et al. 2006), the stimulation light is pulsed and the OSL is measured between pulses. In luminescence dating applications, POSL is mainly used to separate quartz and feldspar OSL signals instrumentally (e.g., Thomsen et al. 2008) and in combination with time-resolved detection to obtain insight into luminescence recombination processes (e.g., Jain and Ankjærsgaard 2011).

Optical stimulation is often achieved using inexpensive and compact arrays of individual light-emitting diodes (LEDs, e.g., Bøtter-Jensen et al. 2010), which can be easily intensity modulated and can have a stable light output. A disadvantage of LED stimulation is the relatively broad emission (half width $\sim 20\text{--}30$ nm) with significant tails. Thus, additional cutoff filters are often required to obtain sufficient spectral separation of stimulation and detection windows (Bøtter-Jensen et al. 1999).

Nevertheless, optical stimulation can be achieved using any optical stimulation source, e.g., filtered lamp systems (Bøtter-Jensen and Duller 1992), lasers (Huntley et al. 1985; Duller et al. 1999; Richter et al. 2013), and laser diodes (Bøtter-Jensen et al. 2000; Richter et al. 2013). One advantage of using a laser-based stimulation source is the monochromatic or very narrow emission band, which reduces the need for filtration to separate the detection and stimulation spectral windows. These stimulation sources further have the advantages of being focusable to narrow spots and high power densities, which greatly reduces the readout time. However, laser sources are often relatively expensive, are sensitive to temperature, and can have long-term stability issues.

Feldspar measurements are generally obtained using infrared (800–900 nm) LED stimulation at ~ 200 milliwatts per square cm (mW/cm^2). For quartz measurements optical stimulation using LEDs is usually obtained using blue (470 nm) and green (520 nm) stimulations at power densities typically varying between 50 and $100 \text{ mW}/\text{cm}^2$. Jain (2009) suggested the use of a violet laser diode (405 eV) to extend the age range using quartz by probing deeper traps not accessible by blue light stimulation. In single-grain dating applications, solid state lasers emitting at 532 and 830 nm are used as stimulation light sources (Duller et al. 2003). The power densities at the sample for these light sources are estimated to be >2 orders of magnitude higher than those achievable with conventional LEDs.

Heating System

In TL dating it is important to be able to heat the samples reproducibly using adjustable (although usually constant) heating rates. The ability to vary the heating rates is particularly important for understanding TL processes. Although OSL is an optical method, samples usually require some thermal pretreatment to be able to compare the luminescence resulting from the natural and regenerated doses (e.g., Ankjærgaard et al. 2006). In quartz and feldspar OSL dating, for instance, it is customary to preheat the samples in the range of $160\text{--}320$ °C. Quartz OSL signals are also generally measured at an elevated but constant temperature (125 °C) to improve the signal-to-noise ratio. Most luminescence dating systems can heat up to 700 °C using heating rates ranging between 0.01 and 10 K/s. From a purely instrumental point of view, it is beneficial to perform heatings above 200 °C in a N_2 atmosphere to prevent oxidization of the heating element. In TL measurements to high temperatures, it has the further advantage of reducing spurious signals.

Irradiation Sources

In luminescence dating the measured natural luminescence signal is converted into an absorbed dose by comparison with regenerated signals induced in the laboratory by administering known doses to the sample. These signals can be regenerated using for instance gamma, beta, or alpha emitters. For practical reasons it is beneficial to be able to perform in situ irradiations. Due to radiation protection issues, beta emitters, particularly $^{90}\text{Sr}/^{90}\text{Y}$, are usually preferred as in situ

reference sources. The maximum $^{90}\text{Sr}/^{90}\text{Y}$ electron energy is 2.27 MeV and the mean electron energy is about 600 keV. Two of the major disadvantages of using a beta source are that the dose rate is fixed and that it may not provide a spatially uniform dose across the sample area (e.g., Spooner and Allsop 2000; although this disadvantage is not so important with a new type of $^{90}\text{Sr}/^{90}\text{Y}$ sources). In contrast, X-ray sources have electronically adjustable dose rates and have been shown to have a high degree of spatial uniformity and are easily shielded. However, X-ray sources are not widely used in luminescence dating, because the dose rate is highly sample dependent, probably because of high local ionization effects (Thomsen et al. 2006; Jain et al. 2007). It has been suggested that by hardening the X-ray spectrum, one can get rid of this sample dependency, but this suggestion has not yet been thoroughly tested. Alpha sources (primarily ^{241}Am) are only used in fine-grained (4–11 μm) polymineral dating and only if one wishes to determine the a-value (alpha to beta efficiency) for the samples in question.

Amino Acid

John Wehmiller*

Department of Geological Sciences, University of Delaware, Newark, DE, USA

Definition

An organic compound containing an amino group (NH₂), a carboxylic acid group (COOH), and any of various side groups, having the basic formula NH₂CHRCOOH.

Amino acids are organic compounds composed of carbon, oxygen, hydrogen, and nitrogen in a specific structure where a central carbon atom is surrounded by a carboxyl group, an amino group, and a side chain that may be a single hydrogen or a more complex chain with multiple carbon-bearing entities. The structure common to all amino acids is shown in Fig. 1. Approximately 20 common amino acids are found in nature, and they combine in sequences of varying lengths to form peptides and proteins that have specific biochemical functions. Amino acids are found in a variety of geological samples and play a role in understanding chemical evolution, the formation and alteration of organic material in sediments, and geochronology (Goodfriend et al. 2000).

The role of amino acids in geochronology is based on the phenomenon of isomerism. Amino acids can exist in two isomeric forms, commonly referred to as “left handed” and “right handed.” These two forms are possible because the central carbon to which the four different side chains are bonded is asymmetric: two mirror-image configurations around this central carbon are possible, and these two are not geometrically equivalent.

Amino acids are found in sediments, soils, and in many common biominerals, as constituents of the structural proteins used by organisms such as mollusks, corals, foraminifera, etc., to synthesize the mineral phase. Amino acids are also found in bone, teeth, and wood. In most cases, the amino acids incorporated into the biomineral during growth are of the 100 % left-handed configuration. Upon death of the organism, these amino acids begin the process of racemization, or conversion from the 100 % left-handed form into an equilibrium mixture of 50 % of each of the two forms. The rate at which this reaction occurs is influenced by many factors, including temperature, sample type, alteration of the sample during its burial history, and specific rates of breakdown of the proteins that are preserved within the mineral matrix of the analyzed samples. Common amino acid racemization (AAR) studies include the use of foraminifera from deep-sea sediments (► [Amino Acid Racemization, Marine Sediments](#)), marine mollusks from coastal deposits (► [Biostratigraphy](#); ► [Amino Acid Racemization, Coastal Sediments](#)), and snails, eggshells, or ostracodes from terrestrial environments (► [Fluvial and Lacustrine](#); ► [Arctic](#); ► [Amino Acid Racemization, Egg Shell](#)). The timescale of these studies ranges from a few hundred years to over a million years, depending on the average temperatures to which samples have been exposed. These biominerals function to isolate the amino acids from the surrounding environment. Wood, soils, and bulk sediments also have been used in some AAR geochronological studies, with mixed success because of the open-system nature of these samples.

Fig. 1 Mirror-image relation between the two configurations of amino acid molecules. The four side chains are bonded to the central carbon atom at the corners of a tetrahedron. The two forms are geometrically distinct; hence the conversion of one form to the other requires breaking a bond and reassembling the amino acid as the other form. H = hydrogen; COOH = carboxyl group; NH₂ = amino group; R = one of many possible side chains that define the different amino acids

Radiocarbon (¹⁴C) dating (Cross-Reference) usually involves extracting carbon-bearing material (either organic carbon or carbonate carbon) from samples that are to be dated. In some cases, it is preferable to extract the amino acid component from these samples as a test of the integrity of the ¹⁴C result (Hatte et al. 2012). Comparison of ¹⁴C dates obtained on a bulk sample and the amino acid fraction of that same sample provide an indication of the integrity of the sample, as the amino acids (bound within the biomineral) would be expected to be less vulnerable to contamination from external sources (Marom et al. 2012).

Feldspars

Michel Lamothe*

Université du Québec à Montréal, Montréal, Québec, Canada

Feldspars are the most ubiquitous minerals in the Earth's crust. They are unique dating targets, in the fields of luminescence and **K-Ar/Ar-Ar** geochronology, as mineral grains in sediments and rocks. Both as grains of sediment and as grains in rocks.

Feldspars are compositionally symbolized as **MT₄O₈** where **M** are **K**, **Na**, and **Ca** and **T** are **Si** and **Al**. End-members composition for alkali feldspars are (**K**, **Al**) **Si₃O₈** (microcline, sanidine) and (**Na**, **Al**) **Si₃O₈** (albite). Plagioclases represent a continuous solid solution with end-members composition between albite and anorthite (**CaAl₂Si₂O₈**).

Feldspars are known as framework silicates, in which corner-sharing (**Al**, **Si**) **O₄** tetrahedra form crankshaft-like chains, assembled along their *a* axis. Cross-linking generates large coordination sites occupied by the charge-compensating cations (Fig. 1).

A most interesting aspect in feldspar mineralogy is in the distribution of **Al** and **Si** in tetrahedral sites. For the K-feldspars, complete disorder is observed for the high-temperature monoclinic sanidine, with an equal probability of finding **Al** at any T sites. At the other extreme, in ordered triclinic microcline, **Al** is found fitting preferentially in T₁ sites.

Due to the inherent complexity of natural crystals, the solid-state physics of feldspar luminescence is poorly known (Krbetschek et al. 1997; Baril 2002). Charge defects have been mostly detected along **Al-O¹⁻-Al** bridges, a likely candidate at the origin of the blue luminescence emission commonly selected in dating K-feldspar. Yellow-green (**Mn²⁺**) and red (**Fe³⁺**) emissions are clearly linked to specific recombination centers (Krbetschek et al. 1997; Baril 2002). Identification of electron traps has proven challenging. A good candidate at this stage is substitution of **Ti⁴⁺** for **Al³⁺** (T site) (Krbetschek et al. 1997; Baril 2002). The phenomenology of feldspar luminescence comprises a distinct instability of latent luminescence over geological time known as anomalous fading. Proposed culprits include **Al/Si** disorder, tunneling-prone electron traps, and instability of recombination centers (► [Feldspar Infrared Stimulated Luminescence](#)).

A minute fraction of the interstitial **K** undergoes radioactive decay to **⁴⁰Ar** and **⁴⁰Ca**. For thermochronometry applications, the argon diffusion processes are parameterized through laboratory step-heating experiments. Thermal diffusion of **Ar** in feldspar is controlled by M-O and O-O lattice configurations, vacancies, and linear and planar defects (Cassata and Renne 2013).

Potassium-Argon (Argon-Argon), Structural Fabrics

Michael A. Cosca*

United States Geological Survey (USGS), Denver Federal Center, Denver, CO, USA

Definition

$^{40}\text{Ar}/^{39}\text{Ar}$ geochronology of structural fabrics: The application of $^{40}\text{Ar}/^{39}\text{Ar}$ methods to date development of structural fabrics in geologic samples.

Introduction

Structural fabrics develop during rock deformation at variable pressures (P), temperatures (T), fluid compositions (X), and time (t). Structural fabrics are represented in rocks by features such as foliations and shear zones developed at the mm to km scale. In ideal cases, the P-T-X history of a given structural fabric can be constrained using stable isotope, cation exchange, and/or mineral equilibria thermobarometry (Essene 1989). The timing of structural fabric development can be assessed qualitatively using geologic field observations or quantitatively using isotope-based geochronology. High-precision geochronology of the thermal and fluid flow histories associated with structural fabric development can answer fundamental geologic questions including (1) when hydrothermal fluids transported and deposited ore minerals, (2) fault activity and displacements, (3) the timing and duration of orogenic stages, and (4) the rates and frequency of these and other geologic processes.

Radioisotope systems (e.g., U–Pb, Rb–Sr, Sm–Nd) that quantitatively retain radiogenic isotopes in minerals that formed at relatively high temperatures ($>500\text{ }^{\circ}\text{C}$) are necessary for dating of structural fabrics that developed deep within the crust. For example, isotope geochronology of large-scale shear zones that define major crustal boundaries in the Grenville Province of Ontario, Canada, indicates that these well-developed structural fabrics define narrow time intervals of Neo- and Mesoproterozoic orogenic compression and extension (e.g., van Breemen and Hanmer 1986; van Breemen et al. 1986; Cosca et al. 1991, 1992; Mezger et al. 1991; van der Pluijm et al. 1994).

Isotopic dating of structural fabrics developed at shallower crustal levels requires isotope geochronometers that are sensitive to rock deformation at lower temperatures. The K–Ar geochronometer, including the $^{40}\text{Ar}/^{39}\text{Ar}$ method (McDougall and Harrison 1999), is well suited for isotopic dating of structural fabrics developed close to the brittle-ductile transition zone ($\sim 250\text{--}\sim 400\text{ }^{\circ}\text{C}$) because such rocks often contain potassium-bearing minerals including mixed-layer illite/smectite, biotite, and muscovite that quantitatively retain radiogenic argon ($^{40}\text{Ar}^*$) at or below $\sim 400\text{ }^{\circ}\text{C}$.

The $^{40}\text{Ar}/^{39}\text{Ar}$ system shown includes two lasers (IR and UV) for liberating Ar from rock and mineral samples. The UV laser has been removed for clarity (the position of the UV laser chamber (UVLC) is indicated). Setup and control of the $^{40}\text{Ar}/^{39}\text{Ar}$ experiments, including automation of the mass spectrometer, lasers, and UHV gas extraction line, is done using computers

$^{40}\text{Ar}/^{39}\text{Ar}$ Geochronology of Structural (Deformation) Fabrics

$^{40}\text{Ar}/^{39}\text{Ar}$ Methods

Dating structural fabric using $^{40}\text{Ar}/^{39}\text{Ar}$ methods can be approached either by incrementally heating separated mineral grains with a furnace or infrared (IR) laser or by in situ laser ablation within small polished rock samples (thereby preserving textural context), with an IR or ultraviolet (UV) laser. The U.S. Geological Survey (USGS) system in Denver (Fig. 1) consists of both an IR laser (CO_2 , wavelength = 10.6 μm) and an UV laser (ArF exciplex, wavelength = 193 nm) attached to an ultrahigh vacuum (UHV) gas extraction system and mass spectrometer equipped with five Faraday detectors and a single compact discrete dynode ion multiplier. Samples for in situ analysis are prepared from polished rock chips, several mm on a side. One or more chips are irradiated by fast neutrons in a nuclear reactor and are placed in a laser sample chamber (Fig. 2) with a window that is transparent to 193 nm UV light. For in situ analysis, UV lasers are preferred over IR lasers because the shorter wavelengths results in minimal collateral heating of adjacent grains within the sample. Because small gas concentrations are liberated during UV laser ablation ($\sim 10^{-16}$ to $\sim 10^{-20}$ mol), isotopic measurements are performed by static mass spectrometry using a single ion multiplier.

Multigrain $^{40}\text{Ar}/^{39}\text{Ar}$ Geochronology

Determining when foliations and shear bands develop is typically done by separating and analyzing pure, multigrain mica samples using either K–Ar or $^{40}\text{Ar}/^{39}\text{Ar}$ methods (e.g., Itaya and Takasugi 1988; Kelley 1988; Hames and Cheney 1997; Jaboyedoff and Cosca 1999; Mulch et al. 2004). Several multigrain $^{40}\text{Ar}/^{39}\text{Ar}$ studies of naturally deformed rocks have demonstrated that smaller grains yield younger ages (e.g., Kligfield et al. 1986; Kelley 1988; Goodwin and Renne 1991; Hess et al. 1993; Kirschner et al. 1996; Mulch et al. 2002; Markley et al. 2002). These multigrain studies

Fig. 2 Photograph of (a) UV laser attached to the extraction line and (b) expanded view from the top of the UVLC containing samples for analysis

show that the mean radius of physically separated grains reasonably approximates the effective length scale of $^{40}\text{Ar}^*$ diffusion, such that different-sized grains from the same sample reflect progressive cooling of the rock and closure to $^{40}\text{Ar}^*$ diffusion. Submicroscopic defects form in minerals during rock deformation (Gapais and White 1982; Passchier and Trouw 2005) and exert a nontrivial effect on intragrain $^{40}\text{Ar}^*$ retention and $^{40}\text{Ar}/^{39}\text{Ar}$ ages (Lee 1995; Kramar et al. 2003). In situ UV laser ablation $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology of individually deformed mineral grains offers a direct means of assessing the timing of deformation, the effective length scales for $^{40}\text{Ar}^*$ diffusion, and thermal histories (Cosca et al. 2011).

In Situ $^{40}\text{Ar}/^{39}\text{Ar}$ Geochronology

In situ $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology has been applied to investigate structural fabrics such as pseudotachylytes that formed rapidly under brittle conditions (e.g., Sherlock and Hetzel 2001) as well as ductilely deformed, slowly cooled rock (e.g., Hodges et al. 1994). The following examples, one

Fig. 3 Photomicrographs of white mica contained in typical structural fabrics. (a) Large, white mica porphyroclast that rotated into a planar shear zone defined by the smaller micas. (b) Strongly deformed white mica porphyroclasts with nonuniform optical properties suggest the presence of submicroscopic defects. (c) White mica porphyroclasts (fish) displaying evidence of internal size reduction as they were rotated into a shear zone fabric. *ms* muscovite, *qz* quartz. All scale bars are 1 mm

with mineral overgrowths and two involving internal mineral deformation, illustrate how intragrain $^{40}\text{Ar}/^{39}\text{Ar}$ age variations from different structural fabrics can be used to interpret geologic histories.

Overgrowths and Fluid Flow

Isotopic dating of texturally and compositionally distinct mineral overgrowths or strain fringes provides a direct measure of rock deformation, fluid flow, and mineral growth (e.g., Muller et al. 2000; Sherlock et al. 2005; Wells et al. 2008). For example, the Proterozoic Telemark detachment in southern Norway contains white mica porphyroclasts (mica fish) that formed during an initial period of upper amphibolite-grade deformation, and during subsequent greenschist facies deformation these grains developed compositionally distinct overgrowths (Mulch et al. 2005). In situ UV laser ablation $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology of the white mica overgrowths revealed that they developed over a period of approximately 10 my, and that occurred roughly 10 my after closure to argon diffusion in the mineral cores. Together with oxygen isotope values in deformed quartz, these observations indicate that a compositionally distinct fluid was present during deformation that facilitated growth or recrystallization of the mica overgrowths.

White Mica Porphyroclasts in Shear Bands

In situ UV laser ablation $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology of mica porphyroclasts in shear bands provides a means of dating past movement (e.g., Mulch and Cosca 2004) and potentially provides a means of reconstructing paleoelevations (Mulch et al. 2004). Greenschist facies micaceous quartz mylonites often contain large (mm-sized) porphyroclasts of variably deformed white mica (Fig. 3a, b). These rocks often develop C'-type shear bands (Berthé et al. 1979) that cut across earlier formed foliations and surviving porphyroclasts. In some shear bands, the so-called mica fish porphyroclasts develop and may undergo progressive mechanical grain size reduction during shearing, resulting in smaller segments of mica (Fig. 3c). This process of grain size reduction has been dated in the Pogallo shear zone of northern Italy (Mulch et al. 2002) in which mica porphyroclasts yielded in situ UV laser ablation $^{40}\text{Ar}/^{39}\text{Ar}$ dates that became younger as both the physical grain size and the length scale for $^{40}\text{Ar}^*$ diffusion decreased.

The extent of structural fabric development and defects on $^{40}\text{Ar}^*$ retention in micas within shear bands at the sub-grain scale can be assessed by in situ UV laser ablation of individual mica porphyroclasts. For example, over 150 individual UV laser ablation $^{40}\text{Ar}/^{39}\text{Ar}$ analyses within one large mica porphyroclast from a Carboniferous quartz-mica pegmatite layer reveal $^{40}\text{Ar}/^{39}\text{Ar}$ dates that correlate, and become younger, with position relative to incipient shear bands within the mica fish (Kramar et al. 2001). When examined by transmission electron microscopy, this mica fish contains abundant stacking faults or microstructural distortions caused by partial dislocations and localized charge imbalances (Kramar et al. 2003). The interconnectivity of these line defects decreases retentivity of $^{40}\text{Ar}^*$ by several orders of magnitude and can explain the range of intragrain $^{40}\text{Ar}/^{39}\text{Ar}$ dates intermediate between known periods of Carboniferous and Oligocene-Miocene deformation (Kramar et al. 2001, 2003).

Summary

$^{40}\text{Ar}/^{39}\text{Ar}$ studies of structural fabrics have shown that retention of $^{40}\text{Ar}^*$ in naturally deformed rock is sensitive to the intensity, duration, temperature, and presence of fluids during rock deformation. Understanding the link between $^{40}\text{Ar}/^{39}\text{Ar}$ ages and microstructures in deformed rock remains a fertile ground for continued research.

Luminescence Dating

Geoffrey A. T. Duller*

Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, Wales, UK

Definition

Luminescence – emission of light from a semiconductor or insulator in response to some form of stimulation such as heat or light. In the context of using luminescence for dating, the luminescence signal arises from the release of energy stored from prior exposure to ionizing radiation such as alpha, beta, or gamma radiation. Thus, luminescence provides a mechanism for measuring the amount of ionizing radiation a sample has been exposed to.

Thermoluminescence (TL)	Emission of luminescence in response to heating of the sample.
Optically Stimulated Luminescence (OSL)	Emission of luminescence in response to exposing the sample to light. In the laboratory this light is normally restricted to a narrow range of wavelengths.

Introduction

Radioactivity is ubiquitous in the natural environment. Luminescence dating exploits the presence of radioactive isotopes of elements such as uranium (U), thorium (Th), and potassium (K). Naturally occurring minerals such as quartz and feldspars act as dosimeters, recording the amount of radiation to which they have been exposed.

A common property of some naturally occurring minerals is that when they are exposed to emissions resulting from radioactive decay (e.g., alpha, beta, and gamma radiations), they are able to store within their crystal structure a small proportion of the energy delivered by the radiation. This stored energy increases as exposure to radioactive decay continues through time. At some later date this energy may be released, and in some minerals this energy is released in the form of light. This light is termed luminescence.

What makes this a useful phenomenon for dating, and what event is being dated? The answer lies in the fact that this energy stored in minerals can be reset by two processes. The first is by heating the sample to high temperatures (typically above 300 °C, as would occur during firing of pottery, or in a hearth). The second process is exposure of the minerals to daylight, as may occur during erosion, transport, and deposition of sediments. Either of these processes will release preexisting energy stored within a mineral and therefore set the “clock” to zero. Thus, in luminescence dating, the event being dated is this resetting, either by heat or by exposure to light.

Major applications utilizing the resetting of the signal by heat include dating when a piece of pottery was produced or when stones in a hearth were last heated. The application to burnt stones includes both stones that were used to form a hearth, but also a large number of important studies have dated flint tools that have inadvertently been burnt. Luminescence dating is now most commonly used to date the last exposure to sunlight of sediments; this is assumed to correspond

with the time of deposition of the sediment. The method is ideally suited to aeolian sediments where there is ample opportunity for sediments to be exposed to daylight such as coastal and desert dunes (see “► [Luminescence, Coastal Sediments](#)” and “► [Luminescence, Desert Dunes](#)”) and windblown dust either deposited on land to form loess (see “► [Luminescence, Loess](#)”) or in the oceans (see “► [Luminescence, Deep Sea Marine and Lacustrine](#)”). Provided that due care is taken with measurements (as detailed below), the method can also be applied to fluvial sediments (see “► [Luminescence, Fluvial Sediment](#)”), and in recent years the method has been extended to look at glacially derived materials (see “► [Luminescence, Glacial Sediment](#)”), though great care is needed in such applications to assess whether the sedimentary grains were exposed to sufficient daylight at deposition to reset the luminescence signal.

Measurements of the brightness of the luminescence signal can be used to calculate the total amount of radiation that the sample was exposed to during the period of burial. If this is divided by the amount of radiation that the sample receives from its surroundings each year, then this will give the duration of time that the sample has been receiving energy:

$$\text{Age} = \frac{\text{Total energy accumulated during burial}}{\text{Energy delivered each year from radioactive decay}} \quad (1)$$

The S.I. (Système International) unit of absorbed radiation is the Gray, abbreviated to Gy. It is a measure of the amount of energy absorbed by a sample, or its dose, and has the units Joules per kilogram. Luminescence measurements are used to calculate the total absorbed dose as measured in the laboratory. The name given to the quantity is the equivalent dose (D_E). The amount of energy absorbed per year from radiation in the environment surrounding the measured material (known as the dose rate) can either be derived by directly measuring the amount of radioactivity or by chemically analyzing the surrounding material and calculating the concentration of radioisotopes in it; this has the units of Gray per year. Thus, the age equation for luminescence can formally be expressed as

$$\text{Age (years)} = \frac{\text{Equivalent dose (Gy)}}{\text{Dose rate (Gy per year)}} \quad (2)$$

A range of different minerals emit luminescence, but the majority of dating applications have used quartz, feldspars, or mixed phases of SiO_2 in flint. A number of different luminescence signals can be obtained from each of these minerals (or rocks in the case of flint). The result is an increasingly diverse range of luminescence dating methods that are possible. They all share the same basic principles outlined above, but the age range over which they can be applied, and the details of their application vary. To understand the reason for these differences and some of the details of the method, it is necessary to understand more about the physical basis of the luminescence signals that are observed.

Physical Basis

Luminescence occurs as result of energy stored within a crystalline solid being released and being emitted in the form of a photon of light. To understand this process, Fig. 1 shows a schematic representation of the band structure of an insulator or semiconductor and various processes that occur within and among the bands. In such materials the valence band is fully occupied by electrons, while no electrons reside in the conduction band. Further information about the band structure of crystalline insulators and semiconductors is given in see “► [Band Structure](#).” There is a forbidden energy gap between the valence and the conduction band and most electrons are unable to reside in this gap. However, if chemical impurities exist within the crystal or other structural defects are present, then these may give rise to traps within the forbidden gap (marked T_1 and T_2 on Fig. 1a) where electrons can be stored in an excited state.

Ionizing radiation interacting with this theoretical crystal can transfer energy to an electron in the valence band, and this process of ionization will excite the electron into the conduction band (Fig. 1a) and leave a hole in the valence band. The electron is unable to remain in the conduction band and one of two events will follow. Either the electron will immediately de-excite to the valence band, releasing the energy absorbed from the radiation, or the electron in rare cases may lose a small amount of energy and become trapped at T_1 or T_2 within the forbidden gap as shown in Fig. 1a. Similarly, the hole created in the valence band by the eviction of an electron can diffuse through the crystal and may become trapped at another class of defects, called recombination centers. A proportion of these recombination centers are capable of producing luminescence (“L” on Fig. 1a). The net effect is that a proportion of the energy deposited by the radioactivity has become stored within the crystal structure. As further ionization occurs, the number of electrons stored in traps (e.g., T_1 or T_2), and hence the amount of energy stored, will increase. If the trap is stable, then these electrons may be stored for periods of thousands to millions of years (Fig. 1b). The stability of the charge in the trap depends upon the amount of energy required to excite charge out of the trap. This energy (indicated by “E” in Fig. 1b) varies from one trap to another. Generally, the deeper the trap, the more stable it is.

The electrons stored in the defects within the forbidden gap can be released by providing sufficient energy (such as light or heat) to excite them into the conduction band. From there they must relax and may recombine with a hole stored at a luminescence center “L” (Fig. 1c). This recombination may result in the emission of light – this is the luminescence signal that is observed.

Thermoluminescence (TL)

Historically (see “► [Luminescence Dating, History](#)”), the first method used to measure luminescence was by heating the sample at a fixed rate (typically between $1\text{ }^\circ\text{C/s}$ and $5\text{ }^\circ\text{C/s}$) from room temperature up to temperatures varying between $450\text{ }^\circ\text{C}$ and $700\text{ }^\circ\text{C}$, depending upon the mineral.

Fig. 2 A typical thermoluminescence (TL) measurement, known as a glow curve. The intensity of the TL signal is shown as a function of the sample temperature as it is steadily increased from room temperature to 450 °C at a rate of 5 °C/s

The emission is termed thermoluminescence (TL) and a graph showing the luminescence signal emitted as a function of temperature (commonly referred to as a glow curve) consists of a series of peaks (e.g., Fig. 2). Each peak may be due to a single type of trap within the mineral being measured, but more commonly the signal is a composite of several traps. Although it is not always possible uniquely to identify the source of the electrons, it is normally true that the TL signal observed at higher measurement temperatures originates from traps that are deeper below the conduction band: this follows because more energy is required to release electrons from deeper traps than electrons released from traps at lower temperatures, and so this only occurs at higher measurement temperatures. A corollary of this is that electrons in deeper traps are more stable than those in shallower traps. For instance, Fig. 2 shows a TL measurement of quartz. The electrons in the trap giving rise to the TL peak observed at ~110 °C are relatively unstable and at room temperature have a mean lifetime of ~20 h, making them useless for dating. In contrast, measurements suggest that the electrons giving rise to the TL peak observed at ~325 °C are stable over many millions of years. These two peaks could be thought of as being derived from traps T_1 and T_2 , respectively, in Fig. 1. The stability of the deeper trap has been confirmed by dating of sediments up to almost a million years old, and it is this trap that is the focus of most methods used for dating with quartz.

Optically Stimulated Luminescence (OSL)

A second way of stimulating the emission of luminescence is by exposing a sample to light. In ground breaking work, Huntley et al. (1985) shone the beam from an argon-ion laser emitting at 514 nm onto their samples of quartz and feldspar. They then observed the luminescence emitted at a wavelength of ~400 nm. This optically stimulated luminescence (OSL) signal occurs as soon as the sample is illuminated, and the intensity of the OSL signal decreases as electrons are removed from the traps as measurement continues (Fig. 3). Unlike TL, the OSL data typically obtained gives little indication from which traps the electrons have been released. Thus, prior to making an OSL measurement, it is important to thermally pretreat the sample so that a signal is obtained from the group of traps of interest. This is achieved by heating the sample prior to measurement so that the shallow traps, whose electrons are unstable over the burial period (e.g., T_1 in Fig. 1), are emptied, leaving only the electrons in deeper, stable traps (e.g., T_2 in Fig. 1). This thermal treatment is called a preheat.

The light used to stimulate the minerals is restricted to a narrow range of wavelengths, and this light must be prevented from reaching the sensitive light detector (the photomultiplier tube) used to

Fig. 3 A typical quartz optically stimulated luminescence (OSL) decay curve. When the optical stimulation source is first switched on, the OSL signal is large (~18,000 counts per second in this example) but then rapidly decreases as the charge stored in the traps is removed. Note that the vertical axis is on a log scale

measure the luminescence signal (see “► [Luminescence Dating, Instrumentation](#)”). This is because the light given off by the sample, the luminescence that is being measured, is emitted at a different wavelength from the stimulation light. Blue light-emitting diodes (LEDs) are commonly used for stimulation and will generate an OSL signal from both quartz and feldspar. An alternative method of stimulation is to use LEDs that emit beyond the visible part of the spectrum, in the infrared. These are the type of LEDs used for remote controls in televisions, and for luminescence work, those centered at 880 nm have been used extensively in infrared-stimulated luminescence (IRSL) dating of feldspar. OSL signals are produced but are more commonly referred to as infrared-stimulated luminescence (IRSL). IRSL is only observed from feldspars; quartz grains do not give an IRSL signal when the sample is measured at room temperature unless the quartz grains contain feldspar inclusions. The fact that pure quartz does not emit an IRSL signal at room temperature can be exploited to provide a method for assessing the purity of quartz separated for luminescence measurements.

In naturally occurring minerals, a range of different traps occur. In quartz it is thought that aluminum substituting for silicon within the SiO_2 structure is an important source of defects, though many other impurities are also important (e.g., Ge) (see “► [Quartz Defects, Optically Stimulated Luminescence and Thermoluminescence](#)”). The relative concentration of these different types of trap varies from one sample of quartz to another. The result is that the intensity and detailed nature of the luminescence signal from quartz varies for different areas. Similarly, different minerals have different impurities (e.g., manganese in calcite) and thus different luminescence behavior. In feldspars the mechanisms by which luminescence is generated are thought to be more complex than in quartz, with some recombination from traps to luminescence centers not involving the conduction band (see “► [Feldspar Infrared Stimulated Luminescence](#)”).

The physical characteristics of the different traps control whether they are suitable for luminescence dating. Only some of the traps that are known in naturally occurring minerals are sensitive to light, while charge in others can only be evicted by heating the sample. Those traps which are sensitive to light are the ones that are most appropriate for dating sediments. Equally important is whether the charge stored within the traps is stable over the period of time that is being dated. A key consideration here is the depth of the trap below the conduction band. This can be measured as the energy required to excite an electron from the trap to the conduction band (marked as E on Fig. 1b). In general terms the deeper the trap (the greater the value of E), the more stable the trap.

Fig. 4 (a) The additive dose method for determining equivalent dose (D_e). Red data points show luminescence measurements made after different laboratory irradiations. (b) The regenerative dose method for determining equivalent dose. The luminescence signal resulting from irradiation in nature (plotted as a square on the y-axis) is interpolated onto a dose response curve that is generated by making measurements after different laboratory irradiations

Measuring Equivalent Dose

In order to calculate the radiation dose that a sample has been exposed to (the equivalent dose, D_e), it is necessary to calibrate the signal using an artificial radiation source in the laboratory whose dose rate is known. The intensity of the luminescence signal arising from the dose received in nature can then be compared with the intensity of a luminescence signal following exposure to known radiation doses in the laboratory. There are two broad strategies for such measurements, additive dose methods and regeneration methods (Fig. 4).

In the additive dose method (Fig. 4a), the intensity of the luminescence signal arising from the dose absorbed in nature is measured. Additional measurements of the luminescence signal are then made after adding known radiation doses in the laboratory. The change in luminescence intensity with laboratory radiation is then fitted and extrapolated to the intersection with the x-axis to calculate what dose must have been absorbed by the sample prior to measurement of the natural – the D_e .

In the regeneration method (Fig. 4b), after measurement of the luminescence signal arising from exposure to radiation in nature, the sample has its luminescence signal reset (normally by exposure to an artificial light source), and then different laboratory radiation doses are given and the subsequent luminescence signal measured. The growth of the luminescence signal with laboratory dose is fitted, and the intensity of the signal resulting from exposure in nature is interpolated onto that curve in order to calculate D_e .

The value of D_e calculated by extrapolation in the additive dose method (Fig. 4a) can be very sensitive to the choice of which mathematical model is used to fit the dose response curve. Mathematically, the regeneration method is simpler since the natural signal (shown as a square on Fig. 4b) is being interpolated between measured data points, and not extrapolated.

Two broad approaches have been developed for making the luminescence measurements necessary for the additive dose or regenerative dose methods. When luminescence was first developed, a number of different subsamples, or aliquots, of each material would be prepared. Different laboratory doses would be given to each group of aliquots. Thus, multiple aliquots were required to calculate a single equivalent dose (D_e). Both multiple aliquot additive dose (MAAD) and multiple aliquot regenerative dose (MAR) methods have been used in the past. Duller (1991) was the first to propose practical methods where all of the measurements necessary to determine D_e could be made using a single aliquot. Since this innovation a series of important breakthroughs have been made, developing a variety of single-aliquot methods for feldspars (Duller 1995) and for quartz (Murray et al. 1997), and there has been a tendency for the majority of measurements to be made using single-aliquot methods.

Fig. 5 Schematic of the single-aliquot regenerative dose (SAR) measurement protocol and how the different luminescence measurements are combined in order to determine the equivalent dose (D_e). The method was first developed by Murray and Wintle (2000) (Figure adapted from Duller (2008b))

A challenge when using single-aliquot methods is that the luminescence sensitivity, defined as the amount of light emitted per unit of absorbed radiation, may vary when repeated measurements are

Fig. 6 Replicate measurements of equivalent dose (D_e) for two different samples. In each case the same data set is shown both as a histogram and as a radial plot. **(a, b)** Replicate measurements of D_e for an aeolian sample form a single population, and an average value can be used for calculating an age (shown by the vertical dashed line in **(a)** and the grey bar in **(b)**). **(c, d)** Fluvial samples (or other incompletely bleached samples) may exhibit much greater variability in D_e . High values (in this case above about 3 Gy) occur because some grains were not reset at deposition and thus inherited a signal. The value of D_e appropriate for calculating an age from this distribution can be found using statistical models and is shown in **(c)** as a vertical dashed line and by a grey bar in **(d)**

made. This problem became apparent when applying single-aliquot methods to quartz (e.g., Stokes et al. 2000). Early attempts to correct for this change in sensitivity used the response of the 110°TL peak in quartz (Murray and Roberts, 1998), but it became apparent that this signal did not completely mimic the changes in sensitivity of the OSL signal. The single-aliquot regenerative dose (SAR) method proposed by Murray and Wintle (2000) for quartz explicitly measures any change in luminescence sensitivity during repeated measurements by monitoring the OSL response to a test dose and corrects for these changes. Figure 5 summarizes the sequence of measurements that are undertaken. After measurement of the luminescence signal arising from irradiation in nature (L_n) or measurement of the luminescence signal arising from a laboratory dose (L_x) (shown at the top of the panel), the aliquot is exposed to a fixed radiation dose to test the luminescence sensitivity. This test dose is kept constant for any given aliquot, and the subsequent luminescence measurement (T_x) would be constant if there were no change in sensitivity. If sensitivity change does occur, then it can

Fig. 7 *Upper*: Focused laser used to stimulate single grains. *Lower*: Sample holder (10 mm diameter) with a grid of 100 holes (each hole 300 μm in diameter). The focused laser strikes each hole in turn, measuring the OSL from each grain of quartz (Photos: G.A.T. Duller)

be seen as changes in T_x . A simple way to correct for these changes in sensitivity is to plot a dose response curve of the ratio of L_x divided by T_x as a function of laboratory radiation dose (bottom of Fig. 5). The critical development in Murray and Wintle (2000) was developing a protocol which made it possible to make all of these measurements using OSL signals.

Advantages of Single-Aliquot Measurements

The use of single-aliquot measurements makes it feasible to make replicate measurements of the D_e of a sample. It is common practice for 20–50 aliquots to be measured for a single sample. This makes it possible to determine whether the values of D_e for a sample are consistent with one another, or whether they show variability. For samples which were either heated uniformly or which were exposed to sufficient daylight at deposition to completely remove their signal, replicate D_e values will form a single population (Fig. 6a, b), and some measure of central tendency (e.g., the mean or weighted mean) can be calculated as used in the age equation (Eq. 2). More complex patterns are seen in samples where the amount of exposure to daylight at deposition varied from one grain to

another or where mixing of the deposit, for example, by bioturbation, has occurred. This is common for samples where the exposure to daylight is limited, as may be the case for fluvial or glacial samples (Fig. 6c, d). In this situation, where a measurement includes grains that were not bleached at deposition, the value of D_e obtained will be the sum of the dose acquired since deposition, plus an inherited signal whose size may vary from a few Gy to many tens of Gy. The result is a skewed distribution where the D_e value corresponding to deposition of the sediment is the lowest value observed. A range of statistical approaches have been proposed to deal with such situations (Galbraith and Roberts 2012). The most commonly used statistical model is the Minimum Age Model (MAM). Complex patterns may also be seen in replicate measurements of D_e if bioturbation has occurred and mixed sediments of different ages (Rink et al. 2013), in which case standard models to deal with this situation have not yet been developed.

An additional advantage of single-aliquot methods of equivalent dose determination is that the number of grains in each aliquot can be varied (Duller 2008a). Where samples consist of a complex mixture of grains with different D_e values, then it may be advantageous to make measurements on single mineral grains (see “► [Luminescence Dating, Single Grain Dose Distribution](#)”). This is not possible for silt-sized samples ($<90\text{ }\mu\text{m}$), but for sand-sized materials, it is possible either to handpick the grains or to use focused laser systems designed to make luminescence measurements on single grains (Fig. 7). Such single grain measurements have proved essential for dating some complex archaeological sites (Jacobs et al. 2008), glacial sediments (Duller 2006), and applications looking at rates of bioturbation in soils (Heimsath et al. 2002). Single grain measurements of quartz consistently show that only a small proportion of grains emit luminescence of sufficient intensity to be useful. It is common for 90 % of the luminescence signal that is emitted to originate in 5 % of the grains. In extreme cases less than 1 % of the grains may emit a signal of sufficient intensity to be useable. When making measurements of feldspars, a higher proportion of grains emit a luminescence signal, but this approach is still in its infancy.

Measuring Dose Rate

The denominator in the luminescence age equation Eq. (2) is the dose rate; this is a measure of the ionizing radiation energy that a sample has been exposed to each year during burial. This energy derives from two main sources (see “► [Luminescence Dating, Dose Rate](#)” and “► [Radiation Dose Rate](#)”). The first of these are naturally occurring radioisotopes which are found in the sediments making up the samples collected for dating. Alpha, beta, and gamma radiations are produced by a variety of radioisotopes, primarily associated with potassium, uranium, and thorium, and to a lesser degree rubidium. The second source of radiation is cosmic rays. These are high-energy particles that originate from high-energy sources in the universe such as supernovae and which bombard the earth and interact with atmospheric gas molecules to produce earth-surface showers of cosmic rays. Cosmic rays are critical in the formation of radiocarbon (see “► [Radiocarbon Dating](#)”) and form the basis for cosmogenic nuclide dating (see “► [Terrestrial Cosmogenic Nuclide Dating](#)”). In luminescence dating cosmic rays are significant because they are sufficiently energetic to excite charge into the conduction band and thus are part of the total radiation dose rate for a given sample.

Cosmic rays are absorbed as they pass through sediments, and thus, the dose rate due to cosmic rays is greatest near the surface and decreases in a predictable manner as samples are buried. Cosmic rays are weakly absorbed by the atmosphere, so cosmic dose rates are greater for samples at high altitude than those near sea level. There is also a weak latitudinal dependence because of interactions between cosmic rays and the Earth’s magnetic field. The cosmic dose rate can be easily calculated based on measurements of burial depth, altitude, longitude, and latitude, using equations described

by Prescott and Hutton (1994). Typical dose rates due to cosmic rays are 0.2–0.05 Gy/ka depending upon the depth of burial.

In most applications of luminescence dating, the greatest contribution to the total dose rate arises from the decay of radioisotopes in the immediate vicinity of the sample. The main elements of relevance here are potassium, uranium, and thorium. The radioactive isotope of potassium (^{40}K) undergoes a single decay to either ^{40}Ca or ^{40}Ar , emitting beta particles and gamma rays. Uranium (^{238}U and ^{235}U) and thorium (^{232}Th) have more complex decay patterns. Each of these three radionuclides is the parent isotope of a series of radioactive daughter isotopes (see “► [Radiation and Radioactivity](#)”) and they form three decay series. The different radioisotopes making up these decay series emit a combination of alpha, beta, and gamma radiations. These three types of radiation have very different properties. Alpha particles consist of two neutrons and two protons and are only able to penetrate very short distances ($\sim 10\text{--}40\text{ }\mu\text{m}$) in Earth materials. Beta particles are electrons, and these are able to penetrate up to 2 mm. Gamma rays are part of the electromagnetic spectrum and are able to penetrate up to 30 cm in rocks and sediments.

When calculating the dose rate, it is necessary to differentiate between the dose from radionuclides that are found inside the material being used for luminescence dating and the dose from radionuclides found in the sediment surrounding the material separated for dating. The former is known as the internal dose, and the latter the external dose. If luminescence measurements are made on grains of quartz separated from sediment, the internal dose is normally very small in comparison with the external dose, and in many cases it is assumed to be zero. In contrast if the luminescence signal from feldspars is used, these grains may contain up to 14 % by weight of potassium, and this yields a large internal dose which forms a critical part of the total dose rate to the grains.

An additional consideration in calculating the dose rate to a sample is the impact of the water content of a sample. In the case of sediments, there will be interstices between mineral grains, and depending upon the environmental conditions at a specific site, these interstices may either be wholly air-filled, wholly filled with water, or more commonly a mixture of the two. Water between grains absorbs a proportion of the radiation energy emitted by radionuclides and thus alters the dose rate. The impact of water upon alpha, beta, and gamma radiations is well understood and is an integral part of the process of calculating a dose rate. A useful rule of thumb is that a 1 % increase in the water content leads to approximately a 1 % increase in the luminescence age. It is therefore necessary to estimate the average water content of the sample during the period being dated. Estimating the water content of sediments during the entire period of burial can be a challenge, and uncertainty in this value is commonly one of the most important controls on the precision with which it is possible to calculate luminescence ages (see “► [Luminescence Dating, Uncertainties and Age Range](#)”).

There are two primary approaches for measuring the dose rate due to radionuclides: chemical methods and emission counting methods. A variety of chemical methods such as AAS, ICP-MS, and NAA are available. It is normal practice to measure only the concentration of K, U, and Th in samples and to assume that the U and Th decay series are in secular equilibrium (see “► [Radiation and Radioactivity](#)”). Emission counting methods directly measure alpha, beta, or gamma emissions from a sample. Alpha particles and gamma rays are emitted with specific energies which means that spectroscopic methods can be used to identify which radioisotope individual alphas and gammas originate from. Alpha spectroscopy is not commonly used because of the lengthy sample preparation procedure, but high-resolution gamma spectroscopy using high-purity germanium detectors is widely used. Beta particles arising from a specific isotope are emitted at a range of energies and thus spectroscopic methods are not possible. However, it is possible to measure the total beta dose rate and to account for the range of expected ranges of beta emission energy which occur with known

Fig. 8 Using a portable gamma spectrometer to measure the in situ gamma dose rate. The detector is in the upper hole that remains after collecting the sample for luminescence dating, and the results of the measurement are being displayed and stored in the yellow and grey unit at the bottom of the picture

proportion. All of the chemical and emission counting methods described above are applied to subsamples returned to the laboratory for testing. These are from the location of the sample. They will give an accurate assessment of the dose rate provided that they are representative of the materials around the sample. The short range that alpha and beta particles can travel means that material from the sample collected for luminescence measurement will be appropriate. However, gamma rays may travel up to 30 cm in sediment. If the characteristics of the material surrounding the sample vary over this scale, then it is either necessary to take multiple subsamples in the field to characterize these variations or to make measurements of the gamma dose in the field in situ. Field measurements can be made using a portable gamma spectrometer (Fig. 8). These portable systems do not have the energy resolution that is achieved by laboratory-based gamma spectrometry, and so it is not possible to identify emissions from a large number of isotopes. However, it is possible to assess the U, Th, and K concentrations.

A final issue relating to dose rate is whether the dose that is measured today has remained constant during the period being dated. A primary concern here is whether the decay series of U or Th are in secular equilibrium or not (see “► [Radiation and Radioactivity](#)” and “► [Radiation Dose Rate](#)” for discussion of secular equilibrium). Where disequilibrium is detected in the decay series, it may be possible to correct for this if the nature and timing of the disequilibrium can be determined (Olley et al. 1996). Fortunately disequilibrium is not a common problem provided that geochemically active environments are avoided. Typical environments at greater risk of disequilibrium include organic-rich sediments, samples with evidence of cementation since deposition, and environments at the interface between saline and fresh water.

Practicalities

Sampling

Sampling is a critical part of the application of luminescence dating. Samples for sediment dating should be collected in a way that ensures that there is no exposure to daylight. A common approach is to clean a sediment face and then hammer an opaque plastic or metal tube (typically 5–7 cm diameter and 20–30 cm length) into the section (Fig. 9). Once in the laboratory, material at each end of the tube which may have briefly been exposed to daylight can be removed. This material can be used for measurement of the dose rate. Material from the middle of the tube can then be used for luminescence analysis and prepared in the manner described below.

At some sites it is not possible to insert tubes, and in this case an alternative method of sampling is to cover the sampling position with a large ($\sim 2 \times 3$ m) sheet of thick black plastic to exclude daylight and then extract a sample while working under the plastic sheet in dim red light conditions (as used in the laboratory).

Sample selection is critical, and if possible samples should be taken at least 30 cm from a major stratigraphic boundary to ensure that the volume from which the gamma dose originates is homogeneous. Where samples have to be taken nearer than 30 cm from a boundary, then measurements should be made of the distance from the sample to the boundary, and a subsample of the adjacent material should be collected so that the dose rate contribution from that material can be calculated.

Sample Preparation

Many of the luminescence signals used for dating are sensitive to light, and all are sensitive to heat. Care needs to be taken during sample preparation to ensure that light exposure is kept to a minimum

and that samples are not unduly heated. Dim red lights similar to those used in photographic laboratories are used to provide room lighting both for sample preparation and luminescence measurement. Most luminescence signals are less strongly affected by light at the red end of the spectrum than at the blue, and the eye retains sufficient sensitivity at these wavelengths to allow safe working conditions.

Sample preparation aims to isolate material suitable for luminescence measurements (Wintle 1997). The majority of luminescence dating applications use either quartz or feldspar as the target for luminescence measurements. If present, it is necessary to remove any organics and any carbonates using hydrogen peroxide (H_2O_2) and hydrochloric acid (HCl). Both reactions are exothermic, and care is needed to ensure that samples are not heated above about 60 °C. The grain size used for luminescence measurements are commonly either fine grains (4–11 μm diameter) or coarse grains (within the range of 90–250 μm). Fine grains are sufficiently small that alpha particles will penetrate the grains completely, while for coarse grains the external ~ 30 –40 μm of the grain surface can be chemically removed using hydrofluoric acid, and this removes the external alpha dose to the grains. Thus, choosing one of these two grain sizes simplifies calculation of the external alpha dose rate. The use of grains between these two sizes is more complex.

When using coarse grains, different mineral phases can be obtained using density separation. Quartz is extracted by isolating material with a density between 2.62 and 2.70 g.cm^{-3} . Some plagioclase feldspar persists through this process but is removed when grains are etched in concentrated hydrofluoric acid to remove the external alpha dose and then re-sieved. Potassium-rich feldspars can be concentrated by isolating grains with a density between 2.58 and 2.53 g.cm^{-3} .

When using fine grains (4–11 μm), density separation is ineffective. It is still possible to chemically isolate quartz by etching grains in hydrofluorosilicic acid (H_2SiF_6) for extended periods of time (typically 1–2 weeks). This will remove feldspars, but not quartz.

After preparation, samples are mounted on steel or aluminum discs about 10 mm in diameter suitable for measurement in instruments built by a number of manufacturers. Fine grains are deposited from suspension in acetone to form a uniform layer covering the entire surface of the disc. Coarse grains are fixed using silicone oil, and this makes it possible to control the proportion of the disc surface that is covered and hence the number of grains on each disc.

Application of Luminescence to Dating

Heated Materials

As luminescence dating has become more established, the number of applications has increased dramatically. The technique was originally developed to date the period of time since pottery had been fired, and this remains an important application (see “► [Luminescence, Pottery and Bricks](#)”). Barnett (2000) undertook an extensive set of analyses of pottery sherds from 18 sites around the United Kingdom that had been assigned a later prehistoric age on the basis of their typology. A total of 135 samples were measured. Of these, 24 had independent age estimates based in part on radiocarbon dating of associated finds and good agreement was found. A much larger suite of samples was also measured, and here the age of the pottery was poorly constrained. The study demonstrated the value of luminescence dating in providing numerical ages for individual pottery sherds. The results were especially valuable where only small fragments of pottery were found, and thus typological distinctions were difficult. An additional application to heated materials has been to dating when bricks were fired. This has been extensively applied to medieval buildings across northwestern Europe and is now being applied further afield. Bailiff et al. (2013) applied OSL to date

Fig. 10 Linear dune in the northern Namib Sand Sea. A series of nine boreholes were drilled along a 500 m transect across the dune to collect samples for OSL dating. Vehicles provide the scale (Photo: G.A.T. Duller)

bricks from domed stupas in Sri Lanka, providing some of the first numerical ages for these important archaeological features.

Pottery and bricks are deliberately fired during their manufacture, but other materials may be inadvertently heated and thus dated using luminescence. This is especially useful at Paleolithic sites where fires were lit. Stone tools, especially those manufactured from flint, cannot normally be dated using luminescence methods, but at some sites a small proportion of tools may have been inadvertently heated and this resets the luminescence signal, making it possible to date the occupation (see “► [Luminescence, Flints and Stones](#)”). This method is proving valuable across a range of sites and has yielded very early ages for Middle Paleolithic tanged tools at the site of Ifri n’Ammar in Morocco, ranging from 83 ± 6 ka to 171 ± 12 ka (Richter et al. 2010). Stones which were not tools but were heated by fires may also be dated using luminescence. These too have provided valuable chronological information, for example, at the site of Blombos in South Africa (Tribolo et al. 2006). Here, luminescence dating of sediments and burnt lithics have provided a chronology extending back to 140 ka for a wide range of Middle Stone Age artifacts including engraved ochres, bone tools, and *Nassarius kraussianus* shell beads that are thought to have been used for personal ornamentation.

Unheated Sediments

In the last three decades, the greatest focus for the application of luminescence dating has been to unheated sediments, where the event being dated is the last exposure to daylight. The method is ideally suited to dating the formation of both coastal and desert dunes because there is normally ample opportunity for the mineral grains to be exposed to daylight prior to deposition. Bristow et al. (2007) collected samples from a transect of boreholes across a linear dune in the northern part of the Namib Sand Sea in order to understand the processes involved in forming the feature and the rates of these processes (Fig. 10). A ground penetrating radar survey was undertaken along the same transect prior to OSL sampling and provided stratigraphic evidence of the pattern of sediment accumulation. This stratigraphic evidence was used to choose the locations of the boreholes and the depths at which samples were collected for OSL dating. The OSL ages demonstrated that this very

Fig. 11 Dungeness foreland, United Kingdom. The rate of growth of this coastal foreland was determined by applying OSL dating to quartz extracted from sands underlying the gravel ridges that form the surface expression of this feature (Figure adapted from Roberts and Plater 2007)

large dune (~500 m wide and over 60 m high) had been completely reworked within the last 5,700 years and that the flank of the dune had moved 300 m laterally during the last 2,500 years.

Luminescence provides insights into very recent geomorphological events and provides a chronological method that can span both the historic record and the more distant past. Roberts and Plater (2007) used quartz OSL measurements on sands underlying the gravel ridges of Dungeness, a coastal foreland in southern Britain, to provide a rate for the growth of this feature (Fig. 11). Ages for these underlying sands ranged from 430 ± 20 to $5,120 \pm 220$ years, and the younger ages were consistent with documentary historical evidence for growth of Dungeness during the Middle Ages. A number of other impressive data sets utilizing luminescence to provide rates for geomorphological

processes have been produced, including Madsen et al. (2010), who calculated 78 OSL ages for quartz extracted from samples collected from the island of Rømø in the Wadden Sea, Denmark, with beach ridges ranging from 220 ± 20 years ago to over 8,000 years ago. The ability of luminescence dating in these environments to date very recent deposition makes the method ideal for this type of study (see also “► [Luminescence, Geomorphological Processes](#)”).

Limits in the Age Range Dated Using Luminescence

The youngest age that can be obtained using luminescence dating is difficult to define (see “► [Luminescence Dating, Uncertainties and Age Range](#)”). The two major limitations are the extent to which the signal was reset by exposure to daylight at deposition, and the sensitivity of the equipment used to measure the luminescence signal (Madsen and Murray 2009). Ballarini et al. (2003) measured quartz OSL ages for a series of coastal dunes on the island of Texel on the coast of the Netherlands. Maps of this area stretching back 260 years provided excellent independent age control, and the OSL ages were accurate across this entire time period, with one of the youngest samples giving a date of $AD\ 1996 \pm 2$ when it was known to have been deposited between 1996 and 2002 AD. For aeolian and beach sediments where there is extended exposure of grains to sunlight prior to deposition, it is normally possible to obtain accurate ages for samples deposited as recently as the last couple of decades. In fluvial environments it may also be possible to achieve such young ages (e.g., Rustomji and Pietsch 2007), though because of the potential for some grains not to have been exposed to sufficient daylight to completely reset their signal, more complex statistical analysis is normally required (e.g., application of the minimum age model). In environments where the exposure to sunlight is more uncertain (e.g., glacial sediments) or where the luminescence sensitivity of the material is low, the limit for dating may be several hundred to a thousand years.

The upper limit to the age that can be dated using luminescence is also difficult to define. The major controls on this limit are the saturation of the luminescence signal, and the stability of the signal. As quartz or feldspar is exposed to ionizing radiation, the amount of charge trapped within defects increases (Fig. 4). At low doses this increase in trapped charge, and hence in the brightness of the luminescence signal measured in the laboratory, is approximately linear. As exposure to radiation continues, traps within the crystalline material fill, and it becomes increasingly unlikely that charge will be trapped. The result is that the rate of growth of the luminescence signal with radiation dose decreases, until at some point no further increase in luminescence is seen; at this point the luminescence is said to be saturated. Growth of the luminescence signal can be described by Eq. (3) where L_D is the intensity of the luminescence signal at a dose D , L_{Max} is the maximum intensity of the luminescence signal, and D_0 describes the rate at which the luminescence signal approaches saturation:

$$L_D = L_{Max} \left(1 - e^{-\frac{D}{D_0}} \right) \quad (3)$$

As a sample approaches saturation, the uncertainties in the D_e increase, and if the measured natural luminescence signal is within 15 % of the maximum luminescence signal (L_{Max}), then it is normally considered to be beyond the range of luminescence dating methods. This same threshold can also be defined as two times the value of D_0 . The value of D_0 varies from one sample to another, and from one luminescence signal to another. For the OSL signal from quartz, typical values of D_0 are 50–100 Gy, meaning that the maximum value of equivalent dose that can be measured ranges from 100 to 200 Gy. The age range that can be dated in this situation depends upon the dose rate. For

sites where the dose rate is low (e.g., 0.5 Gy/ka), it may be possible to date up to 400 ka, whereas in areas where the dose rate is high (e.g., 4 Gy/ka), then it may only be possible to date as far as 50 ka.

The IRSL signal from feldspar typically has a higher D_0 value than the OSL signal from quartz and so may be able to date older samples. However, potassium-rich feldspars have a significant internal dose from the potassium within the grains, meaning that their total dose rate is higher than that for quartz, so reducing the advantage that they would otherwise have. A great deal of research has been undertaken looking for other luminescence signals, both from quartz and feldspar and from other minerals (e.g., calcite, see “► [Luminescence, Biogenic Carbonates](#)”) that may be able to extend the age range over which luminescence methods can be applied. It still remains to be seen whether these new signals such as Thermally Transferred OSL (TT-OSL) and Violet Stimulated Luminescence (VSL) from quartz, or the TL signal from calcite, will have suitable characteristics for dating.

Novel Applications

Luminescence geochronology has seen rapid development in the last few decades and this rate of progress is continuing. Two exciting new applications of luminescence that have been proposed in recent years are (i) its use in thermochronology and (ii) its use for dating the duration that rock surfaces have been exposed at the Earth’s surface.

Thermochronology (see “► [Thermochronology, Landform Evolution](#)”) attempts to understand the thermal history of a rock and primarily the rate at which it has cooled. Most commonly this is of interest in understanding the rate at which rocks have risen in the Earth’s crust. Luminescence signals can be reset by holding them at high temperatures. Rocks held at high temperatures will not retain charge in defects and thus will not yield any luminescence signal. However, as a rock approaches the Earth’s surface and cools, it will become able to store charge. Thus, rocks that have been rapidly uplifted will yield an apparent luminescence age, and this can be used to yield thermochronological information. Initial work (Herman et al. 2010) used the OSL signal from quartz, and this has an effective closure temperature of 30 °C, far lower than other thermochronometers, thus making new areas of study possible. More recent work has provided a sound theoretical framework for this exciting area (Guralnik et al. 2013), and it seems very likely that this will be a major growth area in the application of luminescence in geochronology.

A second area that has seen recent rapid advances has been the use of luminescence to date rock surfaces (see “► [Luminescence, Rock Surfaces](#)”). Here luminescence is being used to date how long a particular rock surface has been exposed to daylight. Some luminescence signals are reset by exposure to daylight. Commonly these signals are reset rapidly, within periods of seconds to minutes. As daylight penetrates through rock, it is very rapidly attenuated, meaning that while a particular luminescence signal (e.g., the OSL signal from quartz) may be reduced to 0.1 % of its initial signal within a few minutes when exposed to daylight at the Earth’s surface, the OSL signal in samples found a few millimeters inside a rock may take days, years, or millennia to be reset. By drilling a core through the upper few centimeters of a rock and making measurements of the luminescence signal remaining at different depths in the rock, it is possible to build up a picture of how the signal has been reset, and this can be used to determine the duration of time that the rock surface has been exposed (Sohbati et al. 2012).

Further Reading

A simple overview of luminescence dating is provided by Duller (2008b) which is freely available at <http://www.english-heritage.org.uk/publications/luminescence-dating/>. Wintle (2008) gives an excellent overview of the development of luminescence dating in the last half of the twentieth century. Rhodes (2011) provides an excellent overview of the application to dating sediments, while Richter (2007) describes applications to dating burnt flints. Jacobs and Roberts (2007) describe the application of single grain OSL measurements in archaeology. Wintle and Murray (2006) give an excellent review of the application of the single-aliquot regenerative dose (SAR) method applied to quartz.

Luminescence, Biogenic Carbonates

Geoffrey A. T. Duller*

Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, Wales, UK

Definition

Biogenic carbonates. Carbonates, especially calcite and aragonite, precipitated as a result of biological processes.

Luminescence dating. The use of the luminescence signal emitted from a mineral to date its formation or some other event.

Introduction

The emission of luminescence from quartz and feldspar has been widely exploited as the basis for dating sediments, pottery, and burnt stones (see “► [Luminescence Dating](#)”). Calcite (CaCO_3) and its polymorph aragonite yield thermoluminescence (TL) signals which grow with exposure to ionizing radiation in the same way as seen for quartz and feldspar. A number of studies have been undertaken to explore whether geochronological information can be obtained from this TL signal from calcite, and these have focused on trying to date the formation of the mineral. Initial efforts in the 1970s and 1980s (Wintle [1978](#); Debenham and Aitken [1984](#)) studied stalagmitic calcite, but more recently a small number of researchers have looked at the potential of biogenic carbonates, produced by bivalves and molluscs. The TL signal from calcite does not bleach rapidly in light, and dating applications have dated the crystallization event rather than the last exposure to daylight. Nonetheless, it is prudent to minimize light exposure during sampling, preparation, and measurement.

Marine Shells

Shells of the Pectinidae family were shown to give TL signals. Ninagawa et al. ([1992](#)) used this TL signal to determine ages of samples with some independent age control and found that they were able to get ages that were near those expected at several hundred thousand years old but that shells expected to be older than a million years gave underestimates. A major challenge with such work was the presence of organic components within the shell which were intimately intermixed with the calcite structure. To avoid combustion of the organic components within the shells, samples were only heated to a maximum of 240 °C, but even when using a low heating rate (1.7 °C/s), this meant that the measured TL signal may not have had sufficient thermal stability over the long geological periods being studied. Studying a wide range of shellfish, Carmichael et al. ([1994](#)) found that the mineralized component varied from 40 % to 80 % by mass, with the remainder being organic.

Fig. 1 Operculum of *Bithynia tentaculata*. The operculum is 4 mm across. The *upper image* is taken using a normal microscope, while the *lower image* shows the TL emitted during measurement following a laboratory irradiation. In this *lower image*, *blue* represents low intensity TL emission, while *green*, *yellow*, and *red* indicate increasing intensity (Photos: G.A.T. Duller)

Terrestrial Molluscs

Two other types of biogenic carbonates have received attention in recent years: slug plates and snail opercula (Duller et al. 2009; Stirling et al. 2012). Slugs of the Limacidae family secrete a small plate of calcite, about 2–3 mm in diameter and 0.2 mm thick, enclosed by their mantle. Snails commonly use an operculum to protect themselves and prevent excessive loss of moisture. In many species this operculum is highly organic, but it is highly mineralized in the species *Bithynia tentaculata* (Fig. 1). These two target materials have been shown to yield intense TL signals that grow with radiation to doses over 6,000 Gy. The methods are still experimental but potentially could be used to date the whole of the Quaternary period (2.58 Ma).

Conclusions

Biogenic carbonates, especially calcite, have very great potential for providing geochronological information over the entire Quaternary period. In comparison with other materials used for luminescence dating, they have the advantage that the event being dated is crystallization, and thus, there are no uncertainties about whether the signal was reset at the time of deposition as may occur when

dating sediments or analyzing heated materials. A number of challenges remain to be resolved before the full potential of biogenic carbonates can be realized, including improving the accuracy with which the dose rate can be determined and most critically comparing the results of these new methods with robust independent chronometers.

Definition

Luminescence dating. A family of chronologic methods typically applied to the commonly occurring minerals quartz and feldspar, which exploits a time-dependent signal that builds up in mineral grains by exposure to naturally occurring ionizing radiation (principally from uranium, thorium, and potassium). The methods assess the time elapsed since these mineral grains were last exposed to sunlight or to heating. In the case of sediments, the event being dated is the last exposure to sunlight, i.e., typically the time of deposition of the sediment.

Loess. A fine-grained terrestrial sedimentary deposit derived from wind-blown dust.

Introduction

Loess deposits preserve one of the most detailed and lengthy terrestrial records of Quaternary climate change on Earth; the key to unlocking these records is the development of a chronology. Early chronologies for loess-paleosol sequences were based largely on correlative techniques, comparing variations in paleoenvironmental proxy data, such as particle size, loess/paleosol thicknesses, and magnetic susceptibility records, and where available using other tie points such as paleomagnetic signatures and tephra layers to link various records. A common assumption in such correlative techniques is a continuous and near-constant sediment accumulation rate over time, with no major hiatus. However, recent high-resolution luminescence dating studies (e.g., Antoine et al. 2001; Frechen et al. 2001; Roberts et al. 2001, 2003; Lai and Wintle 2006) demonstrate that sediment accumulation rates can vary considerably both spatially and temporally and that hiatus can occur (e.g., Lu et al. 2006; Stevens et al. 2006; Thiel et al. 2011a) showing that this assumption is not always valid. This has implications for comparisons of terrestrial, ice-core, and marine oxygen isotope records (e.g., Zhou and Shackleton 1999) and emphasizes the importance of establishing independent numerical chronologies where possible. Luminescence dating has played an increasing role in providing such chronologies for loess sequences, from the earliest applications of the technique to terrestrial sediments through to the most recent proposals for new and/or novel luminescence dating methods and signals.

Much of the early work to derive numerical ages from the upper portions of loess sequences used radiocarbon dating, often applied to paleosol units weathered into the loess. In contrast,

*Email: hmr@aber.ac.uk

luminescence dating offers the opportunity to date the deposition event directly because it records the last exposure to sunlight of the grains of quartz or feldspar that make up the sedimentary deposit. The family of luminescence dating techniques also extends beyond the limits of radiocarbon dating in most sedimentary environments and does not rely on the discovery of appropriate *in situ* material (e.g., organic matter or snail shells in the case of dating using radiocarbon or amino acid racemization) which may pre- or postdate the deposition event and/or which may be rare in wind-blown sediments. These reasons, coupled with improvements in the accuracy and precision of luminescence dating over the last 15 years, mean that increasingly, luminescence dating is becoming the technique of choice for determining a numerical chronology for eolian deposits including loess.

An excellent general review of luminescence dating is given by Rhodes (2011) and see also the volume “► [Luminescence Dating](#).” Specific reviews of the application of luminescence dating to loess are given by Wintle (1990) and Zöller and Wagner (1990) for thermoluminescence (TL), while Singhvi et al. (2001) consider the dating of loess using both TL and optically stimulated luminescence (OSL), and Roberts (2008) charts the developments of luminescence dating as applied to loess from the earliest days to the most recent developments (including OSL) at the time of publication. There have, however, been some significant advances since the publication of this last review, several of which are mentioned within this encyclopedia entry.

Historical Overview of Luminescence Dating of Loess

Loess was the first terrestrial clastic sediment to which luminescence dating was systematically applied, and loess deposits have remained important both for the development and the application of luminescence dating techniques since the earliest pioneering work was conducted (Wintle 1981, 1982; Wintle and Brunnacker 1982). The fine-grained nature of loess tends to imply long-transport distances prior to deposition, ideal for the effective zeroing of the luminescence signal, which is a fundamental assumption and requirement of luminescence dating. The dominance of silt-sized particles in loess means that it is the 4–11 μm diameter “fine-grain” fraction, which is typically prepared for dating. Most of the published luminescence dating studies of loess, particularly the earlier studies, are based on the “polyminerale fine-grain fraction,” which is thus termed because it is a mixture of both quartz and feldspar minerals of 4–11 μm diameter. More recently, with the establishment of methods to monitor and correct for sensitivity changes during the measurement procedure, and given the faster optical bleaching of the quartz OSL signal (Godfrey-Smith et al. 1988) compared to other luminescence signals, some workers have used extended fluorosilicic acid treatments of several days’ duration to isolate pure quartz of 4–11 μm grain size or to isolate quartz of coarse silt size (35–50 μm) from loess which is more representative of the grain size distribution. Occasionally, relatively coarse grains (>63 μm) from loess deposits, usually of quartz, have been examined using luminescence techniques; coarse grains cannot be transported over long distances, and such deposits are typically associated with the transition between deposits of sand (source-proximal deposits) and loess (more distal deposits). Use of the 4–11 μm fine-grain fraction or the hydrofluoric acid-etched >63 μm coarse-grained fraction circumvents the need for complex dosimetry assessments of the alpha and beta dose to the sample that are otherwise required when working with intermediate grain sizes (i.e., 11–63 μm).

The earliest luminescence works published on loess were conducted using thermoluminescence (TL) of polyminerale fine grains. Here, the TL is dominated by the signal from feldspars, although the quartz grains present do also contribute to the TL signal; the relative contributions of these two mineral groups are likely to vary between samples due to changes in mineralogy, and it is not always

clear in TL measurements which mineral is being analyzed. Another concern identified in TL dating is the long daylight exposure times (several hours) required to reset the TL signal to a low level at deposition and the fact that an unbleachable residual TL signal remains after this time. This is of particular significance for young material, e.g., of Holocene age, as it could lead to age overestimation; Berger (1987) showed that modern silt could yield an apparent TL age of ~1 ka, and TL ages determined in a study of Japanese loess by Watanuki and Tsukamoto (2001) overestimated the tephra-derived age of the early Holocene and last glacial sediments by more than 10 and 5 ka, respectively.

Thermoluminescence remained the only signal used for luminescence dating of sediments until the development of optically stimulated luminescence signals for dating. Initially, costly Ar-ion lasers (514 nm) were used to stimulate an optical signal from quartz and feldspar (Huntley et al. 1985), and then shortly afterward much less expensive light sources were used to give an infrared stimulated luminescence (IRSL) signal (880 nm) from feldspar (Hütt et al. 1988). Later still, halogen lamp systems and then green and then blue light-emitting diodes (LEDs) were used for optical stimulation and made the study of OSL signals from quartz more practical on financial grounds than the argon-ion laser that was initially used. Use of an OSL signal for dating sediments has the advantage over TL signals since OSL signals are bleached more rapidly and typically to a lower residual level than the TL signal. For these various reasons, the IRSL signal grew in popularity through the 1990s for dating loess, typically applied to polymineral fine grains. During this time, it was not uncommon to see studies generating and comparing both TL and IRSL ages from loess and also comparing the ages generated for these signals using different methods of measurement (e.g., regenerative dose and additive dose, multiple aliquot methods) too. At this time, there was no clear consensus on the luminescence signal or measurement method which gave rise to the most accurate and precise luminescence ages for loess or for other sediments.

One problem which potentially affected both TL and IRSL signals from feldspars is the phenomenon of “anomalous fading” (Wintle 1973), whereby the loss of unstable charge over time leads to underestimation of the true age of deposition if it is not (or cannot be) corrected. Some authors suggest that anomalous fading of luminescence signals from feldspar is a ubiquitous phenomenon (e.g., Huntley and Lamothe 2001; Little et al. 2002), while others find no significant evidence for anomalous fading in their studies (e.g., Frechen and Dodonov 1998; Frechen et al. 2001), and some other authors using feldspars do not consider it at all in their studies. There is no consensus on the most appropriate method for assessing anomalous fading nor for correcting it if it is detected.

Dating using quartz avoids the problems and uncertainties associated with feldspars because the OSL signal from quartz does not suffer from anomalous fading. However, only since the introduction of the single-aliquot regenerative-dose (SAR) measurement procedure of Murray and Wintle (2000) for dating quartz has the quartz component of loess been systematically examined. The SAR procedure brought about a step change in the accuracy and precision of luminescence dating of quartz and successfully addressed the key impediment to the earlier use of quartz for dating loess, namely, monitoring and correcting for sensitivity change which occurs either during the measurement procedure as a result of thermal pretreatments or during burial of the sample. Since this advance, there have been numerous successful applications of luminescence dating using SAR methods applied to quartz from loess, but the upper age limit of this OSL signal is relatively restricted in loess compared to other sedimentary deposits due to the high dose rate of these fine-grained deposits. An upper limit for quartz OSL ages from loess of ~50–70 ka has been reported by several authors (e.g., Zhou and Shackleton 2001; Buylaert et al. 2007, 2008; Lai 2010), although older ages have been reported by others. Feldspars therefore remained potentially attractive for luminescence dating because they saturate at higher values of equivalent dose (D_e) than quartz and

hence potentially extend the upper age limit of dating; however, feldspar methods were still troubled by the specter of anomalous fading.

A major breakthrough came in 2008 when Thomsen et al. reported that the IRSL signal observed at temperature of 225 °C following a prior IR stimulation at 50 °C was much more stable than the conventional IRSL signal that had been previously commonly used, measured at 50 °C. Use of this and other elevated temperature “post-IR IRSL” signals from feldspars potentially offered a means of minimizing or even overcoming the phenomenon of anomalous fading and quickly gave rise to methods which were applied to and tested on loess deposits (e.g., Thiel et al. 2011b; Li and Li 2011; Roberts 2012), extending the upper age limit far beyond that of quartz OSL to ~200–300 ka in loess (e.g., Buylaert et al. 2012; Li and Li 2012). Work to test and validate these post-IR IRSL signals continues, but the various methods proposed show great promise (e.g., see review by Buylaert et al. 2012), and the work of Thomsen et al. (2008) potentially marks the beginning of a revolution in feldspar dating similar to that which occurred in quartz dating following the proposal of the SAR measurement protocol by Murray and Wintle (2000).

Applications of Luminescence Dating of Loess

Loess deposits have played an important role in the reconstruction of long-term climatic and paleoenvironmental change and in correlations between the terrestrial and marine record. These correlations have often been done in the past by wiggle-matching of proxy records, but increasingly where possible, these records are being linked using independently derived absolute or numerical age control in order to explore whether such records are synchronous between sites and to facilitate the potential investigation of leads and lags within paleoclimate and paleoenvironmental systems. Although the uncertainty associated with an individual luminescence age can be relatively large (typically ~5–10 %), where numerous ages are available, these uncertainties can be reduced using Bayesian age-depth models which exploit the information regarding the relative sequence of ages down-section (e.g., Muhs et al. 2013). The ability of luminescence techniques to generate numerical ages relating directly to the deposition event, and the fact that the methods are applied directly to mineral grains which can be found continuously throughout the loess-paleosol sequence, means that there have been very many applications of luminescence dating of loess relating to paleoenvironmental or paleoclimatic reconstruction. For example, paleoprecipitation (e.g., Rao et al. 2013) and paleotemperature (e.g., Jia et al. 2013) records have been reconstructed on a numerical timescale, and changing pressure gradients have been inferred (e.g., Muhs et al. 2013), as have wind-strength fluctuations, and wind directions, and changes in the monsoon intensity (e.g., Maher and Hu 2006; Stevens et al. 2008). The influence of soil-forming durations on the development of mineral magnetic signatures has also been investigated, using luminescence ages to constrain maximum soil-forming durations by dating the loess units that bracket various paleosols (e.g., Maher et al. 2003).

One of the applications which has grown in importance in recent years is the use of luminescence dating applied to loess sequences to assess the magnitude and changes in dust mass accumulation rates (MARs) over time, measured in $\text{g/m}^2/\text{a}$. Through this work, the traditional view of a constant and linear sediment accumulation rate over time, with no major hiatus occurring in the sedimentary record, has been challenged. Loess deposits were also traditionally viewed as a passive record of past climate change, but increasingly the wind-blown dust that the loess deposits are comprised of is being viewed as a potential *agent* of climate change capable of regional modification of climate and is now being incorporated into some climate models (e.g., Mahowald et al. 2006). Luminescence dating has helped to provide some of the first empirical evidence for this potential for regional modification of climate by dust (e.g., Roberts et al. 2003), and critically luminescence-derived

chronologies underpin several of the high-resolution terrestrial MAR determinations which are providing key inputs to the dust component of climate models (e.g., Albani et al. (2014)).

Current Challenges in Luminescence Dating of Loess

The two key challenges posed in the application of luminescence dating to loess both concern the upper limit of dating using luminescence signals. The first key challenge is recognizing and defining the reliable upper age limit for each of the signals within the family of luminescence dating techniques. For example, OSL signals have been observed to grow in the laboratory far beyond what has been described as a prudent upper limit for dating (i.e., beyond 85 % of the maximum achievable luminescence signal when fitted with a single-saturating exponential function). The reliability of OSL ages beyond this range, particularly when obtained using an additional linear component or a second saturating exponential function, is not clearly established, and the origin of this additional component or second saturating exponential function is not understood. Recent work by Chapot et al. (2012) proposed the comparison of laboratory-generated dose-response curves and a “natural dose-response curve” generated using loess samples of known age taken from the Luochuan section of the Chinese Loess Plateau. This work represents the first clear demonstration that OSL ages can increasingly underestimate the true age of the deposits long before the luminescence signal is saturated, and finds the upper limit of reliable dating at this site to be consistent with (although derived in a totally different way to) the upper limits described by others and discussed earlier in this entry. This novel approach of comparing the response in the laboratory and in nature can also potentially be used to investigate the upper limit of dating using other luminescence signals and measurement protocols and is only made possible due to the long record and stratigraphic framework offered by the loess-paleosol sequence studied.

The second key challenge is to seek new methods and signals which might potentially extend the upper limit(s) of luminescence dating, particularly given the long temporal records preserved in many loess deposits. The situation is exaggerated for loess sediments in particular because the environmental dose rate (Gy/ka) is high compared to many other sedimentary deposits, due in part to its fine-grained size and hence large surface area-to-volume ratio. This high dose rate (commonly ~3.5–5 Gy/ka, i.e., ~2–3 times greater than dose rates typically observed in other deposits) means that the minerals within loess deposits are not capable of extending as far back in time (ka) as they can in other sediments even though the total amount of trapped charge (Gy) can be the same. Several methods of extending the age range of luminescence dating have been proposed and are still being explored, including thermally transferred optically stimulated luminescence (TT-OSL; Wang et al. 2006), which was first developed and applied to loess, and use of the violet stimulated luminescence (VSL) signal which may potentially extend the dating range of quartz to span the entire Quaternary period (Ankjærgaard et al. 2013). However, while these new methods are potentially very exciting, they are in the early stages of development, and much remains to be done to demonstrate their ability to generate reliable numerical ages.

Summary and Conclusions

Loess deposits have played, and continue to play, a critical role in the development of luminescence dating techniques. In turn, chronologies derived using luminescence dating techniques are playing an increasingly significant role in deciphering the long and quasi-continuous record of paleoenvironmental and paleoclimatic change preserved within these temporally and areally extensive deposits of wind-blown dust.

Marine Isotope Stratigraphy

Galen P. Halverson*

Department of Earth and Planetary Sciences/Geotop, McGill University, Montréal, QC, Canada

Definition

Marine isotope stratigraphy is the application of proxies of seawater isotopic composition, as preserved in marine sediments and sedimentary rocks, for correlation and dating purposes.

Introduction

Chemical stratigraphy, or chemostratigraphy, is the application of chemical signatures preserved in sediments and sedimentary rocks for the purpose of correlation, dating, or interpreting past environments and environmental change (Weissert et al. 2008; Halverson et al. 2010). Marine isotope stratigraphy is the most important subdivision of chemostratigraphy and encapsulates diverse stable and radiogenic isotope systems that have been applied to studies of marine strata spanning from Archean to Recent in age. The list of isotope systems that have been investigated is large and growing, spurred in part by significant recent developments in gas source (IRMS) and multi-collector inductively coupled plasma (MC-ICP-MS) mass spectrometry (see also entry on ► [Mass Spectrometry](#)). However, the focus here is on a small subset of established isotope proxies that are widely utilized and particularly useful for chronostratigraphic purposes. Specifically, the light stable isotope systems of oxygen ($\delta^{18}\text{O}$), carbon ($\delta^{13}\text{C}$), and sulfur ($\delta^{34}\text{S}$) and the radiogenic isotope systems of neodymium ($^{143}\text{Nd}/^{144}\text{Nd}$), strontium ($^{87}\text{Sr}/^{86}\text{Sr}$), and osmium ($^{187}\text{Os}/^{188}\text{Os}$) are briefly reviewed.

Underlying Principles

An overarching principle in the application of marine isotope stratigraphy is that targeted materials for analysis, such as shells or organic matter in marine sediments, can be regarded as reliable proxies of the isotopic composition of the seawater in which they formed. Where these data are to be applied for correlation or dating, it is paramount that the residence time of the isotope system in seawater is sufficiently large relative to the mixing time of the oceans ($\sim 10^3$ years) that the isotope proxy retains a global seawater signature. If these conditions are met and the isotope systems have not been significantly disturbed by subsequent diagenesis or other alteration, then fluctuations, or in some cases absolute values, in the isotope ratios can be used to correlate strata deposited in different parts of the global ocean or assign an approximate age based on comparison with a reference marine isotope curve (see also entry on ► [Seawater Sr Curve](#)). Because seawater compositions of most commonly applied isotope ratios have varied secularly over Earth history,

Fig. 1 Schematic illustration of the difference between steady-state and non-steady-state changes in marine isotope ratios. A steady-state shift (*blue line*) results from a change in the isotope ratio of the input to or output from the ocean of a given system. For example, a shift in $^{87}\text{Sr}/^{86}\text{Sr}$ could result from the extrusion of a large continental flood basalt (*time A*) and resulting decrease in average weathering input. The timescale over which the shift occurs is proportional to the residence time of that element in the ocean. A non-steady-state perturbation (*red line*) results in an *excursion*, commonly driven by a relatively rapid input of the element of interest to the ocean reservoir (at *time A*), such as a catastrophic release of low $\delta^{13}\text{C}$ methane from seafloor clathrate reservoirs. The magnitude of the excursion is a measure of the relative size of the non-steady-state addition (or subtraction) of the element to seawater, and the timescale over which the system recovers is governed by the residence time.

a simple isotope ratio or profile is typically insufficient to assign an age, and other chronostratigraphic tools, such as biostratigraphy, magnetostratigraphy, or absolute ages on bounding strata, must be used first to narrow down the possible age range of a given sample or stratigraphic section. The most useful proxies and time intervals in which they are applied are those that show rapid changes in seawater composition (McArthur et al. 2012). Fortuitously, isotopic shifts and excursions (Fig. 1) are common across major geological events, such as mass extinctions, glaciations, and episodes of abrupt warming.

Stable Isotopes

Temporal fluctuations in stable isotope compositions of seawater result from the tendency of isotopes to fractionate at low temperatures due to their relative mass differences. These mass discrepancies give rise to subtle but important differences in the strength of chemical bonds formed in molecules by the different isotopes of a given element. The result is the preferential diffusion, reaction, or biological uptake of one isotope over another, resulting in fractionation of isotope ratios between different molecules or phases. This fractionation generates geological or oceanic reservoirs with contrasting isotopic ratios. For example, the exit channels of carbon from the seawater dissolved inorganic carbon (DIC) pool can be subdivided into inorganic (i.e., carbonate; relatively ^{13}C enriched) and organic sedimentary carbon (^{13}C -depleted) sinks. The relative importance of these sinks controls the $^{13}\text{C}/^{12}\text{C}$ ratio of the DIC pool at steady state.

Many biogeochemical and geological processes can drive the secular variation in isotope ratios in seawater, but those changes that occur at timescales useful in stratigraphy are commonly the result of changing paleoenvironments. Where these changes occur at steady state (i.e., the mass of the seawater reservoir of the element of interest does not change in time), the resulting isotopic change is gradual. However, the most useful isotopic fluctuations are commonly in the form of relatively brief *excursions* (Fig. 1) that result from sudden or catastrophic events, such as glaciation (see section on oxygen isotopes below), flood basalt volcanism, and mass extinctions. Such events

often give rise to precipitous (non-steady state) changes in multiple isotope proxies simultaneously (e.g., fluctuations in carbon and oxygen isotope ratios are commonly correlated or anticorrelated). Importantly, the timescale of these changes may differ due to variable oceanic residence times and the proximal driving mechanism for the perturbation.

Radiogenic Isotopes

Variations in the ratios of radiogenic isotopes in seawater are fundamentally the result of the fractionation of two elements that include the parent and daughter isotopes of a given radiogenic system (e.g., Rb and Sr, where ^{87}Rb decays to ^{87}Sr) between geological reservoirs, rather than isotopic fractionation. Coupled with progressive decay of the radiogenic isotope, this elemental fractionation produces reservoirs, such as the mantle and the continental crust, with distinct radiogenic isotope fingerprints. Progressive decay of the radiogenic isotope results in a first-order, long-term rise in the radiogenic isotope ratio over Earth history. Changes in the relative weight of the flux to the ocean of one of these elements from the different reservoirs result in a steady-state *shift* in the isotope ratio in seawater, over a timescale determined by the residence time of that element in seawater (Fig. 1), and the time span over which the change in flux occurs. In some cases, sharp excursions may occur.

Development and Application of the Method

The origin of marine isotope stratigraphy can be traced to the pioneering work of Harold Urey and his research group at the University of Chicago in the 1950s who analyzed carbon and oxygen isotope ratios in modern and ancient carbonate shells and other biogenic materials. The initial motivation of Urey's group was in reconstructing paleoenvironments, namely, past seawater temperatures (Epstein et al. 1951; Urey et al. 1951). However, Emiliani's (1955) documentation of systematic stratigraphic (hence, temporal) variations in oxygen isotope ratios in foraminifera tests recovered from Pleistocene sediment cores established the great potential of oxygen isotope stratigraphy for correlation and dating purposes (Emiliani 1958). Oxygen isotopes would subsequently prove to be an invaluable and much more effective means of reconstructing the tempo and magnitude of late Cenozoic glacial advances and retreats than the continental record of glacial drift (e.g., Shackleton and Opdyke 1973; Hays et al. 1976; Lisiecki and Raymo 2005).

Although Wickman (1948) first speculated that strontium isotopes were a potentially useful dating tool in marine carbonates and evaporites well before analytical techniques became routine, the full potential of strontium isotope stratigraphy was not realized until Burke et al. (1982) published the hallmark record of Phanerozoic seawater Sr isotope compositions, which demonstrated substantial variations in $^{87}\text{Sr}/^{86}\text{Sr}$. Similarly, carbon isotope stratigraphy did not emerge as an effective and efficient chronostratigraphic tool until the late 1970s and early 1980s (e.g., Berger et al. 1978; Scholle and Arthur 1980), but is now a standard technique when working on sedimentary carbonates of all ages.

Stable Isotope Systems

Due to the relatively small absolute variations in stable isotope ratios, such as $^{13}\text{C}/^{12}\text{C}$ and $^{18}\text{O}/^{16}\text{O}$, most commonly measured stable isotope ratios are expressed as per mil (parts per thousand) units in delta (δ) notation, relative to an international standard:

Fig. 2 The benthic foraminifera oxygen isotope record (LR04) for the past three billion years, as compiled by Lisiecki and Raymo (2005) from a stack of 57 sediment core records. Note that even-numbered stages correspond to glacial maxima and odd-numbered stages to glacial minima. Red numbers refer to *marine isotope stages (MIS)*, although note that only selected stages are labeled. Glacial maxima occur at higher $\delta^{18}\text{O}$ values (positive MIS; see text for explanation), hence the inverse values on the x -axis. The boxes on the right delineate normal (blue) and reversed (white) magnetic polarity chrons. *Mat.* Matuyama, *J* Jaramillo, *Old* Olduvai.

$$\delta (U_{\text{wasyh}}) = 1000 \times \left(\frac{R_{\text{SAM}} - R_{\text{STD}}}{R_{\text{STD}}} \right)$$

where R_{SAM} and R_{STD} refer to the isotope ratio of interest of a measured sample and standard, respectively. Many different isotope ratios are measured on sediments and sedimentary rocks, but of these, few have proven consistently effective in chronostratigraphy. Several other systems have very specific environmental applications, such as boron isotopes (paleo-pH) and clumped C–O isotopes (paleo-temperature) in carbonates. Other proxies, such as Mg, Ca, and Li isotopes in carbonates, have emerged as potentially useful chemostratigraphic tools, but are either not yet well established or are not effective replacements for established isotope systems.

Oxygen Isotopes

Oxygen isotope stratigraphy has proven invaluable in understanding Cenozoic paleoclimate (Emiliani 1958; Hays et al. 1978; Zachos et al. 2001; Lisiecki and Raymo 2005) and has enjoyed wide application to rocks and sediments of all ages. Oxygen isotope ratios are normalized to two different standards: PDB (named for belemnites in the Cretaceous Peedee Formation, which was the original laboratory carbonate standard developed by Urey's group at the University of Chicago, and subsequently recalibrated as VPDB) and SMOW (Standard Mean Ocean Water standard, recalibrated as VSMOW). Oxygen isotope values for a given material can be converted between these two standardizations using the equation

$$\delta^{18}\text{O}_{\text{VSMOW}} = 1.03091 \times \delta^{18}\text{O}_{\text{VPDB}} + 30.91$$

By convention, silicate and phosphate minerals are standardized to VSMOW and carbonate minerals are standardized to VPDB. Here, we are only concerned with those minerals deposited from seawater, most importantly aragonite and calcite, although oxygen in phosphate biominerals is also used for chemostratigraphy. The original oxygen isotope composition of these minerals is determined by temperature at which the mineral formed and the $\delta^{18}\text{O}$ of the oxygen source for that mineral, which, in the case of carbonates, is the oxygen bound to carbon in the dissolved inorganic carbon (DIC) pool (Grossman 2012). The $\delta^{18}\text{O}$ of DIC, in turn, is governed by the $\delta^{18}\text{O}$ of seawater. Hence, oxygen isotope ratios can be used as a paleothermometer, assuming the composition of the waters from which the carbonate was precipitated is known (Epstein and Mayeda 1953).

Carbonates are strongly enriched in ^{18}O relative to the waters from which they precipitate. Because this fractionation is controlled by temperature, with larger fractionations occurring at lower temperatures, if seawater composition is held constant, then increasing temperatures result in carbonates with lower $\delta^{18}\text{O}$ values, and vice versa. However, seawater composition does vary, specifically as a consequence of the growth and decay of continental ice sheets, which are strongly depleted in ^{18}O compared to seawater. The magnitude of this shift between the last glacial maximum and today was about 0.9 ‰ (Schrag et al. 1996). Fortunately, this *ice volume effect* drives the $\delta^{18}\text{O}$ of seawater to higher values during glacial maxima and lower values during glacial minima – that is, in the same direction as the temperature effect. Hence, oxygen isotopes are invaluable in reconstructing late Cenozoic (Pliocene–Pleistocene) glaciation, which is now widely accepted to be modulated by orbital (Milankovitch) cycles (Hays et al. 1976). Indeed, both marine carbonate and ice core $\delta^{18}\text{O}$ records over the past five million years are commonly tuned to oscillations in insolation (typically June 21 insolation at 65°N; e.g., Shackleton 2000; Zachos et al. 2001).

Figure 2 shows the marine benthic foraminifera (i.e., deep water) $\delta^{18}\text{O}$ record (LR04) for the past 3 m.y., as compiled and orbitally tuned by Lisiecki and Raymo (2005). Benthic forams are preferred over planktonic forams for generating seawater curves because the latter are sensitive to local temperature or salinity affects, whereas benthic forams better capture whole ocean values and trends. The LR04 record captures many key features, including a general increase in $\delta^{18}\text{O}$ of marine carbonates through the Pliocene–Pleistocene that is presumably related to gradual intensification of continental glaciation; the well-developed, asymmetric sawtooth 100 k.y. glacial–interglacial cycles over the past 800 k.y.; and the prevalence of 40 k.y. glacial cycles prior to 800 k.a. The peaks and troughs in the marine isotope record are identified as numbered marine isotope stages, beginning with the present low (interglacial) stage (MIS 1) and extending back through the Pliocene (Lisiecki and Raymo 2005). Correlating stages between a given oxygen isotope record and the LR04 or other compilation provides a means of dating sediment (or ice) cores and enables

Fig. 3 Compilation of oxygen (a) and carbon (b) isotope data from benthic foraminifera, spanning the Paleocene–Eocene Thermal Maximum (*PETM*) event, which is attributed to a catastrophic input of ^{13}C -depleted carbon to the ocean–atmosphere system (see Zachos et al. (2007) for a review of possible mechanisms and consequences of this event). Carbon and oxygen isotope records (extracted from the database of Cramer et al. 2009) from individual cores from the North Atlantic (ODP1051), Pacific (ODP865), and Southern Oceans (ODP690) are shown for comparison.

direct correlation and comparison of equivalently aged strata, which remains valid even if the timescale of the compilation is subsequently revised. This technique is most reliably applied to deep-sea strata that experience consistent, uninterrupted sedimentation.

Oxygen isotope stratigraphy is also widely applied to older strata and successfully delineates many key climatic events and trends over the Cenozoic Era, including the Paleocene–Eocene Thermal Maximum (Fig. 3a), the onset of Antarctic glaciation (Eocene–Oligocene boundary), and mid-Miocene climatic optimum (Zachos et al. 2001). The utility and reliability of this proxy decreases back in time with diminished deep-sea sediment records and increasing degree of alteration of most carbonate sediments and rocks. Nevertheless, $\delta^{18}\text{O}$ anomalies and trends that are consistent with known events such as glaciations have been documented in rocks spanning the Phanerozoic (Grossman 2012).

Inorganic Carbon Isotopes

The carbon isotope ratio ($^{13}\text{C}/^{12}\text{C}$) of the marine-dissolved inorganic carbon (DIC) pool has varied secularly over Earth history. The steady-state $\delta^{13}\text{C}$ value of DIC reflects the composition of carbon input to the ocean (commonly assumed to be -5‰ to -6‰ over long timescales; Kump and

Fig. 4 A simple schematic model of the coupled atmosphere–ocean carbon cycle at present, which illustrates the carbon isotope composition of the major fluxes and reservoirs that affect the $\delta^{13}\text{C}$ value of dissolved inorganic carbon (DIC) in seawater and sedimentary carbon over geological timescales. Steady-state changes in the $\delta^{13}\text{C}$ value of DIC can be effected by (1) a change to the composition of the input to the coupled ocean–atmosphere system, (2) a change in the relative amount of carbon removed from the ocean–atmosphere system and buried in sediments, and (3) the $\delta^{13}\text{C}$ composition of organic carbon. A non-steady excursion can be brought about by a sudden input of isotopically distinct carbon to the DIC–atmosphere reservoir.

Arthur 1999), the relative partitioning of that carbon into inorganic (carbonate; $\delta^{13}\text{C}_{\text{carb}}$) carbon and sedimentary organic carbon ($\delta^{13}\text{C}_{\text{org}}$) that is buried within marine sediments (f_{org} = fraction of carbon buried as organic matter), and the isotopic difference between these two reservoirs ($\delta^{13}\text{C}_{\text{carb}} - \delta^{13}\text{C}_{\text{org}} \approx \delta^{13}\text{C}_{\text{DIC}} - \delta^{13}\text{C}_{\text{org}}$) (Fig. 4). Because $\delta^{13}\text{C}_{\text{carb}}$ is close to the value of the DIC reservoir and the fractionation between the two species is effectively insensitive to temperature, the carbon isotope composition of marine carbonates is treated as an approximation of seawater from which it derives.

This approximation is most applicable to pelagic carbonates, which are deposited in the open ocean. The predominant sources of pelagic carbonate are calcareous nannoplankton (e.g., Cocolithophora) and planktonic foraminifera. Although these two groups evolved earlier, neither was widespread in the global ocean until the early Cretaceous (Saltzman and Thomas 2012). Consequently, most middle Mesozoic–Cenozoic marine carbon isotope compilations are derived from deep-sea sediment cores. These may be either bulk carbonate records, which dominantly comprise planktonic nannofossils (Milliman 1993), or records developed from individual planktonic or benthic foraminifera (e.g., Fig. 5). Because the DIC of the surface mixed layer may be heavily modified by primary productivity (photosynthesis), planktonic and bulk records may vary considerably from the benthic foraminifera records, which are a more faithful proxy for whole ocean DIC composition. Combined planktonic and benthic foraminifera records may be used to quantify the effect of the biological pump, which produces a surface-to-deep $\delta^{13}\text{C}$ gradient where surface waters are relatively ^{13}C enriched.

Even benthic foraminifera records may not precisely record the carbon isotope composition of the integrated oceanic DIC pool. As shown in Fig. 5, the present Pacific and North Atlantic basins are offset from one another by about 1 ‰. This carbon isotope gradient between the two ocean basins first developed in the middle Miocene. For the remainder of the Cenozoic Period, the North Atlantic and Pacific records align reasonably well, and both capture major shifts in $\delta^{13}\text{C}$, including a large decline across the Paleocene–Eocene boundary (punctuated by the PETM event; see below), the ca. 17 Ma Monterey carbon burial event, and a steady decline starting about 8 million years ago and presumably related to the expansion of C4 plants (Fig. 5; Zachos et al. 2001). Such

Fig. 5 Compilation of carbon isotope composition of benthic foraminifera over the past 65 million years (Cenozoic). Blue data points represent all data from deep-sea sediment cores, as compiled by Cramer et al. (2009), adjusted to the timescale of Gradstein et al. (2004). White swaths indicate intervals with extensive data coverage. Black and grey lines are fits to the North Atlantic and Pacific data, respectively (Cramer et al. 2009). Several carbon isotopic features are apparent in this curve, including the Paleocene–Eocene Thermal Maximum (PETM) negative excursion (see also Fig. 3), the Monterey Carbon Burial Event, and a decline in marine $\delta^{13}\text{C}$ corresponding to the expansion of C4 plants beginning about eight million years ago (Zachos et al. 2001). Note the gap between Pacific and North Atlantic $\delta^{13}\text{C}$ beginning in the middle Miocene, indicating an increasing isotopic gradient between ocean basins.

salient trends are important from the perspective of chronostratigraphy because they permit correlation and approximate dating of poorly age-constrained sections by comparison with a reference seawater $\delta^{13}\text{C}$ curve. However, because both positive and negative steady-state shifts are relatively common occurrences in the geological record, they typically require additional chronological constraints or a long record with enough structure that it can be confidently correlated to the reference curve.

Non-steady-state perturbations to the seawater DIC isotopic composition, known as *carbon isotope excursions*, may provide a unique solution when correlating and dating marine sediments. Perhaps the best-studied example of such a non-steady-state excursion is the carbon isotope anomaly that spans the Paleocene–Eocene Thermal Maximum (PETM) (Fig. 3). This anomaly features an abrupt decline in the $\delta^{13}\text{C}$ composition of benthic foraminifera of 2–3 ‰, followed by a gradual recovery over a few hundreds of thousands of years (Fig. 3b); this timescale is governed by the c. 100–200 thousand-year residence time of DIC in the oceans. It is widely accepted that this excursion must have resulted from the geologically instantaneous addition of a large mass of ^{13}C -depleted carbon to the marine DIC pool. However, the actual source of this carbon and its precise link to the corresponding temperature change evinced by the oxygen isotope record (Fig. 3a) remain debated (Higgins and Schrag 2006).

Carbonates deposited on continental margins tend to show greater variability than pelagic carbonate records. One reason for this discrepancy in signals is that they are more susceptible to local and regional affects that generate heterogeneity in seawater DIC, such as input of ^{13}C -

depleted surface and groundwater or elevated bioproductivity and removal of ^{13}C -depleted organic matter. This problem is particularly acute in restricted water bodies, such as epeiric seas, where local carbon cycling processes can strongly influence the $\delta^{13}\text{C}$ record preserved in carbonate sediments (e.g., Holmden et al. 1998; Panchuk et al. 2005). Another reason for the variability is that platform carbonates are more susceptible to overprinting by meteoric diagenesis, particularly during glacial epochs where they are periodically exposed during glacioeustatic lowstands (Swart 2008). Nevertheless, because deep-sea pelagic carbonates are absent from the pre-Mesozoic record and other deepwater records are sparse, carbon isotope stratigraphy is heavily dependent on records derived from shallow-water carbonate platforms (Saltzman and Thomas 2012). The reliability of these archives for chemical stratigraphy remains highly debated (Derry 2010).

Organic Carbon Isotopes

The carbon isotopic composition of marine sedimentary organic matters ($\delta^{13}\text{C}_{\text{org}}$) also yields important paleoenvironmental information and in some cases is a useful chemical stratigraphic tool. Most carbon isotope data produced on sediments and sedimentary rocks are measured on bulk total organic carbon (TOC). To the extent that this TOC reservoir is largely derived from primary biomass and has not been heavily altered isotopically during diagenesis and metamorphism, it should closely parallel the original DIC pool from which that carbon was fixed (Hayes et al. 1999). For this reason, the carbon isotopic composition of bulk sedimentary organic carbon ($\delta^{13}\text{C}_{\text{org}} \approx -20$ to -30 ‰) has been widely applied in place of or as a supplement to carbonate carbon isotopes (where carbonate is scarce) to capture secular evolution and excursions in the DIC reservoir (e.g., Knoll et al. 1986).

Paired carbonate and organic carbon data can additionally be used to calculate the net isotopic fractionation between the inorganic and organic carbonate fractionations (ϵ_{TOC}), which is an approximation of the initial fractionation between DIC and the primary (photosynthetic) organic carbon pool (Hayes et al. 1999). This figure can vary considerably due to a several factors, but mainly to differences in the initial fractionation between dissolved CO_2 and primary biomass (ϵ_{p}) which is imparted by primary producers and principally controlled by dissolved CO_2 concentrations, growth rate, and cell geometry (Popp et al. 1998). Not surprisingly, ϵ_{TOC} has varied considerably over geological time, with highs of up to 34 ‰ during the Neoproterozoic (100–541 Ma) and current values below 22 ‰ (Hayes et al. 1999). As a consequence, $\delta^{13}\text{C}_{\text{TOC}}$ cannot simply be used as a replacement for $\delta^{13}\text{C}_{\text{carb}}$, even though it commonly captures the major excursions and trends in the DIC reservoir and hence can be applied to chronostratigraphy.

Sulfur Isotopes

Sulfur isotope stratigraphy has been applied to a wide range of paleoenvironmental questions, for which the ratio $^{34}\text{S}/^{32}\text{S}$ is commonly used. Sulfur occurs in seawater mainly in the oxidized form of sulfate (SO_4^{2-}), but locally and at times in the past has also been abundant in its reduced form of hydrogen sulfide (HS^-). Sulfate is delivered to the ocean mainly through continental weathering ($\delta^{34}\text{S} = 0$ –10 ‰) and removed as both sulfate and sulfide. The sulfate is sequestered in evaporite minerals (gypsum and anhydrite), barite (CaSO_4), and as a trace constituent in carbonate minerals (carbonate associated sulfate), all of which may be used as proxies for seawater sulfate isotopic compositions. Under anoxic conditions, sulfate is also utilized as the electron acceptor during bacterial sulfate reduction (BSR). This metabolic pathway, along with complex redox recycling of intermediate sulfur species, produces sulfide that is depleted in ^{34}S relative to seawater sulfate typically by ~ 30 –60 ‰. The highly variable figure results in a wide range of $\delta^{34}\text{S}_{\text{sulfide}}$ values in the sedimentary record (Canfield 1998). For this reason, $\delta^{34}\text{S}_{\text{sulfide}}$ is not an especially useful tool in

Fig. 6 A LOWESS fit sulfur isotope curve to the marine barite $\delta^{34}\text{S}_{\text{SO}_4}$ record for the past 130 million years (Paytan et al. 2004), modified from Paytan and Gray (2012). Barite, which is a trace constituent in many deep-sea sediments, is presumed to preserve primary seawater sulfate isotope ratios and is a robust during diagenesis, which makes it a well-suited mineral for reconstructing ancient seawater composition.

chronostratigraphy, although distinct ranges in $\delta^{34}\text{S}_{\text{sulfide}}$ are characteristic of certain time intervals over Earth history (e.g., Canfield 1998).

The generally highly depleted values of sedimentary sulfide are responsible for the relatively high $\delta^{34}\text{S}$ of sulfate in seawater. Sulfate is the second most abundant anion (after Cl^-) in modern seawater and has a residence time of nearly ten million years. Hence, sulfate is effectively uniform in the modern ocean ($\delta^{34}\text{S}_{\text{SO}_4} = 21.0 \pm 0.1$ ‰ in modern seawater; Rees et al. 1978), and its isotopic composition is expected to remain relatively stable over timescales of millions of years (Paytan and Gray 2012). Nevertheless, $\delta^{34}\text{S}_{\text{SO}_4}$ has varied considerably over Earth history, in large part as a result of significant changes in the size of the sulfate reservoir and hence its sensitivity to perturbations by changes in other parameters controlling its isotopic composition, namely, the net fractionation accompanying BSR and sulfide burial and the fraction of sulfur buried as sulfide. Due to high intrinsic variability of $\delta^{34}\text{S}_{\text{SO}_4}$ values recorded in pre-Mesozoic sedimentary rocks and difficulty in establishing their fidelity as seawater proxies, sulfur isotope stratigraphy has limited application as a dating tool throughout most of Earth history. However, in some cases, sulfur isotope chemostratigraphy can be used to apply rough age constraints. For example, distinctly ^{34}S -enriched values ($\delta^{34}\text{S}_{\text{SO}_4} > 30$ ‰) characterize the latest Precambrian and Cambrian sulfur isotope record (Kampschulte and Strauss 2004). The sulfur isotope record for the past 130 million years shows many distinct features, notably a 5 ‰ decline between 130 and 120 Ma and a rise of similar magnitude around 55 Ma (Fig. 6; Paytan et al. 2004; Wortmann and Paytan 2012). This unique structure to the seawater $\delta^{34}\text{S}_{\text{SO}_4}$ record presents potential of using sulfur isotopes for age determinations in sedimentary rocks of middle Mesozoic and younger age, although in many cases, other proxies would be more effective.

Fig. 7 A LOWESS fit Sr isotope curve for the Ordovician to present (McArthur et al. 2012), plus the Sr isotope fit to data for the Cambrian from Shields and Veizer (2002) and Halverson et al. (2010). See entry on “► Seawater Sr Curve” for a more detailed discussion of this record and its application to chronostratigraphy.

Radiogenic Isotope Systems

In addition to their direction applications in geochronology, several different radiogenic isotopes systems serve as important chemical stratigraphic tools. Although many different radiogenic isotope systems have been applied to marine sedimentary records for multiple purposes, only a limited number of these techniques enjoy routine application with chronostratigraphic relevance. Radiogenic isotope ratios are conventionally reported with a stable isotope with a radiogenic contribution of a given element as the numerator (e.g., ^{87}Sr) and a stable isotope with no or a negligible radiogenic component as the denominator (e.g., ^{86}Sr).

Neodymium Isotopes

Nd isotopes, specifically the ratio $^{143}\text{Nd}/^{144}\text{Nd}$, are applied to both recent and ancient and carbonate and clastic sediments and sedimentary rocks. Neodymium isotope ratios in sedimentary rocks are commonly reported in epsilon notation ($\epsilon\text{Nd}(t)$), where the $^{143}\text{Nd}/^{144}\text{Nd}$ ratio is normalized against the chondritic uniform reservoir (CHUR) and both are corrected for radiogenic ingrowth of ^{143}Nd (DePaolo and Wasserburg 1976).

Neodymium isotope stratigraphy owes its utility to the fact that Sm is preferentially retained in mafic rocks relative to Nd, leading to a greater contribution of radiogenic ^{143}Nd resulting from decay of the parent isotope ^{147}Sm . This elemental fractionation gives rise to relatively radiogenic (higher $^{143}\text{Nd}/^{144}\text{Nd}$) mafic rocks and less radiogenic felsic rocks, which makes the $^{143}\text{Nd}/^{144}\text{Nd}$ ratio a powerful tracer of sediment and solute sources. However, due to the low solubility of the rare

Fig. 8 Compilations of seawater $^{87}\text{Sr}/^{86}\text{Sr}$ and $^{187}\text{Os}/^{188}\text{Os}$ data spanning from 70 million years ago until the present [Modified from Misra and Froehlich (2012)]. Note the short-lived anomalies in $^{187}\text{Os}/^{188}\text{Os}$ across the Cretaceous–Paleogene and Eocene–Oligocene boundaries (*dashed vertical lines*), which are not mirrored in the $^{87}\text{Sr}/^{86}\text{Sr}$ record.

earth elements (which include both Sm and Nd) in seawater, their tendency to adsorb to settling particles, and isotopic exchange between sediments and seawater, the effective isotopic residence time of Nd in the oceans is small: ~200–1,000 years (Tachikawa et al. 1999). Consequently, seawater is not uniform with respect to $^{143}\text{Nd}/^{144}\text{Nd}$ ratios, and no unique seawater Nd curve can be generated. Rather, Nd isotopes, as typically measured in carbonates, phosphates, and ferromanganese nodules, are more commonly used to track the sources and circulation of ancient water masses (Banner 2004). Neodymium isotopes measured in fine-grained siliciclastic sediments are used to track tectonic, volcanic, and geographic evolution of the drainage basins supplying those sediments. To the extent that shifts in the initial $^{143}\text{Nd}/^{144}\text{Nd}$ composition of sediments can be linked to specific events, such as basement uplift or an episode of flood basalt magmatism, the Nd isotope record can have important chronostratigraphic applications to poorly dated sedimentary sequences.

Strontium Isotopes

Strontium isotope stratigraphy is one of the most powerful and widely applied chemostratigraphic tools to determine ages in otherwise undated marine rocks (see also entry on the ► [Seawater Sr Curve](#)). Similar to the Nd isotope system, strontium isotope ratios, namely, $^{87}\text{Sr}/^{86}\text{Sr}$, are useful because of the elemental fractionation between felsic and mafic rocks. In this case, Rb is concentrated in felsic rocks, resulting in higher $^{87}\text{Sr}/^{86}\text{Sr}$ ratios in felsic continental crust from the decay of ^{87}Rb . In contrast, mafic continental and oceanic crust have low (unradiogenic) $^{87}\text{Sr}/^{86}\text{Sr}$. Distinct from Nd, however, the Sr budget of seawater includes not only a riverine input reflecting typically radiogenic continental sources but also a large unradiogenic component from the hydrothermal alteration of oceanic crust. The residence time of strontium is also much higher than neodymium:

4–5 million years, meaning that oceans are uniform with respect to $^{87}\text{Sr}/^{86}\text{Sr}$, except in rare cases where local water masses are heavily influenced by isotopically distinct freshwater or hydrothermal input.

Because the Sr^{2+} cation readily substitutes for Ca^{2+} , marine strontium isotope ratios can be preserved in evaporite, carbonate, and phosphate minerals precipitated directly from seawater. However, Sr isotope ratios are highly susceptible to diagenesis, during which these minerals are commonly subjected to loss of total Sr and input of radiogenic strontium from the detrital sediment fraction or meteoric fluids. Hence, constructing the seawater Sr curve (Fig. 7) and using Sr isotopes as a correlation and dating tools requires the selection of high-quality samples and a combination of petrographic and geochemical screening for the affects of diagenesis (McArthur et al. 2012).

The secular evolution of seawater $^{87}\text{Sr}/^{86}\text{Sr}$ (Fig. 7) is conventionally interpreted in terms of competing influence of continental weathering (riverine) and seafloor hydrothermal Sr inputs. However, other factors also influence the long-term evolution of seawater Sr isotope ratios, including the progressive decay of ^{87}Rb , which imparts a long-term rise in $^{87}\text{Sr}/^{86}\text{Sr}$, and both tectonic (e.g., rifting or mountain building) and climatic effects. The result is a seawater Sr isotope curve with structure at multiple different timescales (Burke et al. 1982). Strontium isotope stratigraphy is most useful as a correlation and dating tool at time periods where $^{87}\text{Sr}/^{86}\text{Sr}$ changes rapidly (DePaolo and Ingram 1985), such as across the Permo-Triassic boundary and in the latter half of the Cenozoic (Figs. 7 and 8). Due to the considerable fluctuations in $^{87}\text{Sr}/^{86}\text{Sr}$ over the past billion years (McArthur et al. 2012; Fig. 7), obtaining a single, precise and accurate $^{87}\text{Sr}/^{86}\text{Sr}$ value from a marine sedimentary rock is not sufficient to establish a date. Rather, additional age or chemostratigraphic constraints, or a distinct $^{87}\text{Sr}/^{86}\text{Sr}$ profile is necessary to link to the composite strontium reference curve (Fig. 7). However, where this connection can be made, strontium isotope stratigraphy can be used in many cases to establish relatively precise (<1 m.y.) ages (McArthur et al. 2012).

Osmium Isotopes

Osmium isotope ratios, which owe their heterogeneity and utility to ongoing radioactive decay of ^{187}Re to ^{187}Os , are commonly reported as $^{187}\text{Os}/^{188}\text{Os}$ ratios. Osmium has a residence time in the modern oceans of 10–50 thousand years, and its isotopic composition ($^{187}\text{Os}/^{188}\text{Os} = 1.06 \pm 0.005$) reflects the balance between an unradiogenic mantle component ($^{187}\text{Os}/^{188}\text{Os} \approx 0.13$) and a radiogenic continental component ($^{187}\text{Os}/^{188}\text{Os} \approx 0.14$), with a small contribution from the dissolution of unradiogenic cosmic dust (Peuker-Ehrenbrink and Ravizza, 2000, 2012). Hydrogenous osmium is removed from seawater dominantly in metalliferous and organic-rich sediments. Whereas ferromanganese nodules serve as an important archive for Cenozoic Os isotope ratios (Fig. 8), organic-rich sediments are important in determining pre-Cenozoic $^{187}\text{Os}/^{188}\text{Os}$. However, because organic-rich sediments also concentrate Re, this requires an isochron approach to measure initial $^{187}\text{Os}/^{188}\text{Os}$ ratios.

As seen in Fig. 8, the Cenozoic marine Os isotope record ($^{187}\text{Os}/^{188}\text{Os}$) broadly resembles the Sr isotope record with both displaying a prominent, first-order rise toward more radiogenic ratios. However, due to the much shorter residence time of Os in seawater, it is sensitive to certain perturbations where the Sr isotope system is buffered. Specifically, prominent low $^{187}\text{Os}/^{188}\text{Os}$ excursion occurs across the Cretaceous–Paleogene and Eocene–Oligocene boundaries. The sensitivity of the Os isotope system to events such as flood basalt volcanism (Cohen and Coe 2002; Turgeon and Creaser 2008), abrupt warming (Ravizza et al. 2001; Schmitz et al. 2004), and large meteorite impacts (Paquay et al. 2008) highlights its importance as a chronostratigraphic tool. For example, Ravizza and Peuker-Ehrenbrink (2003) used Os isotope stratigraphy on deep-sea cores to

resolve the timing of Deccan Trap volcanism from the Cretaceous–Paleogene boundary and hence link the main mass extinction event to the Chicxulub bolide impact. Similarly, to the extent that events that were large enough to leave an imprint in the seawater Os isotope record are well dated, then the Os isotope system provides an indirect but robust way of dating sedimentary records.

Summary and Conclusions

Marine isotope stratigraphy is a widely applied tool in correlating and dating marine strata. It complements many other dating techniques, such as direct radiometric dating, biostratigraphy, and magnetostratigraphy. A large number of stable and radiogenic isotope systems are used in marine isotope stratigraphy, including both a core suite of well-established systems (C, O, and Sr) and a growing list of nontraditional isotope systems. Each isotope system has specific benefits and drawbacks, and no single system is universally applicable across sediment types and ages. Indeed, in many studies, multiple isotope proxies, along with other chemical stratigraphic tools, are applied, with each providing distinct constraints on the timing and origin of geological events. Important considerations in the application of isotope systems are the residence time and behavior of the chemical species of the element in seawater, the types of sediments in which the element is preferentially removed, and the potential of the isotope ratios to be preserved against diagenetic and metamorphic disturbances. Seawater isotope reference curves for the Cenozoic, and in some cases for the entire Phanerozoic, have been produced for many isotope systems, and these provide an excellent framework for indirect dating sediments and sedimentary rocks whose precise ages are not known.

(U-Th)/He dating; Helium dating; U-He dating; U-Th-Sm/He dating

Definition

U-Th/He dating is a method for determining the age of geological materials. The method is based on the accumulation of helium atoms produced by the alpha decay of U, Th, and in some cases Sm isotopes. Most recently, the method's chief use has been in measuring the temperature history of rocks at relatively low temperatures of between ~40 °C and ~250 °C.

Introduction

U-Th/He dating is the most venerable of all geochronological methods: the very first radiometric dates of any kind were helium dates reported at the very start of the twentieth century, starting with a 1905 lecture by Ernest Rutherford (1906; Strutt 1905, 1908). These early helium dates had perhaps the greatest intellectual impact of any ages ever measured. They provided independent and quantitative evidence for the great antiquity of rocks, thus establishing a modern framework for understanding Earth history and, of particular importance, providing firm evidence for the great spans of time required by biological evolution. Summaries of these heroic early measurements and their impact on the intellectual history of science can be found in a number of texts (e.g., Burchfield 1975; Hallam 1989; Dalrymple 1994; Lewis 2000).

History

For much of the twentieth century, work in geochronology focused on determining the absolute formation ages of rocks, and in this context the better results obtained by using the K-Ar, Rb-Sr, and U-Pb methods caused the development of U-Th/He dating to languish. From the 1950s to 1970s, studies of the mineral zircon and other materials such as corals, bone, and whole-rock volcanics continued intermittently but overall gave mixed results at best (Hurley 1954; Damon and Kulp 1957; Fanale and Kulp 1962; Fanale and Schaeffer 1965; Damon and Green 1963; Turekian et al. 1970; Bender 1973; Leventhal 1975; Ferreira et al. 1975).

Renewed interest in helium dating was rooted in the work of Dodson (1973), who provided a quantitative framework to explain how temperature-sensitive diffusion can result in “cooling” rather than formation ages for many minerals. Along with observations being made about the temperature significance of fission-track annealing (e.g., Wagner and Storzer 1972), this development launched the subdiscipline of thermochronology. Thermochronology turns the nuisance of

*Email: peter.zeitler@lehigh.edu

apparently “reset” ages into a tremendous asset, given how important heat is in powering the solid Earth: fundamental geological processes such as magmatism, metamorphism, deformation, and erosion all significantly perturb local temperatures. Based on experience with fission-track and argon thermochronology, Zeitler et al. (1987) examined U-Th/He dating of apatite with the expectation that helium diffusion should be rapid at relatively low temperatures, and their measurements confirmed a closure temperature for helium retention during slow cooling of 100 °C or lower. At the same time, Lippolt and coworkers (e.g., Lippolt and Weigel 1988) began to explore helium dating of other phases.

In the early 1990s Ken Farley and colleagues wrote an important series of papers that confirmed and refined the results of Zeitler et al. (1987) on apatite, of greatest importance showing that the slow-cooling closure temperature of this mineral is close to 70 °C. These papers also developed basic analytical techniques and addressed the issue of helium loss by alpha ejection (e.g., Wolf et al. 1996; Farley et al. 1996). Subsequent to this essential work, the technique was extended to other minerals such as zircon (Reiners et al. 2002) and titanite (Reiners and Farley 1999), increasing numbers of laboratories were set up, and the technique became an important contributor to studies of landscape and basin evolution. To a significant degree, development of (U-Th)/He dating coevolved with a surge of interest in coupling between tectonic processes and surface processes, largely because the low temperatures that (U-Th)/He dating can address allow it to constrain the rates, timing, and magnitudes of erosion and incision.

Most recently, apatite (U-Th)/He geochronology was further extended by Shuster and Farley (2004), who developed the $^4\text{He}/^3\text{He}$ technique. By revealing diffusion gradients within individual grains of apatite, this approach can address temperatures as low as ~40 °C (Shuster et al. 2006). Current research in the field is addressing a better understanding of diffusion kinetics in minerals of interest, improved methods of coping with and even exploiting U and Th zoning, the use of laser spot analysis to improve sample throughput and accuracy as well as better handle alpha ejection, and the application of the method to a wider range of materials and problems in thermochronology and geochronology.

At this point the (U-Th)/He dating literature can appear dauntingly extensive. The review article by Farley (2002) provides a good comprehensive overview of the method. Many of the articles in the volume edited by Reiners and Ehlers (2005) comprise an excellent introduction to both technical issues and applications. The classic book by Ozima and Podosek (2002) and the volume edited by Porcelli et al. (2002) provide overviews of noble-gas geochemistry relevant to (U-Th)/He dating.

Systematics

Decay

Alpha particles associated with radioactive decay are ^4He nuclei and become neutralized to accumulate as atoms of ^4He , providing the basis for the U-Th/He dating method. A number of nuclides undergo decay by alpha ejection. Most of these are members of the decay chains associated with ^{238}U , ^{235}U , and ^{232}Th . Of the other naturally occurring nuclides that experience alpha decay, only ^{147}Sm may produce significant ^4He in some samples. The other nuclides have half-lives that are too long or abundances that are too small. Of the commonly dated materials, production from ^{147}Sm is usually important only in the mineral apatite.

The accumulation of ^4He in the U-Th-Sm/He system can be summarized as follows:

$${}^4\text{He} = 8 \cdot {}^{238}\text{U} \cdot (e^{\lambda_{238}t} - 1) + 7 \cdot {}^{235}\text{U} \cdot (e^{\lambda_{235}t} - 1) + 6 \cdot {}^{232}\text{Th} \cdot (e^{\lambda_{232}t} - 1) + 1 \cdot {}^{147}\text{Sm} \cdot (e^{\lambda_{147}t} - 1) \quad (1)$$

with decay constants $\lambda_{238} = 1.55125 \times 10^{-10} \text{year}^{-1}$, $\lambda_{235} = 9.8485 \times 10^{-10} \text{year}^{-1}$, $\lambda_{232} = 4.948 \times 10^{-11} \text{year}^{-1}$, and $\lambda_{147} = 6.539 \times 10^{-12} \text{year}^{-1}$; t is the elapsed time in years since the system closed, and ${}^4\text{He}$, ${}^{238}\text{U}$, ${}^{235}\text{U}$, ${}^{232}\text{Th}$, and ${}^{147}\text{Sm}$ are the amounts in moles. The decay constants for U and Th nuclides reflect the total decay to lead isotopes, and the pre-exponential coefficients in Eq. 1 account for the number of alpha decays produced in each decay chain. Note that compared to other dating systems, the (U-Th)/He dating enjoys a fast effective decay rate owing to the multiple alpha particles generated by each decay chain.

In most substances the modern production rate of ${}^4\text{He}$ is dominated by ${}^{238}\text{U}$ and ${}^{232}\text{Th}$; for equal amounts of *elemental* U, Th, and Sm, the relative production rates normalized to the production from Sm are

$${}^{238}\text{U} : {}^{232}\text{Th} : {}^{235}\text{U} : {}^{147}\text{Sm} = 1266 : 305 : 51 : 1 \quad (2)$$

keeping in mind that for modern U and Sm, ${}^{238}\text{U}/{}^{235}\text{U} = 137.88$ and ${}^{147}\text{Sm}$ is 14.99 % of total Sm.

Decay Chains and Secular Equilibrium. Equation 1 is only accurate for a system with decay chains that are in secular equilibrium, that is, a system in which the decay rate for all intermediate daughters is the same. This will be true for systems that have been in equilibrium for at least ~1 m.y., and thus for thermal history studies of preexisting rocks, disequilibrium will not be an issue. However, for applications that involve dating of young newly formed rocks like volcanics, the presence of disequilibrium must be assessed and if necessary corrected for (e.g., Farley et al. 2002). Note that disequilibrium can result in ages that are too old or too young, depending on whether during formation or alteration of the mineral phase or rock, longer-lived intermediate daughters like ${}^{230}\text{Th}$ have been lost or gained relative to equilibrium values.

Age Calculation

Equation 1 cannot be solved algebraically. An iterative technique such as the Newton-Raphson method can be used to obtain a solution to any degree of accuracy provided sufficient iterations are made (usually just a few are required). Meesters and Dunai (2005) derived a non-iterative approximation that uses a weighted mean decay constant having ${}^4\text{He}$ production rates as the weighting factors. Their expression is accurate to within 0.05 % for ages of less than 300 Ma and is quite useful for numerical modeling applications that involve very large numbers of age calculations. Vermeesch (2008) discussed alternative methods for calculating average ages when multiple aliquots of a sample have been analyzed, with the best data treatment depending on such factors as the number of grains analyzed per aliquot and the range in parent isotope composition.

Requirements and Assumptions for Age Determination

For a sample analysis to yield an age, (U-Th)/He dating shares a core set of requirements with other radiometric techniques. Above all, the sample in question must have been a closed system with respect to both parent and daughter nuclides, without changes due to processes such as weathering, alteration by fluids, or recrystallization. This requirement applies to attempts to determine the timing of either mineral formation or complete resetting, that is, it applies to geochronological applications. However, most (U-Th)/He dates that have recently been reported were measured for the purpose of thermochronology. In this context, the core requirement is that the sample in question has been

closed with respect to parent nuclides and that the observed daughter product represents the net result of accumulation due to radioactive decay and loss due to thermally activated diffusion.

Note that unlike other methods of noble-gas dating like the K-Ar method, (U-Th)/He ages are calculated without any correction for atmospheric contamination. Given the very large $^4\text{He}/^3\text{He}$ ratio in the atmosphere ($\sim 730,000$) and the great variability of this ratio in geological environments, applying a correction would be difficult; this difficulty is compounded by the exacting technical requirements for measuring very small amounts of ^3He at natural abundance levels. Fortunately, the concentration of ^4He in the atmosphere is low (5.2 ppm), and any adsorbed atmospheric ^4He will be rapidly removed under vacuum conditions prior to analysis (Ozima and Podosek 2002). The bottom line is that experience with dating age standards has shown that a correction for atmospheric ^4He is not required.

Accuracy and Precision

The component methods routinely used in conventional (U-Th)/He dating can achieve analytical precisions of 1–2 % depending on sample size, age, and U and Th concentration. Most laboratories monitor their work using internal standards as well as widely used de facto standards such as Durango apatite (31.4 Ma; McDowell et al. 2005) and Fish Canyon zircon (28.48 Ma; Schmitz and Bowring 2001). Replicate analyses of standards and calibration gases verify the accuracy of the method and its precision with respect to laboratory methods. Analyses of some unknowns, in particular slowly cooled samples, often show greater scatter, with precision on replicates at times approaching 10 % at the 95 % confidence level. This is not surprising given the range of factors that can influence the diffusive properties of a single grain (see below) – under conditions of slow cooling, even small difference in diffusivity can translate into large differences in measured age.

Alpha Ejection

Alpha decay involves ejection of an energetic ^4He nucleus from its parent nuclide, with energies in the range 4–8 MeV, and Farley et al. (1996) first addressed the implications of this ejection for (U-Th)/He dating. The distance traveled by the alpha particle, termed its stopping distance, will vary depending on its kinetic energy and the nature of the medium through which it is traveling. For typically analyzed minerals (apatite, zircon, and titanite), these stopping distances range from roughly 15–25 μm for various members of the U and Th decay chains (Ketcham et al. 2011). Due to the minimum amounts of sample mass needed for U, Th, and He analyses as well as the natural size distributions of accessory minerals in many rocks, grains of 50–100 μm in radius are usually analyzed. As a result, alpha ejection will clearly impact the helium content of such grains: for example, a spherical grain of apatite 50 μm in radius would suffer some 25 % of helium loss due to ejection.

It is possible to calculate a correction factor F_t to account for ejected helium. F_t gives the fraction of alpha particles lost to ejection and depends on grain size and shape. Spherical grains can be treated with a simple analytical expression. Other geometries require Monte Carlo simulations to determine geometry-specific coefficients that can be used to calculate F_t based on the grain's surface-to-volume ratio. Ketcham et al. (2011) provided a detailed investigation and updated tabulation of correction factors and protocols. Complex 3D geometries in general require direct Monte Carlo simulation of the exact grain shape. Very large samples or internal samples for which all material is in effect more than one stopping distance from the surface obviously do not require an alpha-ejection correction to be made.

Once an F_t correction factor has been calculated that reflects the content-weighted contributions from U, Th, and Sm, the measured age is adjusted to account for missing alphas by correcting the sample's helium concentration and then recalculating the age:

$${}^4\text{He}_{\text{corrected}} = {}^4\text{He}_{\text{measured}} / F_t \quad (3)$$

For young ages of $< \sim 100$ Ma, it suffices within 0.1 % to apply the correction to the age itself; beyond that the nonlinearity in helium accumulation over time requires the correction to be made on the helium content, not the age. Note that this correction can also be viewed as an adjustment to the efficiency of U and Th decay in producing alpha particles that are retained.

This correction is accurate for quickly cooled samples that are deficient in helium due to alpha ejection. For samples with complex thermal histories in which the helium content represents a balance between loss by diffusion and accumulation by decay, alpha ejection will modify the diffusion profile. Accurate modeling requires mathematical treatment of the complete diffusion/ejection/accumulation process and interpretation of the resulting ages in this context. However, for samples having simple monotonic cooling histories, Eq. 3 gives appropriate results that restore ages to values consistent with the sample's cooling history.

Diffusion

From the very beginning of geochronology, workers were aware that (U-Th)/He ages will likely be minimum ages, owing to the ease with which the small helium atom can diffuse through materials (e.g., Rutherford 1906; Strutt 1909). As noted above, this mobility explains both the relatively infrequent use of the method for much of the twentieth century and the great expansion in its application over the past 20 years. Helium is a highly incompatible trace element in minerals, so to first order, helium diffusion occurs according to the well-understood principles of simple volume diffusion. While relatively little quantitative is known about He solubility in rocks and minerals, especially at high temperatures and pressures (see Ozima and Podosek 2002 for a discussion), it is known that helium solubility in geological materials is extremely low. Common laboratory experience with noble gases shows that they will diffuse out of minerals when heated, even in the presence of significant He and Ar (e.g., if heated when exposed to atmosphere). Experimental evidence suggests that for apatite, the most commonly dated mineral, the physical grain itself is the effective diffusion dimension, not some interior domain (Farley 2000). As such, it is relatively simple to perform diffusion experiments using the assumption that the concentration at the crystal margin is zero and so determine diffusion data at various temperatures. Such kinetic data enable the application of U-Th/He dating to thermochronology and also permit assessment of whether a particular (U-Th)/He determination is likely to represent an original age or be an overprinted or a cooling age. Harrison and Zeitler (2005) provide an overview of the fundamentals of noble-gas thermochronometry.

Radiation Damage

Sufficiently large combinations of either time or U and Th concentration can lead to accumulated alpha-radiation doses that are sufficient to break down crystal structures, a process known as metamictization. This will significantly alter diffusion properties and the retentivity of minerals. Fortunately, the effect is not observed in lower-U minerals like apatite and titanite and is modest even in higher-U phases like zircons. Reiners (2005) notes that to influence the diffusion properties and retentivity of zircons, radiation doses equivalent to several hundred millions of years of accumulation in a 1,000 ppm grain are required. For monazite, Boyce et al. (2005) noted that

closure to helium diffusion takes places at substantially higher temperatures than annealing of radiation damage, such that the kinetics of closure will not be impacted by radiation damage; in addition, the relatively low temperature for radiation damage annealing in monazite suggests that low-temperature post-closure leakage of helium should not be common.

In apatite, Shuster et al. (2006) and Flowers et al. (2009) have shown that accumulation of radiation damage in the modest amounts typical for this mineral leads to a counterintuitive increase in retentivity, rather than any leakage. The likely explanation for this behavior is that radiation damage serves as isolated traps for diffusing helium atoms, retarding the progress of their normal diffusion jumps. The effect appears to be quite reproducible and is a function of U and Th content, time, and also thermal history because at higher temperatures the radiation damage will anneal away. Although this makes calculations more complex, the effect may actually be useful by creating a spread in retentivities within a single apatite population proportional to its variation in U and Th content (Flowers 2009; McKeon et al. 2014).

Artifacts and Other Issues

Several technical and sample-specific issues complicate (U-Th)/He dating and need to be considered when assessing dating results. Fitzgerald et al. (2006) discussed a number of these.

Unlike the case of K-Ar dating, where potassium is a major element in the host mineral or rock, the parent nuclides for (U-Th)/He dating tend to be trace or minor elements that can be distributed with considerable zoning; U and Th variations of 10× or far more are possible and commonly observed in zircon and, to a lesser degree, apatite. The greatest problem associated with such zoning is that it confounds a simple alpha-loss correction that is based on a bulk estimate for a grain's He content and the assumption that U and Th are uniformly distributed. In the end-member case where all parent nuclides are more than one stopping distance from the surface, no F_t correction would be needed, and applying one would lead to an age overestimate of some 10–20 % or more. The other extreme, where all parent nuclides are located only across a grain's surface, would lead to an underestimate of the amount of alpha ejection and could in theory lead to a 50 % or greater underestimate in age. In practice, zoning can be assessed using sample characterization (microprobe analyses, radiographic imaging) and to some degree by analysis of replicates (which will be misleading if mineral grains are all consistently zoned). It is worth noting that the end-member scenarios are unlikely, and the reasonable mean ages seen in many samples along with only a slightly greater-than-expected scatter between aliquots are probably evidence for only mild zoning in most samples. In the special case of helium implantation from a grain's surface or external sources, Spiegel et al. (2009) showed that abrasion of grain exteriors can greatly improve both accuracy and precision for ages, but this approach is of no significant help for zoning interior to a grain because in a zoned grain, ejection of helium between zones will occur and it is impossible to know if any abraded material was either a sink or source for helium. Methods of better handling zoning remain an area of particularly active research and technique development.

Mineral inclusions can serve as sources of unexpected “extra” ^4He , and if the method chosen to measure U and Th does not equally sample the inclusions as well as the bulk grains, this extra He will be “parentless” in terms of the age analysis. This is of greatest concern if there are refractory inclusions of a high-U or high-Th phase in an easily dissolved, lower-U phase like apatite. The problem can be minimized by careful grain selection; just as with other dating methods, good data simply require good samples and care in their selection and preparation. Alternatively, samples can be dissolved using methods that guarantee total dissolution, in which case any small inclusion ends up behaving as point source of helium. This can improve replication between aliquots (Vermeesch et al. 2007).

Grain size and variations in grain integrity can also lead to age scatter and imprecision if not addressed, especially from very slowly cooled rocks where subtle variations can amplify difference in age. As predicted from diffusion theory, grain size controls retentivity, as demonstrated empirically by Reiners and Farley (2001), so it is important to keep grain sizes similar, certainly within an aliquot. Brown et al. (2013) pointed out that analysis of broken crystals that expose internal volumes can lead to significant age dispersion in slowly cooled samples. Because apatite has a strong parting perpendicular to its C-axes, it can be difficult to identify broken grains even for well-crystallized euhedral prisms. Both grain size and fragment effects can be used to recover thermal history information, but this requires good sample characterization and experimental planning.

Analytical Methods

Materials

Most modern U-Th/He dating has been done on the minerals apatite (Zeitler et al. 1987; Farley 2000), zircon (Reiners et al. 2002), titanite (also called sphene; Reiners and Farley 1999; Stockli and Farley 2002), and monazite (Boyce et al. 2005). Interesting data have also been obtained for epidote and garnet (Nicolescu and Reiners 2005), hematite (Lippolt et al. 1993), magnetite (Blackburn et al. 2007), complex substances such as weathering rinds and oxides (Lippolt et al. 1998; Shuster et al. 2005), and even gold (Cabral et al. 2013). For most laboratories, only single crystals need to be analyzed except for very young samples. However, for conventional work it is important to choose unbroken crystals of similar shape and size, free of mineral and fluid inclusions, so in practice it is important to obtain several hundred crystals from which to select samples. Although there is great variation between rock types and sample to sample, mineral-separation processing of 0.5–1 kg of material is necessary for routine work.

The accessory minerals most often used in U-Th/He dating are quite common in a wide variety of rock types. Zircon in particular occurs very frequently, albeit in small amounts. For analyses aimed at determining the formation age of a rock, felsic volcanic rocks are the most useful as they cool nearly instantly and frequently contain zircon and other accessory minerals. Studies of thermal history require rocks that formed or have been reheated at sufficiently high temperatures to “zero” the (U-Th)/He clock. Conversely, provenance studies that use U-He ages as tracers require clastic sedimentary rocks that have not been buried and reheated to temperatures that have perturbed the helium concentration of the mineral(s) of interest.

Conventional Analyses

Conventional U-He work involves extraction and measurement of ^4He from a sample using a noble-gas mass spectrometer connected to an ultrahigh vacuum system, followed by the measurement of U, Th, and if appropriate Sm content using isotope-dilution analysis by ICP/MS. Measurement of ^4He is possible in a relatively inexpensive quadrupole mass spectrometer, although a full magnetic-sector instrument can also be used. Helium is liberated from samples by heating, either in a vacuum furnace or by laser. The gas-extraction line must be connected entirely of metal owing to the high diffusivity of helium in glass.

Typical Conventional Analysis. After selection of grains for analysis, they are photographed to record their shape and dimensions (necessary for calculation of the alpha-ejection correction). Note that unlike the traditional K-Ar method, where different splits of samples are used for potassium and argon analysis, for (U-Th)/He dating it is essential to make all measurements on the same sample given the variability in U and Th between grains. The selected grains are loaded in small niobium or

platinum packet, loaded into the vacuum system, and, after baking to achieve a clean vacuum, heated by either a resistance furnace or a laser. The evolved gas is purified of active gases, and its helium content is then measured, usually by spiking, that is, by adding a pipetted ^3He aliquot of known amount. Performance of the mass spectrometer in measuring ratios is monitored using a pipette of known $^4\text{He}/^3\text{He}$ ratio and ^4He amount, and age standards are run along with unknowns to monitor overall performance of the system over the longer term.

Once samples have been outgassed, they are retrieved from the vacuum system and subjected to U-Th-Sm analysis. This involves acid digestion appropriate to the mineral or material in question and spiking with U and Th isotope tracers. These solutions are then analyzed using ICP/MS methods to determine U, Th, and Sm if likely to be present, e.g., in apatite.

To get a sense for what these analyses entail, a grain of the Durango apatite standard will contain about 3.5×10^{-13} mol of ^4He , 1.5×10^{-12} mol of ^{238}U , 3.0×10^{-11} mol of ^{232}Th , and 5×10^{-12} mol of ^{147}Sm . The time for analysis of a batch of say 10 samples, including mineral separation, sample picking and loading, He analysis, and U-Th-Sm analysis, would take perhaps 5–10 working days.

Laser Spot Analyses. Several laboratories are actively pursuing direct laser-ablation analysis for both He as well U and Th. High-power excimer laser systems have been developed that cleanly excavate pits of regular geometry within single grains without heating. Such systems require sequential analysis, first for helium and then again for U and Th. Challenges to the method are the need to obtain sufficient helium for an acceptable analysis and in calibrating the He and U-Th concentrations with respect to one another. Boyce et al. (2006) have reported encouraging data from monazite. Although the equipment needed is more elaborate than for conventional analysis (it costs more to dig a smaller hole!), potential advantages of this approach are higher sample throughput, better handling of U-Th zoning, and avoidance of the need to make an alpha-loss correction since the edges of a grain can be avoided. Drawbacks include the higher equipment cost, the challenge of analyzing single grains of younger, lower-U apatites, and difficulties in accurately recording any fine-scale diffusion profiles near grain edges.

$^4\text{He}/^3\text{He}$. This variant of the (U-Th)/He method was developed by Shuster et al. (2004) and Shuster and Farley (2004). The technique involves proton irradiation to convert a range of atoms in the target mineral to ^3He nuclei; because most atoms in the mineral serve as targets, the ^3He will be uniformly distributed. By analogy to the $^{40}\text{Ar}/^{39}\text{Ar}$ method, this ^3He provides a reference by which the distribution of ^4He can be inferred through stepwise heating. However, because the ^3He is not produced from the parent nuclides U and Th, the $^4\text{He}/^3\text{He}$ ratio of a heating step cannot determine a geological age in the way that a $^{40}\text{Ar}/^{39}\text{Ar}$ ratio can; determination of age spectra require calibration of the bulk $^4\text{He}/^3\text{He}$ ratio against the conventionally determined bulk age of the sample. The method requires use of a sensitive noble-gas sector mass spectrometer due to the small amounts of ^3He produced by proton irradiation as well as the need to resolve this ^3He from isobaric interferences such as HD. The method also requires pristine apatite grains of regular geometry that are not zoned in U and Th.

A great advantage of the technique is that it permits recovery of a continuous segment of an apatite sample's thermal history and can also determine an individual sample's kinetics as part of the step-heating experiment. This allows apatite $^4\text{He}/^3\text{He}$ dating to address a temperature range of ~50 °C beginning at temperatures as low as 40 °C, greatly extending applications of (U-Th)/He thermochronometry to crustal levels as shallow as 1–2 km.

Applications

(U-Th)/He dating has been applied to a great range of problems in the Earth sciences. Most of these applications have revolved around the temperature sensitivity of the technique and the way that various geological processes alter temperature in the Earth. Full appreciation of the impact of (U-Th)/He dating requires some understanding of the principles of thermochronology as well as an appreciation for how particular sets of processes can lead to setting or resetting of the (U-Th)/He system. The following set of studies illustrate the great range of applications of the (U-Th)/He method.

Tectonics and Erosion

Erosion will alter the temperature field beneath the surface, and in many environments such as mountain belts, erosion occurs in response to uplift of this surface; the two processes can in some circumstances become coupled due to isostasy and crustal dynamics. A number of studies have used (U-Th)/He dating to examine the timing of rock uplift, erosion, and the interplay between the two in mountain belts, across a great range of time scales. For example, Finnegan et al. (2008) examined feedbacks between tectonics and erosion in the extremely active northeastern Himalaya, where (U-Th)/He cooling ages can be as young as 0.4 Ma. In contrast, Flowers et al. (2006) examined rocks in the Canadian Shield that give exceptionally old apatite (U-Th)/He ages of up to ~1,000 Ma, thus documenting equally exceptional crustal stability over this time period. When combined with fully 3D thermomechanical models, (U-Th)/He and other thermochronological data of sufficient density can be inverted for comprehensive constraints on the timing or rates of deformation and erosion, as shown by van der Beek et al. (2010) for the morphological evolution of the Western Alps.

Landscape Evolution

The (U-Th)/He technique has permitted geologists to go beyond broader estimates of orogenic evolution to focus on such specific processes and features as relief development and incision. House et al. (1997, 1998) used the (U-Th)/He method to date the topographic evolution of the Sierra Nevada and show that relief in these mountains is old. Shuster et al. (2011) used $^4\text{He}/^3\text{He}$ data to determine the timing and pervasive nature of fjord cutting in southern New Zealand, and Flowers and Farley (2012) used apatite (U-Th)/He and $^4\text{He}/^3\text{He}$ data to make the controversial argument that parts of the Grand Canyon are quite old. Workers are also beginning to apply (U-Th)/He dating to suites of detrital minerals found in sandstones, as these minerals give a unique form of thermochronological provenance information, particularly if multiple methods are applied to each grain (double or even triple dating; e.g., Rahl et al. 2003).

On a shorter time scale and at locations nearer to or at the Earth's surface, clever applications of (U-Th)/He methods can return valuable information about the nature of processes. Riihimäki et al. (2009) used the thermal overprint associated with the formation of clinkers, produced by spontaneous combustion of coal, to determine the rate and timing of arroyo cutting, linking this to climate fluctuations. Reiners et al. (2007) examined apatites from hillslopes and stream channels in an attempt to constrain wildfire impact and frequency.

Geochronology and Stratigraphy

Although far less common in the “modern” era of (U-Th)/He dating, the method has been used in a strictly geochronological context and this will continue. Farley et al. (2002) examined the dating of tephra using zircon and apatite, and Blondes et al. (2007) dated young basalt lavas using entrained xenocrystic zircons. Shuster et al. (2005) investigated the use of weathering products to date laterite

formation. Finally, successful work on magnetite (Blackburn et al. 2007) and gold (Cabral et al. 2013) opens up the possibility of using the (U-Th)/He method to date ore deposits.

Conclusion

With numerous laboratories now in operation and nearly 2,000 journal articles published, (U-Th)/He dating is clearly a mainstream tool for earth scientists interested in the timing and rates of a number of surface and near-surface processes. Given research currently in progress, improvements in accuracy and precision are likely to be forthcoming due to an increased understanding of both the kinetic behavior of helium loss as well as technical artifacts such as U and Th zoning. Technical advances such as laser-probe dating should contribute to this, and by improving sample throughput, these advances should increase the volume of data that can feasibly be brought to bear on a research question. Laboratory advances in sample handling and measurement also hold promise of dating new materials in such challenging locations as the very near-surface and diagenetic environments.

Acknowledgment

Thanks to Ken Farley for the useful comments that helped me clarify several technical points.

Definition

Geomagnetism is a domain of geophysics which studies the origin and nature of the Earth's magnetic field. Geomagnetism involves integrated approaches to decipher ancient and contemporary magnetic fields of the Earth and other planets of the solar system.

Structure and Properties of the Earth's Magnetic Field

The Earth's magnetic field or geomagnetic field surrounds the planet where $\sim 98\%$ of it the field generated by geodynamo, creating the magnetosphere (Merrill et al. 1996). Geodynamo is the compositional and thermal convection in the outer liquid core of the conductive material (mainly iron). Convective electrical current produces geomagnetic field. The main part of the field is produced in the Earth's core and is described near the Earth's surface as a magnetic field of a dipole (Jones 1977; McFadden and Merrill 1984). The dipole has its magnetic South Pole oriented toward the geographical North Pole (see Fig. 1). The field structure is deformed by the solar wind above the Earth's atmosphere (1–2 % of a total measured field at the Earth surface) (Courillot and Le Mouel 1988). In reality, there is a deviation between the best-fit dipolar magnetic field on the Earth and the actual field. In the mantle, the shape of the magnetic field is changed to a quadrupole or multipole system. Additional disruption of the field (1–2 %) comes from the magnetized crustal rocks (Merrill 2010).

Presently, the horizontal component of the field is directed roughly into the geographic north–south direction. The local deviation from this alignment is called declination (see Fig. 2). In the middle and high latitudes, the magnetic flux lines change from the pointing horizontally vector to a much stronger more vertical vector (see Fig. 1). The inclination angle of the field lines can be measured with a compass needle, whose axis of rotation is mounted horizontally (see Fig. 2). At the magnetic North and South Poles, the inclination is 90° , and at the magnetic equator, it is 0° . Currently, the axis of the geomagnetic dipole field deviates at about 11.5° relative to the Earth's axis of rotation. The present-day dipole moment of the geomagnetic field is $M = 7.746 \times 10^{22} \text{ Am}^2$ and can be calculated from the most recent International Geomagnetic Reference Field of 2010 (IGRF-11) (International Association of Geomagnetism and Aeronomy, Working Group V-MOD 2010). It changes constantly with the current annual decrease of $-0.006 \times 10^{22} \text{ Am}^2/\text{year}$.

Fig. 1 The geomagnetic dipole position in the center of the Earth with its axis tilted relative to the Earth's axis. Magnetic field lines are shown with horizontal magnetic compass needle pointing along the lines. The needle indicates magnetic inclination, the angle measured from the horizontal surface at the point of observation. Positive values of inclination indicate that the magnetic field of the Earth is pointing downward, into the Earth, and negative values indicate that it is pointing upward

Fig. 2 Illustration of the coordinate systems used for representing the Earth's magnetic field. The geomagnetic field can be described by north (X), east (Y), and vertically downward (Z) Cartesian components and by the angles of declination (D) and inclination (I) together with the total field intensity (B)

Fig. 3 Illustration of the paleomagnetic age determination (modified from Blanco et al. (2013) with Elsevier permission). The pole and the circle of confidence are projected over the minimum distance point on the APWP. The intersection points 1 and 2 will constrain the error in age

Paleomagnetism

Paleomagnetism studies the past geomagnetic field recorded in rocks and sediments. Since the magnetic minerals are abundant in the Earth's crust, paleomagnetic studies can be applied to a wide range of rocks and sediments. When a rock, containing ferromagnetic minerals, is heated to temperatures above the Curie point and then cooled in the ambient geomagnetic field, it is magnetized in the direction of the existing geomagnetic field (McElhinny and McFadden 1999; Tauxe 2010). This applies to volcanic rocks, bricks, pottery, and terracotta. During sediment formation, the magnetic grains align themselves with the local magnetic field until they become locked into place. The acquired magnetization is called a remnant magnetization and can be described by its inclination, declination, and intensity or by the related values of paleolatitude and paleolongitude which define a virtual geomagnetic pole (VGP). When a sequence of VGPs (paleomagnetic poles) has reliable ages, they can be used to produce an apparent polar wander path (APWP). This path is constructed using different poles of known age for a stable continental block and represents the APWP through time for that continent (Tauxe 2010).

Geomagnetic Reversals, Excursions, and Secular Variations

The direction of the ancient magnetic field has been continuously registered in the mid-ocean ridges when the erupted magma cools down. It enables one to study the geomagnetic polarity reversals, i.e., when the Earth dipolar field reverses 180° relatively to the present-day orientation. Such reversals are common throughout Earth's entire geological history. The most recent polarity reversal occurred at ~780,000 years ago (Brunhes-Matuyama reversal) (Langereis et al. 2010). Recent study suggests that an actual pole shift takes around 1,000 years (Valet et al. 2012). Reversals are very well documented until about 160 million years ago from the marine magnetic anomalies (Cande and Kent 1995; Gee and Kent 2007) and are less reliably known for older geological times.

A geomagnetic excursion is a significant change in the prevailing geometry of the geomagnetic field, which lasts on the order of the first thousands of years. The geomagnetic field, however, does not flip to a stable position at 180° during excursion. The most common contemporary conception states that the excursion occurs due to localized disturbances in the geomagnetic field caused by the convection of electrical currents in the outer core and its interaction with the mantle (Olson et al. 2013).

Geomagnetic secular variations are the changes in the field over periods of a year or more; they reflect shorter-term changes in the Earth's outer core. The variations that predate historical observations and recorded in archaeological and geological materials are called paleomagnetic secular variations or paleosecular variations (PSV).

Paleomagnetic Dating

For paleomagnetic dating, the APWP is used to determine the age of a paleomagnetic pole obtained from rocks or sediments of undefined age by projecting the pole on a sphere to the nearest point on the APWP (Symons and Sangster 1991; Blanco et al. 2013) (see Fig. 3).

A similar idea arises with PSV. The secular variation reference curves are created to display inclination, declination, and the intensity of the magnetic field for a given region through time. The PSV curves are typically defined for only the last few thousand years, which is useful when dating young material such as archaeological artifacts (Hangstrum and Blinman 2010; Pavon-Carrasco et al. 2011; Tanguy et al. 2003). Recently there have been great strides made in creating well-defined techniques and useful computer software to date archaeological artifacts using inclination, declinations, and intensities (Le Goff et al. 2002; Pavon-Carrasco et al. 2011).

Magnetostratigraphy

Polarity change is a global phenomenon which occurs simultaneously all over the world. Magnetostratigraphy studies polarity change registered in the geological sections, drilling cores, and magnetic anomalies in the ocean. The polarity change pattern can be used for stratigraphic correlation and dating of the geological section separated from meters to thousands of kilometers. Creating a universal reference scale of polarity changes using biostratigraphic and radiometric ages produces the geomagnetic polarity time scale (GPTS). This scale provides valuable stratigraphic markers for short- and long-range correlations of geological sections (Langereis et al. 2010). Oceanic and marine magnetic anomalies are very important for determining the spreading velocities between two plates on either side of a mid-ocean ridge.

Paleointensity

The value of ancient intensity of the geomagnetic field is called geomagnetic paleointensity. Independent records of paleointensity from sediment cores in different areas of the world are stacked together and represent the reference curve of the variations of the geomagnetic dipole moment (Valet et al. 2005; Channell et al. 2009). This provides information regarding the processes governing the geodynamo. So far, this procedure has been limited to the last two million years. The reference curve from the sedimentary records is calibrated with the absolute dipole moments derived from volcanic

lavas. Intervals of low intensity often correspond to the geomagnetic excursions and reversals. Comparison of the continued paleointensity records for sediments with unknown age to the reference paleointensity curve results in a possibility to date sediments when other means of dating are not reliable (e.g., Lake Baikal sedimentary cores, Kravchinsky et al. [2007](#)).

Archeomagnetism

Archeomagnetism is based on the variation of the intensity and direction of the geomagnetic field, and on the property of baked clay to record the situation during firing, as it remains fixed in the arrangement of the particles of iron oxides in it, immobilized by heating temperatures of about 650–700°.

The direction of the Earth's magnetic field does not vary in a consistent manner over time or space, and the changes have been recorded by scientists from only the sixteenth century. It is therefore necessary for each region to determine what were the geomagnetic changes through the examination of samples which remained in the same position from the time of heating. In the field of archaeology, once the reference curves are established, this can be used for dating other artifacts (Tarling [1975](#)). The accuracy of dating can vary depending on the rapidity of changes in the Earth's magnetic field at different times, and in general, it is possible to obtain ages with accuracy of decades or quarter century. While other forms of dating are based at the decay of radioactive elements, such as carbon dating, magnetic dating allows archaeologists to figure out the age of more varied and older artifacts.

Summary

The main geomagnetic field is formed in the outer core of the Earth and can be measured on the surface or in space. In the first approximation, the geomagnetic field of the Earth can be represented by the field of a dipolar magnet placed in the center of the planet. Geomagnetic poles migrate at the Earth's surface continuously, and reversals of the geomagnetic field direction occurred many times in the Earth's geological history. Short-term and long-term changes of the geomagnetic field are constantly monitored and studied by geophysicists because they carry important information about the current state of the geomagnetic field and past magnetic events.

The magnetic field has an effect on a variety of phenomena on Earth, in the atmosphere, and closest space. Magnetic measurements are commonly used for chronology and are important in geophysical exploration, for navigation, aerospace, and geodesy.

Impact Glass (Fission Tracks)

Giulio Bigazzi^a and Maria Laura Balestrieri^{b*}

^aCNR- Institute of Geosciences and Earth Resources, Pisa, Italy

^bCNR- Institute of Geosciences and Earth Resources, UOS Florence, Italy

Definition

Glass formed by melting of a siliceous rock exposed on the Earth surface due to the impact of a meteorite with the ground. Fission-track dating is a radiometric dating technique used for dating those glasses, and it is based on the damages (tracks) produced by the decay by fission of ^{238}U .

Introduction

Innumerable extraterrestrial bodies reach our planet every day. Most of them, due to their high speed, fully vaporize when they cross the atmosphere or their size is strongly reduced. So, these meteorites do not produce relevant effects. Only the largest bodies have probability to reach the Earth surface with a kinetic energy sufficient to produce recognizable impact structures. Luckily, large-sized meteorites are rare in comparison with the high number of those that reach the terrestrial atmosphere. For this reason impact craters, which are evidence of a collision of a heavy body occurred sometime in the past, are relatively rare. The fall of a large meteorite may have catastrophic effects, such as long-lasting climate changes. It is known that the abrupt ecosystem changes with extinction of many species, which represent the Cretaceous/Tertiary boundary, might be correlated to such an event. Therefore, it is an important task to study the chronology of significant impacts in order to establish possible correlation with environmental changes and to investigate on their periodicity, if any.

During an impact, due to transferring of a high amount of kinetic energy to the ground, target rocks suffer high shock-wave pressures, and their temperatures grow instantaneously up to 1,000 °C. This phenomenon, named shock-wave metamorphism, involves various effects – such as vaporization, melting, and fracturing – depending on the kinetic energy of the extraterrestrial body and on the original setting of the rock in relation to the impact. When duration and amount of temperature are sufficient to provoke the total annealing of preexisting tracks in a mineral phase containing U as trace element, the fission tracks one can etch and count are those formed after the impact, and the resulting age is the age of the impact itself. Thus, the fission-track technique may result to an efficient method for the age determination of impacts, providing that a suitable mineral phase is present in the target rocks. For the lower thermal stability of fission tracks and for its abundance, apatite is commonly preferred, but also sphene and zircon have been used. A crucial point is to establish whether the total annealing of preexisting tracks really occurred. Therefore, track length measurements are needed in order to compare their distribution with those of rocks that suffered fast cooling, such as volcanic rocks.

		287 ± 43	Size	Storzer (1971)

When siliceous rocks are present in the target area of a meteorite, the impact produces melting of these rocks. The newly formed glass starts track recording as soon as it cools, and its age is the age of the impact. Glasses are frequently found in impact structures, and most of these structures were dated using glass, that is, an ideal material (homogeneous distribution of uranium, easy etchability) for fission-track dating.

Impact Structures

Ages determined on impact structures by various authors since the early times of fission-track method are shown in Table 1. Location is shown in Fig. 1. Ages are distributed over a long time span, from few 1,000 years up to about 300 Ma. Commonly, ages measured by different authors are in agreement, except in few cases, especially those of the 1960s, probably due to uncertainties on the calibration of the fission-track system. Only in the early 1980s the problem of the calibration of the fission-track system was tackled, and international age standards were identified, in order to

Fig. 1 Location of the terrestrial impact structures dated with the fission-track method (numbers are referred to Table 1). The tektite terrestrial (red) and oceanic (pink) strewn fields with their mean ages are also shown. The dashed strewn field represents the extension of the Australasian s.f. southward to Antarctica, as suggested by recent discovery of microtektite trapped in sediments of the Transantarctic Mountains in northern Victoria Land (Redrawn with modifications after Wagner and Van den Haute (1992))

Fig. 2 (a) Fission tracks etched for 240 s in 20 % HF at 40 °C on a polished surface of Libyan Desert Glass; (b) a 2,140 g sample of Libyan Desert Glass “sculptured” and incrustated by the Sahara sand

allow comparison of measurements from different laboratories. The stability of fission tracks in glasses is rather poor: a certain amount of partial annealing occurs also at ambient temperature. For this reason an age on glass is considered a minimum age, even if a technique for correcting thermally lowered fission-track ages – namely, the size correction method or the plateau method – is applied (Storzer and Wagner 1969; Storzer and Poupeau 1973).

Commonly the $\text{Ar}^{40}/\text{Ar}^{39}$ dating method is preferred to fission tracks, substantially for its higher precision, considering that the main component of the experimental error of a fission-track age is related to the number of spontaneous tracks one can count under a microscope. However, in several cases the $\text{Ar}^{40}/\text{Ar}^{39}$ method failed and only fission tracks yielded a reliable age. A significant example is the Libyan Desert Glass (LDG) shown in Table 1 and Fig. 1. Several authors tried to apply the $\text{Ar}^{40}/\text{Ar}^{39}$ method on it but only using fission tracks a reliable age for this glass was obtained (Bigazzi and De Michele 1996 and references therein). This was possible because, due the absence of inclusions, the identification and counting of spontaneous tracks can be performed without uncertainties and for the relatively high areal density – more than 10,000 tracks for cm^2 (Fig. 2a). LDG is a magnificent very pure quartz glass (about 98 %) (Fig. 2b), known since the antiquity, used for tool making during prehistoric times as well as for jewelry in the ancient Egypt. LDG is found in blocks and fragments of various sizes in the Great Sand Sea of the Libyan Desert in Egyptian territory. It is distributed mostly in a relatively large area of the desert, northward in direction of the Mediterranean Sea. Systematic exploration of the Libyan Desert, since the expeditions of Patrick Clayton, in the 1920s and 1930s of the last century, has shown that spreading of LDG is substantially due to anthropic transportation, the original location being in a rather restricted area – few tens of kilometers – relatively close to the Libyan border. LDGs lie on the Cretaceous Nubian basement, along the “corridors,” north–south directed – located in between the

Fig. 3 Samples of Moldavite from different deposits of Bohemia and Moravia (After Bouška 1994)

sand dunes. Origin of LDG was a puzzling issue and various hypotheses were made – sedimentary glass and volcanic glass possibly extraterrestrial – but the most reliable is that LDG is due to melting of the desert sand caused by an impact. However, although various craters have been considered, no correlation of LDG with a specific structure has been found.

Tektites

Tektites are other puzzling natural glasses in our planet that caused long debate since they were described for the first time in 1774 by Count František Josef Kinský as “chrysolites and topazes” and later on, with a scientific approach, by Prof. Josef Mayer at the 1786 meeting of the Czech Academy of Sciences. On the Earth surface four main areas exist – named strewn fields (Fig. 1) – where mysterious glasses are spread, showing an “alien” chemical composition not recalling that one of the sediments where they are found. They have various shapes depending on the history they experienced after they formed – such as reworking of the original sediments, long-distance transportation, and redeposition in younger deposits – meteoric sculpturation. In Fig. 3, samples of the Central European tektites – named Moldavites – are shown, their lengths being between about 3 and 6 cm. Except for the European tektites whose whole strewn field is on ground, the remaining three strewn fields extend in the adjacent Atlantic, Indian, and Pacific oceans where microtektites were discovered in the marine sediments.

Sizes of tektites are relatively small; those of Central Europe do not exceed 300 g of weight and those exceeding 100 g are very rare. Only in Southeastern Asia significantly larger samples were found among the “Muong Nong”-type tektites. Nowadays, the most accepted hypothesis is that tektites have a terrestrial origin and are produced by impacts of heavy extraterrestrial bodies. The high-energy shock wave preceding the meteorite vaporizes the siliceous target rocks, which are

Fig. 4 *Up*: microtektite from the Transantarctic Mountain trapped in fine-grained detritus. *Bottom*: two ^{238}U fission tracks etched for 120 s in 20 % HF at 40 °C in the polished section of a microtektite grain at a magnification of 100× (*left*) and of 500×

ejected in the high atmosphere, and they solidify and fall at distances of 100 and sometimes 1,000 km. In this scenario, comparison of ages of tektites with the age of impact craters, their “potential source,” may result essential for proving the above-described mechanism.

The four strewn fields have well-distinct ages. The oldest tektites are those of the Central American strewn field (age 34.6 ± 0.6 Ma, Storzer and Wagner 1977) which extends in Texas (Bediasites) and Georgia (Georgirites) – in the continent – and in the Caribbean Sea. Although various impact structures of the American continent have been studied, no correlation with these tektites was found. The next strewn field is the Central European one. Moldavites are found in deposits of various ages, since Middle Miocene, Pliocene, and Pleistocene in South Bohemia and Moravia up to Holocene in Elba riverbanks. The fission-track age of Moldavite, 14.7 ± 0.4 Ma (Wagner 1966; Storzer and Wagner 1977), is the same determined by the same authors for the Ries crater (Table 1) located in Bayer, Germany. This represents an important confirmation of the terrestrial origin of tektites and of the formation model described above. Moldavite is an excellent glass, with relatively high-track densities, without defects that might produce “spurious” tracks, so fission-track identification during counting is unequivocal. In addition, many age determinations obtained by several authors using also K-Ar and $\text{Ar}^{39}/\text{Ar}^{40}$ are available. For these reasons it has been distributed as reference material for fission-track dating in glass (Balestrieri et al. 1998). The next Ivory Coast tektites are significantly younger (1.08 ± 0.10 Ma, Storzer and Wagner 1977), confirming the rarity of the event responsible for the formation of these glasses. Also in case of this strewn field, an associated impact structure was identified, i.e., the Bosumtwi crater located in Ghana (1.04 ± 0.11 Ma, Table 1). The youngest strewn field, the Australasian, is the largest one. It extends in Southeastern Asia and Australia and in the Indian and Pacific Ocean. These tektites have been named Indochinites, Javanites, Philippinites, Billitonites, and Australites, according to the

area where they were found. Their age (0.71 ± 0.07 Ma, Storzer and Wagner 1977; 0.693 ± 0.025 Ma, Storzer and Wagner 1980; 0.77 ± 0.08 Ma, Bigazzi and De Michele 1996) is in agreement with the age of the Darwin crater in Tasmania (0.74 ± 0.04 Ma, Table 1), but this crater is relatively small (ca. 1 km), so it is highly unlikely that it could have been the source of such extended strewn field. All the known Asian craters, potential sources of the Australasian strewn field, have been considered, but none of them shows an age consistent with the tektites. In addition, it has been also hypothesized that this large strewn field may have been produced by more than one impact: Storzer and Wagner (1980) determined for some Australian tektites ages older (0.830 ± 0.028 Ma) than those of Southeastern Asia cited above. Therefore, this topic needs further investigation.

A recent research has shown that the Australasian strewn field might be even more extended than expected. Microtektites were recently discovered on the Victoria Land Transantarctic Mountains (Fig. 4). They were found trapped in the fine-grained local detritus accumulated in weathering pits of the glacially eroded summits of Miocene age known as Transantarctic Mountain micrometeorite traps (Folco et al. 2008). Petrographic studies, major and trace element compositions, Sr and Nd isotopic compositions, and a low-resolution, yet Quaternary, $^{40}\text{Ar}/^{39}\text{Ar}$ age of 0.76 ± 0.98 Ma suggested that these microtektites most likely represent a major southern extension of the Australasian tektite strewn field. In order to better constrain the formation age of Transantarctic Mountain microtektites, their fission-track age was determined. The obtained fission-track plateau age of 0.85 ± 0.17 Ma, although affected by a relatively large experimental error due to the low number of counted spontaneous tracks owing to the small surface suitable for the analysis, is well consistent with the ages determined for the Australasian tektites.

Summary and Conclusions

Impacts of large meteoritic bodies with the Earth ground in presence of siliceous rocks may produce impact glasses through melting. By dating these glasses, one obtains the age of the related impact events. Since the early days of the fission-track method, various attempts have been successfully made in order to date impact glasses that usually are ideal material where to apply this technique as most of them show a relatively high number of tracks that can be unequivocally identified. Although the fission-track method usually relies lower precision ages in comparison with other radiometric methods, its application supplied precious information for correlating – or for excluding correlation – of impactites with specific craters and for reconstructing tektite strewn fields. Impressive examples of the performance of fission tracks in this field are those quoted above of the Libyan Desert Glass and of the Antarctic microtektites. This method produced unique efficacious data where other techniques failed.

Magnetic Anomalies

Roi Granot*

Department of Geological and Environmental Sciences, Ben Gurion University of the Negev, Beer Sheva, Israel

Definition

A magnetic anomaly is the magnetic field remaining after the Earth's magnetic field has been removed from the observed amplitude of the local magnetic field. The remanent magnetization of rocks records past variations of the geomagnetic field whereby spatial changes in their magnetization give rise to magnetic anomalies. We can date the oceanic crust by studying the unique pattern of lineated positive and negative magnetic anomalies that arise due to past reversals of the geomagnetic field with known age. Besides the primary signal that is related to past polarity reversals, the shape and tiny variations (wiggles) of the anomalies can be used to further constrain the age of the crust. Altogether, magnetic anomalies provide the main source of dating for the oceanic basins and lay the foundations for global plate reconstructions which place important constraints on the development of the lithosphere, biosphere, hydrosphere, cryosphere, and global climate.

Introduction

The Earth's magnetic field (the geomagnetic field) is generated by convection motions in the liquid outer core. The field is not steady but varies with time due to the dynamic of motions within the outer core leading to the ever-changing strength and position of its poles. In extreme cases and in irregular occurrences, hundreds of rapid reversals in the polarity of the field have taken place (Amit et al. 2010). The direction and strength of the geomagnetic field may get permanently imprinted into iron-rich rocks during their formation. The resultant remanent magnetization gives rise to local magnetic fields that generate "magnetic anomalies." Although continental magnetic anomalies may, in certain circumstances, provide some age constraints on the magnetized rocks, it is the marine magnetic anomalies that have crucial implications for the dating of the oceanic crust and serve as the basis for the Mesozoic and Cenozoic global plate reconstruction models (e.g., Seton et al. 2012).

The oceanic crust is formed along mid-ocean ridges, where melt rises and cools to form the crust (Vine and Matthews 1963). The cooling crust becomes magnetized in the direction of the geomagnetic field and retains magnetization proportional to its strength. After initial formation, the newly formed crust moves away and ages progressively from the ridge in a process known as seafloor spreading. In that way, a symmetric and unique magnetization pattern is formed across the spreading ridges. Although the oceanic crust is formed in a complex accretion process that varies in space and time, a remarkably consistent pattern of lineated anomalies are found globally (Maus et al. 2009). This pattern of anomalies predominantly reflects past reversals of the dipolar geomagnetic field and has been calibrated with radioisotopic age control at certain tie points, or astronomical cyclicity in stratigraphic sections, to form the basis for the geomagnetic polarity timescale (GPTS, Cande and Kent 1995; Channell et al 1995). Comparison of the predicted pattern of anomalies (based on

*Email: rgranot@bgu.ac.il

the GPTS and a simple two-dimensional magnetic structure) with the observed marine magnetic anomalies (for example see Fig. 1) allows researchers to globally map lines of equal and known age (i.e., isochrones) (Fig. 2).

Magnetic Anomaly Data and Their Physical Properties

The collection of marine magnetic data is traditionally made with magnetometers that measure the magnitude of the magnetic field. To avoid contamination of the signal by the survey platform (e.g., submarine vehicles, ships, helicopters, and airplanes), the magnetometers are usually towed some distance away from the towing platform. The measured values are the summation of the strength of the present-day geomagnetic field and the magnetic fields induced by the igneous crust in the direction of the geomagnetic field. The contribution of the geomagnetic field is computed and subtracted from the total value using the appropriate International Geomagnetic Reference Field model (e.g., Finlay et al. 2010). Minor additions are induced by external magnetic fields but these are usually rather negligible and contain shorter wavelengths as compared to the typical geological signature. These additions can be accounted for using gradiometer data or data collected in a reference magnetic base station. Modern magnetometers have an absolute accuracy of ~ 1 nanotesla (nT), which is two to three orders of magnitude smaller than the target magnetic anomalies.

The shape of a magnetic anomaly depends on the orientation of the spreading axis, the direction of the ambient geomagnetic field, the magnetization direction of the source rocks, and the shape of the magnetic boundaries. Therefore, in most places, the anomalies are skewed and spatially shifted from the actual location of the magnetization contrasts that generate them. To assign an accurate location for each of the magnetic contrasts with known age, it is essential to take into consideration the various parameters affecting the shape of the anomalies through a comparison against a two-dimensional forward magnetic modeling computed with the appropriate parameters (Blakely 1995 and Fig. 1). The resultant magnetic anomaly picks (Fig. 2) delineate isochrons of the igneous oceanic crust. These isochrons, found on both sides of the spreading ridges, together with fracture zone locations, provide the basis for the computation of relative motions between adjacent plates and serve as the basis for the construction of global plate reconstruction models.

Outstanding Issues

Marine magnetic anomalies have outstanding issues that stem from the physical principles that govern their formation and from limitations that relate to the recorded geomagnetic field. In the equatorial region, where spreading ridges are oriented in a north–south direction parallel to the direction of the geomagnetic field, no obvious (i.e., large amplitude) magnetic anomalies exist. Hence, locating magnetic anomalies there is virtually impossible, leading to the absence of accurate age models for the equatorial Atlantic and Pacific (Fig. 2). Oriented three-axial magnetometers that measure the components of the anomalous field allow the detection of the magnetization boundaries with better confidence (Gee and Cande 2002). Although efforts have recently been made to constrain the age of the oceanic crust in certain equatorial regions (Barckhausen et al. 2013, 2008), the age of the oceanic crust there remains poorly defined and is the focus of geophysical investigations.

Thus far, dating of the oceanic crust has been based on reversals-related anomalies. Therefore, the spatial resolution of which magnetic anomalies can date the crust depends on past reversal frequency

Fig. 1 A representative magnetic anomaly profile (NBP9707 cruise) across the Pacific–Antarctic Ridge. **(a)** Observed magnetic anomalies along the NBP9707 track. The synthetic magnetic anomaly profile **(b)** is calculated based on the geomagnetic polarity timescale of Cande and Kent (1995) where the positive chrons used are shown in the bar graph **(c)**. The numbers beneath the graph are ages (in millions of years) and the key polarity chrons are identified above the graph. The forward synthetic model uses this polarity pattern in a 0.5-km-thick source layer that has a mean magnetization of 10 Am^{-1} . Spreading rates that were used to construct the model follow Croon et al. (2008). Seafloor depth **(d)** was used as the *top* of the magnetic source layer. The location of the NBP9707 track is shown in panel **(e)**, projected on top of a satellite-derived free-air gravity anomaly map (Sandwell and Smith 2009)

Fig. 2 Identified locations of marine magnetic anomalies with known age (compiled by Seton et al. 2014). Note the absence of identifications in the equatorial regions and in the Cretaceous quiet zones

of the geomagnetic field. Periods that had frequent reversals, such as during the Cenozoic period, allow for the construction of well-constrained crustal age models (Fig. 2). However, during the Cretaceous period, the reversal frequency of the geomagnetic field was low (less than once every million years), with the extreme case of the Cretaceous Normal Superchron that lasted between

121 to 83.5 million years ago (Cande and Kent 1995; He et al. 2008). Therefore, the age of the crust that was formed during the superchron period (termed “quiet zone,” Fig. 2) remains poorly resolved. Luckily, past fluctuations in the intensity of the dipolar geomagnetic field are also recorded by the magnetized rocks, resulting in globally correlatable wiggles found between the primary, reversals-related magnetic anomalies (Bouligand et al. 2006; Cande and Kent 1992; Gee et al. 2000; Granot et al. 2012). Ongoing efforts are being made to refine the existing crustal age models using these magnetic wiggles as a means to establish internal isochrones between the primary anomalies.

Remanent magnetization directions of the magnetic source layer influence the shape of magnetic anomalies. Therefore, if a plate drifted during its geological history in a known fashion, one could potentially utilize the predicted remanent magnetization directions to constrain the age of the crust. “Paleomagnetic poles,” the magnetic poles of a certain plate, are calculated from independent paleomagnetic sites with known ages (see entry “Palaeomagnetism, Continental Drift”). These poles place constraints on past motions of the plates, thereby allowing the prediction of the directions of magnetization for every location on a given plate. Forward modeling of the expected magnetic anomalies for different periods of time based on the paleomagnetic poles of the appropriate plate until a reasonable match is found provides a crude, yet important, age constraint on the source rocks. This methodology may, under certain conditions, help to constrain the age of continental magnetic anomalies.

Meteorites (Lu–Hf)

Audrey Bouvier*

Department of Earth Sciences, The University of Western Ontario, London, ON, Canada

Definition

Radiogenic dating of meteorites and tracing of planetary differentiation using the radiogenic decay of ^{176}Lu to ^{176}Hf and variations in their isotopic abundances.

Introduction

The ^{176}Lu – ^{176}Hf radiogenic isotopic system (^{176}Lu half-life ~ 37 Ga) is a powerful chronometer and tracer of geochemical processes and planetary evolution. It was formerly assumed that the Lu–Hf system would be a valuable complement to the short-lived (^{146}Sm – ^{142}Nd with a ~ 68 Ma half-life) and long-lived (^{147}Sm – ^{143}Nd with a ~ 106 Ga half-life) Sm–Nd radiogenic systems. The Lu–Hf and Sm–Nd systems involve refractory and lithophile elements, all of which have mostly incompatible behavior (e.g., Patchett and Tatsumoto 1980; Boyet and Carlson 2005; also see entry on “► [Samarium–Neodymium, Dating](#)” for further details). The Lu–Hf pair has an advantage over the Sm–Nd pairs in that it includes two elements with distinct chemical behaviors: Lu is a heavy rare-earth element (REE) and Hf is a high field strength element (HFSE). Elemental fractionation between Hf and Lu is consequently greater in geological systems than for two REEs that have similar chemical behavior.

There has been tremendous progress made over the last few years for measuring Lu and Hf isotopic abundances with the development of multi-collector inductively coupled plasma mass spectrometry techniques (MC-ICP-MS). Such technical advances have led to the collection of enormous volumes of high-precision Hf isotopic data over the last 15 years. By measuring precisely small variations in the abundance of ^{176}Hf in various minerals and rocks with different Lu/Hf (parent/daughter) ratios, we can now date, with ~ 1 – 10 % precision, geological, and extraterrestrial processes as recent as ~ 15 Ma in igneous, metamorphic, or sedimentary rocks. Many recent studies have been focused on understanding the differentiation of the mantle and crust, and the dynamics of these reservoirs on the Earth, Moon, Mars, and planetesimals (e.g., Vervoort et al. 1996; Blichert-Toft et al. 1999, 2002). Studies in igneous geochemistry and metamorphic petrology particularly benefit from minerals that highly fractionate Lu from Hf during geological processes. Such minerals include zircon and ilmenite with very low Lu/Hf to track crustal evolution, and garnet and phosphate with very high Lu/Hf, to establish the chronology of metamorphic events. These accessory minerals are nevertheless rare in extraterrestrial materials, which sample primitive, ultramafic, and rarely evolved planetary crust. Also, because of the low concentration levels of Hf and REE in meteorites and limited supplies of these precious planetary materials, most of the cosmochemical studies have been focusing on bulk-rock analysis. Occasionally, silicate separates such as pyroxene, feldspar series, and olivine (Bouvier et al. 2008a; Thrane et al. 2010) oxides (e.g., chromite; Lapen

*Email: audrey.bouvier@uwo.ca

et al. 2010), and phosphates (Amelin 2005) have been analyzed for chronological studies of meteorites.

One area of considerable activity in geochemistry is the isotopic analysis of Hf in parallel with U–Pb zircon studies, either to constrain early crustal growth and evolution or as a complement to detrital zircon studies (e.g., Harrison et al. 2005). Interpretation of these data, however, relies on the availability of unambiguous and well-constrained decay constants for these isotope systems. At the moment, a major issue for deciphering planetary differentiation processes is that the apparent ages deduced from the Lu–Hf isochron method in planetary materials are variable by ~5 %. Consequently, there is an uncertainty for estimates of the initial Hf isotopic composition of the solar system and consequently an even larger uncertainty for the Earth’s bulk composition. The following sections detail the recent determination of the ^{176}Lu – ^{176}Hf parameters for solar system evolution and potential building blocks of the Earth. A third section discusses the recent findings of irradiation effects on Hf isotopes due to the long-term exposure of planetary materials to cosmic rays in space and how it affects the interpretation of Lu–Hf and Sm–Nd systematics in many meteorites and lunar samples. Finally, the last section will present Lu–Hf chronological studies for Martian meteorites, which are not affected by these processes and can therefore be used to constrain the formation times of these rocks.

Lu–Hf Isotopic Composition of the Solar System

The β^- decay of 176-Lutetium (^{176}Lu ; 2.56 % of Lu) produces 176-Hafnium (^{176}Hf ; 5.26 % of Hf). Dixon et al. (1954) reported that ^{176}Lu also decays by electron capture to ^{176}Yb with a branching ratio of ~3 %. Determinations of the ^{176}Lu decay constant ($\lambda^{176}\text{Lu}$) by physical counting experiments vary widely, leading geochemists to use the Lu–Hf isochron method in various meteoritic and geological samples of known U–Pb ages (see Albarède et al. 2006 for a review). This method deduces the value of the decay constant λ from the slope s of the isochron of an object of known age t by the relationship $s = e^{\lambda t} - 1$ (Fig. 1). An important requirement is that both systems closed rapidly to diffusion and remained subsequently undisturbed.

An unsolved discrepancy of ~5 % exists between the determinations of $\lambda^{176}\text{Lu}$ (and consequently Lu–Hf ages) based on meteorites at $\sim 1.93\text{--}1.99 \times 10^{-11} \text{ year}^{-1}$ (e.g., Patchett and Tatsumoto 1980; Blichert-Toft et al. 2002; Bizzarro et al. 2003; Thrane et al. 2010) and those based on terrestrial samples at $1.867 \times 10^{-11} \text{ year}^{-1}$ (Scherer et al. 2001; Söderlund et al. 2004). It was suggested that this difference was caused by an early episode of irradiation in the solar system that generated ^{176}Hf excesses in chondrite, eucrite, and angrite meteorites (Albarède et al. 2006; Thrane et al. 2010; Fig. 1). This effect, however, is not observed by the time of formation of phosphates from ordinary chondrite (4,551 Ma) and acapulcoite (4,557 Ma) meteorites (Amelin 2005). This discrepancy hampers accurate determination of the initial Hf isotopic composition of the solar system and the Earth, leading to an uncertainty of as much as seven epsilon Hf units for the composition of the modern BSE (denoted εHf , expressed as the deviations in parts per ten thousand relative to the reference CHUR parameters) (Fig. 1).

There are now several additional Lu–Hf isotopic datasets on bulk chondrites that have been gathered using MC-ICPMS since the pioneering work by Blichert-Toft and Albarede (1997). When comparing metamorphosed (petrologic types 4–6) and unmetamorphosed (petrologic types 1–3) chondrites, it is evident that there is a disturbance of the Lu–Hf bulk chondrite isochron during thermal metamorphism on the chondrite parent body. Metamorphism on chondrite parent bodies is the consequence of accretionary and radiogenic heat that lasted for at least 10–100 Ma on planetesimals with tens of kilometer diameters. Later planetary impacts may also have contributed to such

Fig. 1 Lu–Hf compositions of unmetamorphosed (petrologic types 1–3, *red symbols*) and metamorphosed (petrologic types 4–6, *blue symbols*) bulk chondrites obtained using efficient dissolution methods (Bizzarro et al. 2003; Patchett et al. 2004; Bouvier et al. 2008b; Dauphas and Pourmand 2011) with corresponding isochron regression lines. Thermal metamorphism produces a redistribution of Lu relative to Hf on the chondrite parent bodies and consequently a rotation and larger spread of the Lu–Hf compositions of the petrological types 4 to 6 bulk chondrites. Proposed initial solar system, and modern CHUR and BSE compositions are also indicated (Bouvier et al. 2008b); see text for additional details

disturbances at depth in the planetary bodies. Recently determined internal Lu–Hf isochrons of individual refractory inclusions (4,568 Ma) and chondrite, eucrite and angrite meteorites also show variability in the deduced $\lambda^{176}\text{Lu}$ values and initial Hf isotopic compositions, showing that secondary processes such thermal metamorphism and impact must have heterogeneously affected the parent bodies of these meteorites.

Building Blocks of the Earth

Because the Lu–Hf and Sm–Nd systems involve refractory and lithophile elements, it has been always assumed that the average composition of bulk terrestrial planets should be the same as that of primitive chondrites, and for this reason, the term Chondritic Uniform Reservoir was defined (CHUR). Knowing the bulk composition of the Earth is essential for these isotopic tools to realize their potential in planetary studies. The starting composition of terrestrial planets (e.g., Earth, Mars) is commonly assumed to be chondritic for Lu–Hf and by extension for Sm–Nd, which are both refractory elements. There are nevertheless variations in stable isotopic compositions of many elements that show that the Earth is made of different types of chondritic and unknown planetary materials such as potentially differentiated materials and comets.

The hypothesis of collisional erosion during accretion and differentiation would lead to fractionated bulk composition of planets. This mechanism was suggested to explain the so-called missing reservoir for the Earth or super-chondritic composition (Boyet and Carlson 2005; Caro et al. 2008; O'Neill and Palme 2008), but such fractionation and missing component is nevertheless not observed for large ~400 km diameter planetesimals such as 4 Vesta, the accepted parent body of basaltic eucrite meteorites

which have near-chondritic Lu–Hf compositions (Blichert-Toft et al. 2002). Evidence from lunar Lu–Hf and Sm–Nd isotopic compositions also suggests that the chondritic model holds for these two systems for the Moon and consequently also for the Earth (Sprung et al. 2013).

Lu–Hf Isotopic Variations in Meteorites

The improvements made on the precision of isotopic measurements allow scientists to generate new insights into the origin of isotopic variation and the stellar contribution (e.g., giant stars, supernovae) to the matter present in the solar system (e.g., Carlson et al. 2007). Some isotopes of interest (e.g., ^{178}Hf , ^{152}Sm , ^{146}Nd) can also be affected by neutron capture which is a quite common process in meteorites and planetary materials (e.g., lunar rocks) due to their journey into space or long-term exposure on planetary surfaces. If there are large isotopic anomalies due to cosmic-ray exposure on the normalizing isotopes, it will ultimately result in incorrect normalizations of all the ratios used for Lu–Hf dating.

Nucleosynthetic anomalies. It was suggested that Lu and Yb isotopic variations could potentially explain discrepancies in the ^{176}Lu decay rates deduced in meteorites if there were detectable irradiation effects for Lu or a branching decay of ^{176}Lu to ^{176}Yb (Amelin and Davis 2005; Scherer et al. 2005). $^{175}\text{Lu}/^{176}\text{Lu}$ ratios have been measured in planetary materials and do not show any resolvable variations that could explain such discrepancy (Wimpenny et al. 2013). For Hf, Sprung et al. (2010) show that there is no resolvable variation in the stable isotopic composition of bulk chondrites (Sprung et al. 2010), while small variations in leached chondrites (Qin et al. 2011) and refractory inclusions (Akram et al. 2013; Bouvier and Boyet 2013) were most recently found and likely caused by nucleosynthetic anomalies but are too small to affect Lu–Hf dating of meteorites.

Irradiation effects. The Lu–Hf dating of meteorites can be significantly affected by variations in stable isotopic abundances for Lu and Hf isotopic compositions due to irradiation effects from cosmic-ray exposure. The isotope ^{149}Sm is very useful as it has a large thermal neutron capture cross section and can be used to monitor irradiation effects on isotopic compositions (e.g., Lingenfelter et al. 1972). For example, it has been used for correcting irradiated Nd isotopic compositions of lunar samples (Nyquist et al. 1995). Secondary neutron capture effects on Hf isotopes have been detected in some achondrites (mesosiderites, aubrites) and lunar samples (Sprung et al. 2010) and were corrected using the measured $^{149}\text{Sm}/^{144}\text{Sm}$ ratio of the meteorites. These findings have changed the view of Hf–Nd isotopic evolution and differentiation of the lunar mantle and crust and also provided an additional constraint on the validity of the chondritic model for the Hf–Nd isotopic system for the Moon and by extension the Earth (Sprung et al. 2010).

Lu–Hf Dating Martian Meteorites

Martian meteorites are the only meteorites not affected by nucleosynthetic anomalies and irradiation effects that affect most of the planetary materials, as described in the previous sections. There has been extensive geochemical and chronological research on Martian meteorites as more than 150 individual specimens have been found so far. Using Lu–Hf chronometry, the unique orthopyroxenite Allan Hills 84001 (found in 1984 in Antarctica) has been dated at 4.1 Ga (Lapen et al. 2010) consistent with its Pb–Pb age (Bouvier et al. 2009), while shergottites show a broad range of Lu–Hf ages from about 185 Ma for Zagami (fell in 1962 in Nigeria) (Bouvier et al. 2005) to 580 Ma for Tissint (fell in 2012 in Morocco) (Grosshans et al. 2013) contrasting with their

corresponding Pb–Pb ages of 4.1 Ga and 4.3 Ga, respectively (Bouvier et al. [2008a](#)). The explanation for why only the Lu–Hf ages of shergottites are much younger than their corresponding Pb–Pb ages is an intensive area of current research. It is good to note that shergottite meteorites have been extremely shocked by impact on the surface of Mars and contain abundant impact melt and high-pressure polymorphs of many minerals (maskelynite replacing plagioclase, stishovite replacing quartz, ringwoodite replacing olivine). These observations may explain why Lu–Hf and other similar parent-daughter radiogenic isotopic chronometers have been disturbed in these meteorites (El Goresy et al. [2013](#)).

Summary or Conclusions

The most accurate value for $\lambda^{176}\text{Lu}$ deduced from geological materials is $1.867 \times 10^{-11} \text{ year}^{-1}$ with a corresponding half-life of 37.1 Ga. There is no robust evidence for an accelerated decay of ^{176}Lu in meteorites. The calculated initial ratio of $^{176}\text{Hf}/^{177}\text{Hf} = 0.27979$, as deduced from the modern CHUR parameters of $^{176}\text{Lu}/^{177}\text{Hf} = 0.0336$ and $^{176}\text{Hf}/^{177}\text{Hf} = 0.282785$, remains the best estimate for the initial isotopic composition of the solar system. The Lu–Hf system is extremely useful for tracking early planetary processes and chemical reservoirs formed in the interior of planets. Its chronological applications to meteorites are nevertheless limited due to its lower precision (a few million years to tens of millions years) and higher susceptibility to disturbance compared to the Pb–Pb chronometer, which is the most accurate and precise absolute chronometer used to establish the time scales of formation of meteorites, planets, and solar system (see entry on “► [Uranium–Lead, Extraterrestrial, Planetary Materials](#)”).

Rb–Sr Chronology of Meteorites

Rb–Sr Isotopic Systematics

The Rb–Sr isotopic system has been used to constrain the evolution of Solar System since it was first applied to basaltic achondrite meteorites by Papanastassiou and Wasserburg (1969). Although this method was first used to obtain an age by Hahn et al. (1943), it was not until Nier-type mass spectrometers (see entry “► [Mass Spectrometers](#)”) were readily available that it came into widespread use. The principles of the Rb–Sr system and its application to geologic materials are discussed by several authors (e.g., Dickin 2005; Faure 1998; see entry “► [Rb–Sr Dating](#)”) and are not reiterated here. However, it is important to understand that Rb–Sr ages are based on the isochron method in which several aliquots, usually separated mineral fractions, of a sample are analyzed for $^{87}\text{Rb}/^{86}\text{Sr}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios and then plotted on an isochron diagram. The slope of a regression line through the data defines the age of the sample, and the y intercept defines the initial Sr isotopic composition of the fractions at the time they formed from a common source. Uncertainty in the ages is based primarily on the scatter of the data points on the isochron diagram. Ages determined from this method are only valid if the aliquots that define the isochron regression were in isotopic equilibrium when they formed. Thus, the age records the time elapsed since the aliquots shared a common Sr isotopic composition. This is usually considered to be when the minerals crystallized from a magma.

In order to obtain an age from the slope of the isochron, the ^{87}Rb decay constant must be known. Unfortunately, the decay of ^{87}Rb to ^{87}Sr is a low-energy transformation of only 275 keV, involving the emission of a beta particle and an antineutrino ($_{37}^{87}\text{Rb} \rightarrow _{38}^{87}\text{Rb} + \beta + \nu^- + Q$), and is therefore difficult to measure accurately. As a result, meteorite Rb–Sr ages have been calculated using several decay constants ranging from $1.39 \times 10^{-11} \text{ year}^{-1}$ to $1.42 \times 10^{-11} \text{ year}^{-1}$ (Aldrich et al. 1956; Steiger and Jäger 1977). Ages reported in the literature must therefore be adjusted to a common decay constant for comparison. After a detailed analysis of published ^{87}Rb decay constants, Begemann et al. (2001) suggested using the value of $1.402 \times 10^{-11} \text{ year}^{-1}$ determined by Minster et al. (1982) and Shih et al. (1985). This is the value most commonly used for meteorite and lunar chronology studies today. Another factor that must be considered when examining Rb–Sr data in the literature is the range of $^{87}\text{Sr}/^{86}\text{Sr}$ values obtained on standards. This is complicated by the fact that early investigations used different strontium isotopic standards, such as seawater or plagioclase separated from meteorites. In the mid-1970s, the NBS-987 standard became widely used, and individual laboratories often normalized their data to the certified $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.71014. More recently, the consensus of the Rb–Sr isotope community is that $^{87}\text{Sr}/^{86}\text{Sr}$ value of this standard is 0.71025. In this discussion, all $^{87}\text{Sr}/^{86}\text{Sr}$ data are renormalized to this $^{87}\text{Sr}/^{86}\text{Sr}$ value, and Rb–Sr ages are recalculated using an ^{87}Rb decay constant of $1.402 \times 10^{-11} \text{ year}^{-1}$.

Chondrites, Angrites, and Eucrites

Ideally the slope of a regression line constructed to pass through a suite of whole rock and/or mineral fractions, and typically shown on a Rb–Sr isochron diagram, is used to constrain the age of a sample. In some cases, ancient Rb–Sr ages have been obtained for individual basaltic achondrites, such as Ibitira and Juvinas (Allègre et al. 1975; Birck and Allègre 1978), which record the crystallization age of the sample. However, many meteorite samples either have limited internal variation in $^{87}\text{Rb}/^{86}\text{Sr}$ or demonstrate evidence for significant disturbance of the Rb–Sr system by secondary processes occurring on their parent bodies or on Earth. To address these problems, ages of individual samples have been calculated from an assumed initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio. In one of the first investigations of meteorite samples, Papanastassiou and Wasserburg (1969) measured Rb–Sr in a group of basaltic achondrites obtaining an age of 4.35 ± 0.24 billion years (Ga) and an initial $^{87}\text{Sr}/^{86}\text{Sr}$ of 0.699099 ± 0.000044 (Fig. 1). This is a whole rock isochron and is based on the premise that all the analyzed meteorites are derived from a common source region at the same time. As such, the initial Sr isotopic composition determined from the isochron records the value of the source region. This initial value is known as BABI (Basaltic Achondrite Best Initial) and is used as a reference point for model ages calculated from the Rb–Sr isotopic compositions of other meteoritic samples. BABI model ages have proven invaluable in constraining the relative age of the earliest meteorite samples (e.g., Papanastassiou 1970) due to the disturbed nature of their Rb–Sr isotopic systematics.

A summary of initial $^{87}\text{Sr}/^{86}\text{Sr}$ values from the most ancient meteorite samples is presented in Table 1. From this table, it is apparent that BABI is not the least radiogenic Sr isotopic composition measured in the Solar System. This reflects the fact that other meteorite samples, such as calcium–aluminum–rich inclusions (CAIs) from carbonaceous chondritic meteorites and angrite meteorites, are older than the basaltic achondrites. The initial Sr isotopic compositions measured by Gray et al. (1973) of these samples were given acronyms as follows: Allende (ALL) and Angra dos Reis

Table 1 Initial Sr isotopic compositions of ancient samples

Sample	Measured initial $^{87}\text{Sr}/^{86}\text{Sr}$	Normalized initial $^{87}\text{Sr}/^{86}\text{Sr}^a$	Reference
Allende CAI D7 ($\equiv$ ALL)	0.69876 ± 0.00004	0.69887 ± 0.00004	Gray et al. (1973)

Basaltic Achondrites ($\equiv$ BABI)	0.69899 ± 0.00004	0.69910 ± 0.00004	Papanastassiou and Wasserburg (1969)
Basaltic Achondrites	0.69899 ± 0.00004	0.69909 ± 0.00004	Birck and Allègre (1978)

^aData normalized to NBS-987 = 0.71025. Initial isotopic compositions calculated from isochron or least radiogenic sample using of $\lambda^{87}\text{Rb} = 1.402 \times 10^{11} \text{ year}^{-1}$. More significant figures are often available from original references

(ADOR). Subsequent measurements on the same sample types are often slightly different than the original values and are listed separately in Table 1.

Martian Meteorites

Whereas obtaining internal Rb–Sr isochron ages for the most ancient meteorites has often proven to be a difficult task, defining Rb–Sr ages for young meteorites from differentiated bodies, such as Mars and the Moon, has been less difficult. The first unequivocal young Rb–Sr date was determined for the meteorite Nakhla, which belongs to the SNC (shergottite-nakhlite-chassigny) group of meteorites. Ages of $1.30 \pm 0.02 \text{ Ga}$ and $1.23 \pm 0.01 \text{ Ga}$ were determined by Papanastassiou and Wasserburg (1974) and Gale et al. (1975). Young ages of 163–178 million years (Ma) were later obtained on the related Shergotty and Zagami meteorites by Nyquist et al. (1979a) and Shih et al. (1982). Initially the young ages obtained on the SNC meteorites were interpreted to reflect isotopic re-equilibrium associated with extensive metamorphism of their parent body. The extent of metamorphism required to reset the Rb–Sr system led Nyquist et al. (1979b) to conclude that the parent body was very large and likely to be the planet Mars. Later petrologic work (Jones 1986) and isotopic analysis involving the Sm–Nd chronometer (Borg et al. 1997) demonstrated that the ages most likely recorded a crystallization event rather than a metamorphic event. Numerous Rb–Sr (and Sm–Nd) ages have now been obtained of the SNC suite of Martian meteorites. The shergottites define 4 general age groups of ~170 Ma, ~330 Ma, ~475 Ma, and ~575 Ma (see summaries by Nyquist et al. 2001a; Borg and Drake 2005). Several additional nakhlites have also been dated at 1.3 Ga (e.g., Shih et al. 1999). An age of $2,089 \pm 81 \text{ Ma}$ has been reported for NWA7034 meteorite (Agee et al. 2013). This meteorite is a breccia, and mineral fractions were derived from the bulk sample. Implicit in this age determination is the assumption that all of the breccia fragments and matrix minerals crystallized from the same magma at the same time. Finally a Rb–Sr age of $3.90 \pm 0.04 \text{ Ga}$ was determined on secondary carbonates handpicked from the orthopyroxenite ALH84001 (Borg et al. 1999).

Initial $^{87}\text{Sr}/^{86}\text{Sr}$ values have been determined from the Rb–Sr isochrons and demonstrate a huge range from ~0.701 (e.g., Borg et al. 1997) to 0.723 (e.g., Nyquist et al. 1979a). The initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios, along with initial $^{143}\text{Nd}/^{144}\text{Nd}$ ratios, indicate that the shergottites are derived from source regions that have elemental abundances that range from incompatible-element depleted to

Table 2 Representative ages and initial Sr isotopic compositions of Martian meteorites

Sample	Rb–Sr age	Initial ⁸⁷ Sr/ ⁸⁶ Sr	Reference
Zagami (E)	171 ± 8 Ma	0.721566 ± 0.000082	Shih et al. (1982)
EET79001B (I)	172 ± 18 Ma	0.71217 ± 0.00003	Nyquist et al. (1986)
ALH77005 (I)	187 ± 12 Ma	0.71037 ± 0.00005	Shih et al. (1982)
QUE94201 (D)	327 ± 12 Ma	0.701298 ± 0.000014	Borg et al. (1997)
Nakhla	1.30 ± 0.02 Ga	0.70232 ± 0.00006	Papanastassiou and Wasserburg (1974)
Chassigny	1.22 ± 0.01 Ga	0.70253 ± 0.00004	Nakamura et al. (1982)

Letters after shergottite names refer to incompatible-element characteristics of their source regions (E) = enriched, (D) = depleted, and (I) = intermediate

incompatible-element enriched. The shergottites have consequently been subdivided on this basis (Symes et al. 2008). A sampling of Rb–Sr ages determined for the various types of Martian meteorites is presented in Table 2, with an emphasis on the first age determinations for each meteorite.

Lunar Meteorites

Several relatively young ages have also been determined for lunar meteorites. For the most part, however, Rb–Sr ages have been confined to basaltic samples. Like highland rocks returned by the Apollo missions, the Rb–Sr isotopic systematics of highland clasts present in brecciated meteorites appear to be disturbed by metamorphic processes associated with impact. A good example of such disturbance is in anorthositic meteorite Y86032 that yields a Rb–Sr age of 4.62 ± 0.89 Ga (Nyquist et al. 2006). Metamorphism appears to result in the mobilization, and loss, of Rb from the mafic mineral fractions. Thus, Rb–Sr isochrons are generally disturbed to the older side of the age spectrum.

A few basaltic lunar meteorites have been dated using the Rb–Sr chronometer. An age of $2,990 \pm 18$ Ma was reported for the incompatible-element-enriched LaPaz 02205 meteorite (Rankenburg et al. 2006), whereas low Ti-basaltic meteorites NWA 032 and NWA 4734 yielded ages of $2,947 \pm 16$ Ma (Borg et al. 2009) and $3,083 \pm 42$ Ma (Elardo et al. 2014), respectively. Many of the lunar meteorites were found in desert environments and consequently have Rb–Sr systematics that have been disturbed by terrestrial weathering. The Rb–Sr systematics of NWA4734, for example, is based on a two-point tie line. Luckily this age was confirmed by a more robust Sm–Nd isochron that was derived from additional mineral fractions. Ages determined on lunar basaltic meteorites demonstrate that these samples have crystallization ages that are younger than any samples returned by the Apollo and Luna missions. In fact, the meteorites are the youngest lunar samples known (Borg et al. 2004). This is consistent with the hypothesis that they are derived from different localities on the Moon.

Sm–Nd Chronology of Meteorites

Introduction

Samarium-neodymium ages of meteorites are derived from two independent parent-daughter isotope pairs. The first decay reaction is $^{147}_{62}\text{Sm} \rightarrow ^{143}_{60}\text{Nd} + \alpha + \text{Q}$. The parent isotope ^{147}Sm has a well-defined half-life of 106 billion years corresponding to a ^{147}Sm decay constant of $6.54 \times 10^{-12} \text{ year}^{-1}$. Like the ^{87}Rb – ^{87}Sr decay system (see entry “► [Rb–Sr Dating](#)”), this system is based on the isochron method in which separated mineral fractions of an individual samples are analyzed for $^{147}\text{Sm}/^{144}\text{Nd}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ and plotted on an isochron diagram (Dickin 2005; Faure 1998; see entry “► [Sm–Nd Dating](#)”). Ages determined from this method are only valid if the aliquots that define the isochron

regression were in isotopic equilibrium. It should be noted that different laboratories have used different Nd isotopic ratios, including $^{142}\text{Nd}/^{144}\text{Nd}$, $^{146}\text{Nd}/^{144}\text{Nd}$, and $^{148}\text{Nd}/^{144}\text{Nd}$, as well as different isotopic compositions, to correct for instrument mass fractionation. Caution must therefore be taken when comparing the initial $^{143}\text{Nd}/^{144}\text{Nd}$ values reported from different laboratories.

The second decay reaction is $^{146}_{62}\text{Sm} \rightarrow ^{142}_{60}\text{Nd} + \alpha + \text{Q}$. The parent isotope, ^{146}Sm , is extinct so this system can only be used to date samples older than ~ 4.3 Ga. As a consequence, this system is used almost exclusively to date meteorite samples. Model ages are obtained by determining the initial $^{146}\text{Sm}/^{144}\text{Sm}$ ratio of the sample at the time it formed from the slope of a $^{144}\text{Sm}/^{144}\text{Nd}$ – $^{142}\text{Nd}/^{144}\text{Nd}$ isochron plot. A model age is defined by the time required to produce the initial $^{146}\text{Sm}/^{144}\text{Sm}$ ratio of the sample starting from the initial $^{146}\text{Sm}/^{144}\text{Sm}$ ratio Solar System at 4,567 Ma. In turn, the initial $^{146}\text{Sm}/^{144}\text{Sm}$ ratio of the Solar System is calculated from the initial $^{146}\text{Sm}/^{144}\text{Sm}$ ratio measured on a reference sample of known age. The reference samples used to determine ^{146}Sm – ^{142}Nd ages have traditionally been angrite meteorites (e.g., Nyquist et al. 1994), although eucrites (Boyet et al. 2010) and CAIs (Marks et al. 2014) have been proposed more recently. One obstacle to the application of the short-lived Sm–Nd system to date meteorite samples has been defining the appropriate half-life for ^{146}Sm . Values of 68 Ma (Kinoshita et al. 2012) and 103 Ma (Friedman et al. 1966; Meissner et al. 1987) have both been used to calculate ^{146}Sm – ^{142}Nd ages. Either half-life appears to reproduce Pb–Pb ages on the oldest samples, because the uncertainties on the ^{146}Sm – ^{142}Nd ages are often larger than the difference in ages calculated using the 68 Ma and 103 Ma half-lives. The 103 Ma half-life appears to better reproduce the Pb–Pb and ^{147}Sm – ^{143}Nd ages of young lunar samples, however (Marks et al. 2014).

The chemical purification procedures developed to separate Sm and Nd from matrix start with the purification of Rb–Sr. As a consequence, most Sm–Nd isochrons obtained today on meteorite samples are accompanied by Rb–Sr data from the same fractions. The simultaneous analysis of Sm–Nd and Rb–Sr has made the interpretation of some ages significantly easier, because concordant Sm–Nd and Rb–Sr ages typically indicate that these chronometers record the timing of igneous crystallization. Co-analysis of Sm–Nd and Rb–Sr has demonstrated that the Sm–Nd system is less easy to disturb by post-crystallization metamorphism and secondary alteration than the Rb–Sr system. Thus, many of the most reliable ages obtained on meteorites are currently derived from the Sm–Nd system.

Primitive Achondrites

Lugmair (1974) first proposed using the ^{147}Sm – ^{143}Nd system as a dating method and demonstrated its feasibility by obtaining an age of 4.56 ± 0.08 Ga on the eucrite Juvinas. This was followed by application of the Sm–Nd system to the angrite Angra dos Reis, yielding an age of 4.55 ± 0.04 Ga (Lugmair and Marti, 1977), as well as to lunar samples (e.g., Lugmair et al. 1976). Early in the development of the Sm–Nd chronometer, evidence for live ^{146}Sm was sought, but the results were equivocal (Notsu and Mabuchi 1973; Lugmair et al. 1975). The first clear evidence for live ^{146}Sm came from analysis of Angra dos Reis by Lugmair and Marti (1977). They reported a 60 ppm difference between phosphate and pyroxene mineral fractions and attributed the difference to radiogenic decay of ^{146}Sm . The ^{146}Sm – ^{142}Nd and ^{147}Sm – ^{143}Nd isotopic systems have been used to date many differentiated achondrite meteorites including angrites, eucrites, mesosiderites, a brachinite, and an alcapulcoite. A forthcoming manuscript by Marks et al. (2014) provides a summary of some of these results.

Table 3 Representative ages and initial Nd isotopic compositions of Martian meteorites

Sample	Sm–Nd age	Initial ϵ_{Nd}	Reference
Zagami (E)	166 ± 12 Ma	-7.23 ± 0.17	Borg et al. (2005)

ALH77005 (I)	173 ± 6 Ma	$+11.1 \pm 0.2$	Borg et al. (2002)
QUE94201 (D)	327 ± 19 Ma	$+47.6 \pm 1.7$	Borg et al. (1997)
Governador Valadares	1.37 ± 0.02 Ga	$+16.7 \pm 0.4$	Shih et al. (1999)

Letters after shergottite names refer to incompatible-element characteristics of their source regions (E) = enriched, (D) = depleted, and (I) = intermediate

Martian and Lunar Meteorites

The Sm–Nd system has also been applied to the Martian suite of meteorites that includes shergottites (basalts), nakhlites (clinopyroxenites), chassignites (dunites), as well as an orthopyroxenite (ALH84001). Application of the Sm–Nd chronometer to these samples is very difficult because they have very low abundances of Sm and Nd, contain phosphate minerals that host the vast majority of the Sm and Nd in the rock, and often contain copious amounts of impact melt. As a consequence, mineral fractions derived from Martian meteorites have some of the lowest abundances of Nd of any planetary sample. Not surprisingly, initial attempts to date Martian meteorites yielded highly disturbed Sm–Nd isochrons (e.g., Shih et al. 1982) that seemed to confirm the original hypothesis that these meteorites underwent extensive metamorphism. Thus, young Rb–Sr and U–Th–Pb ages determined from these meteorites were interpreted to record the timing of this event (Papanastassiou and Wasserburg 1974; Nyquist et al. 1979a, b; Chen and Wasserburg 1986). However, Borg et al. (1997) obtained high purity mineral fractions from QUE94201 that were devoid of impact melt glass that yielded young concordant Rb–Sr and Sm–Nd ages of ~330 Ma and suggested that the young ages recorded the crystallization of the sample. Concordant ages for numerous Martian meteorites have now been obtained using Rb–Sr, Sm–Nd, U–Pb, and Lu–Hf chronometers that support this contention. Although most researchers consider these ages to record igneous crystallization, some still support the older hypothesis that the young ages reflect secondary resetting of the isotopic systems by metamorphism (e.g., Bouvier et al. 2009).

Summaries of Sm–Nd ages for Martian meteorites can be found in Nyquist et al. (2001a) and Borg and Drake (2005). Like the Rb–Sr system, the Sm–Nd system can be used to define 4 general age groups for the shergottites of ~170 Ma, ~330 Ma, ~475 Ma, and ~575 Ma. In addition, the initial ϵ_{Nd} values (see entry “► [Samarium–Neodymium, Model Ages](#)”) determined from the Sm–Nd isochrons demonstrate a huge range from -7 to $+48$ (e.g., Borg et al. 1997, 2005). The initial ϵ_{Nd} values, along with initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios, indicate that the shergottites are derived from source regions that have elemental abundances that range from incompatible-element depleted to incompatible-element enriched. Samarium–neodymium ages of ~1.3 Ga have been determined from the nakhlites (e.g., Shih et al. 1999), and ages ranging from 4.0 to 4.5 Ga have been obtained for ALH84001 (Nyquist et al. 1995a; Lapen et al. 2010). A sampling of Sm–Nd ages determined for the various types of Martian meteorites is presented in Table 3. In contrast to the Rb–Sr ages presented in the Rb–Sr chronology of meteorites (see entry “► [Rb–Sr Chronology of Meteorites](#)”), this table emphasizes the more recent chronology for each meteorite because the newer data is generally less disturbed.

Several lunar meteorites have been dated using the Sm–Nd system. Unlike many Apollo samples, the Sm–Nd isotopic systematics of most meteorites appear to be minimally affected by the capture of thermal and epithermal neutrons that are produced in the lunar subsurface by bombardment of

galactic cosmic rays. The oldest sample is an anorthositic clast from Y86032 which yields an age of 4.43 ± 0.03 Ga (Nyquist et al. 2006), making it one of the oldest dated rocks from the Moon. Most other Sm–Nd chronometry has been applied to lunar basaltic meteorites. Samarium-neodymium ages of $2,931 \pm 92$ Ma, $2,993 \pm 32$, $3,106 \pm 44$ Ma, and $2,922 \pm 85$ Ma have been determined for NWA032, NWA773 NWA 4734, and LAP02205 (Borg et al. 2004, 2009; Elardo et al. 2014; Rankenburg et al. 2006) that are in good agreement with Rb–Sr ages determined on the same samples. This suite of basalts is the youngest group of lunar rocks that have been dated from the Moon so far and serves to demonstrate that there is significantly more geologic variation on the Moon than is represented in the Apollo (or Luna) sample collections.

Finally, the age of differentiation of both Moon and Mars has been estimated from Sm–Nd whole rock isochrons completed on lunar samples, including meteorites, and Martian meteorites. The age of lunar differentiation is determined using the Sm/Nd ratio estimated for basalt magma sources from measured $^{143}\text{Nd}/^{144}\text{Nd}$ ratios and $^{142}\text{Nd}/^{144}\text{Nd}$ ratios measured for the whole rocks. The model age is calculated from the slope of a line regressed through whole rock data on a ^{146}Sm – ^{142}Nd isochron plot. The basis of these model ages is the assumption that isotopic variation observed in the basalt source regions reflects fractionation of Sm from Nd associated with solidification of the lunar magma ocean. Ages of $4,329^{+40}_{-56}$ Ma (Nyquist et al. 1995a), $4,352^{+21}_{-23}$ Ma (Rankenburg et al. 2006), $4,313^{+25}_{-30}$ (Boyett and Carlson 2007), $4,340^{+20}_{-24}$ (Brandon et al. 2009), and $4,355^{+31}_{-39}$ Ma (Gaffney and Borg 2014) have been determined by these studies. All ages are within uncertainty of the original model age obtained by Nyquist et al. (1995a) and yield a weighted average age of $4,341 \pm 21$ Ma.

The model age of Martian differentiation has been estimated using the slope of shergottite whole rock $^{142}\text{Nd}/^{144}\text{Nd}$ – $^{143}\text{Nd}/^{144}\text{Nd}$ isotopic data to be $4,513^{+27}_{-33}$ Ma (Borg et al. 2003), $4,525^{+19}_{-21}$ Ma (Foley et al. 2005), and $4,502 \pm 5$ Ma (Symes et al. 2014). It has also been determined from ^{146}Sm – ^{142}Nd whole rock isochron to be $4,527 \pm 18$ Ma (Caro et al. 2008) and from model age determined on individual samples to be $4,535 \pm 7$ Ma (Debaille et al. 2007). All ages are within uncertainty of the original model age determined on QUE94201 of $4,525 \pm \sim 25$ Ma (Borg et al. 1997). The weighted average of all these ages is $4,505 \pm 11$ Ma, indicating that the Moon differentiated significantly after Mars.

Seawater Sr Curve

Galen P. Halverson* and Lucie Théou-Hubert

Department of Earth and Planetary Sciences/Geotop, McGill University, Montréal, QC, Canada

Definition

The seawater Sr curve is a proxy record of the $^{87}\text{Sr}/^{86}\text{Sr}$ value of seawater through time, as reconstructed from well-preserved minerals precipitated from seawater.

Introduction

Prior to the development of the analytical technique to measure precise strontium isotope ratios, Wickman (1948) predicted that the ratio of radiogenic to unradiogenic strontium ($^{87}\text{Sr}/^{86}\text{Sr}$), as measured in carbonates and evaporate minerals precipitated from seawater, might be used as a tool to date ancient marine sediments. Wickman's rationale was straightforward, even if, upon hindsight, partially incorrect and incomplete: the gradual concentration of Rb in the continental crust and decay of radiogenic ^{87}Rb would result in monotonically increasing $^{87}\text{Sr}/^{86}\text{Sr}$ values of the crust and hence a steady rise in seawater strontium isotope composition over geological time. He presciently noted that due to the effective separation of Sr and Rb in carbonates, in particular mollusk shells, limestone was the ideal target for determining ancient seawater Sr isotope ratios. Although $^{87}\text{Sr}/^{86}\text{Sr}$ is now measured on a wide variety of minerals, well-preserved foraminifera tests and brachiopod shells are among the prime targets for Sr isotope chemostratigraphy of Phanerozoic sediments (Veizer et al. 1999; McArthur et al. 2012).

Burke et al. (1982) published the first comprehensive record of Phanerozoic $^{87}\text{Sr}/^{86}\text{Sr}$, which revealed multiple peaks and troughs that correspond in part to major plate tectonic events. This entry firmly established the application of strontium isotope chemostratigraphy as a geochronological tool with wide applications in Earth history. The history of the development of the seawater Sr curve and the fundamentals of its application are briefly reviewed here. For a thorough treatment of strontium isotope stratigraphy and its geochronological applications, the reader is referred to the recent review by McArthur et al. (2012).

Development and Application of the Method

With the development of techniques to separate strontium and analyze its isotopic ratios by solid source mass spectrometry, Wickman's (1948) hypothesis that seawater $^{87}\text{Sr}/^{86}\text{Sr}$ changed through time was put to the test in the 1950s and 1960s. Early results suggested that due to a combination of lower-than-predicted variation in Rb/Sr ratios in rock-forming minerals, poor age control on samples, and as yet limited analytical precision, strontium isotopes might not live up to their

Fig. 1 The seawater $^{87}\text{Sr}/^{86}\text{Sr}$ curve for the past 1.0 billion years. The Ordovician–Present portion of the curve is the LOWESS fit from McArthur et al. (2012), updated from McArthur et al. (2001). The Neoproterozoic–Cambrian portion of the curve (*dashed line*) is much more poorly calibrated and of lower resolution (Adapted from Shields and Veizer (2002) and Halverson et al. (2007, 2010))

promise as an effective tool in dating ancient marine sediments (Gast 1955). However, geochemists did not give up, and subsequent application of the technique highlighted the potential to unravel past geological processes, including growth of the continental crust, using the strontium isotope system (e.g., Hurley et al. 1962; Hedge and Walthall 1963).

Another early target of the Sr isotope method was in characterization of seawater (e.g., Compston and Pidgeon 1962; Hedge and Walthall 1963; Faure et al. 1965). This work demonstrated that the strontium isotope composition of the present oceans is effectively uniform (0.7092) due to the long residence time of strontium in the oceans ($\sim 3\text{--}5 \times 10^6$ years) versus the effective mixing time of the oceans ($\sim 10^3$ years). Faure et al. (1965) further argued that seawater composition at any given time was the result of a mixture of Sr from several different reservoirs with strongly contrasting strontium isotope ratios, most notably mafic versus felsic continental crust and marine carbonates. Armstrong (1971) proposed that weathering related to continental glaciation might also exert a strong influence on seawater Sr isotope compositions.

Hedge and Walthall (1963) published the first dataset on ancient carbonates and argued that these limited data supported a roughly linear evolution in marine $^{87}\text{Sr}/^{86}\text{Sr}$ over geological time, consistent with Wickman's (1948) hypothesis. However, Peterman et al. (1970) published the first Phanerozoic seawater strontium isotope curve, which, although at a low resolution (by modern standards) and limited by poor age constraints, showed that $^{87}\text{Sr}/^{86}\text{Sr}$ both rose and decreased during the Phanerozoic, with a notable trough across the Jurassic–Cretaceous boundary. Veizer and Compston (1974) subsequently upgraded the Phanerozoic record, taking into account diagenetic effects on $^{87}\text{Sr}/^{86}\text{Sr}$ in marine carbonates and applying the now canonical principle that the lowest $^{87}\text{Sr}/^{86}\text{Sr}$ values for rocks of any given time interval most reliably record coeval seawater

Fig. 2 A basic box model illustrating the marine Sr cycle with present strontium isotope compositions for fluxes and reservoirs. The main sources of seawater Sr are the seafloor hydrothermal flux and the continental weathering flux. The sizes of the arrows scale to the relative size of the associated flux into and out of the ocean (from Banner 2004). Note that the flux from diagenesis of marine sediments (dominated by carbonates) is effectively negligible because it releases strontium with nearly the same composition as the seawater reservoir (Kump 1989). Strontium is removed from seawater as a trace component of marine carbonates (and to a minor extent sulfates)

composition. This compilation confirmed the late Jurassic–Cretaceous $^{87}\text{Sr}/^{86}\text{Sr}$ trough and also revealed a prominent Cenozoic rise in $^{87}\text{Sr}/^{86}\text{Sr}$ (Fig. 1).

A decade later, Burke et al. (1982) published a much higher-resolution Phanerozoic seawater $^{87}\text{Sr}/^{86}\text{Sr}$ compilation that reproduced the broad patterns documented by Veizer and Compston (1974) but also demonstrated a more complex history of seawater strontium, with multiple peaks, troughs, and intervals of rapid change. Burke et al. (1982) interpreted the fluctuations in seawater $^{87}\text{Sr}/^{86}\text{Sr}$ in terms of the competing influence of unradiogenic (~ 0.7035) strontium derived from mid-ocean ridges (i.e., hydrothermal) and radiogenic strontium (~ 0.720 at present) derived from weathering of the continents (Fig. 2), with carbonate-derived (weathered) strontium acting as a buffer rather than a driver of change. These fluctuations, they argued, corresponded to tectonic events and reorganization of the continents during the Phanerozoic. This compilation also implicitly demonstrated a much improved potential for using strontium isotopes in marine carbonates as a dating tool, in particular during intervals of rapidly evolving $^{87}\text{Sr}/^{86}\text{Sr}$, such as the Cambro-Ordovician, Permian, and Jurassic (McArthur et al. 2001). DePaolo and Ingram (1985) later showed how high-precision Sr isotope chemostratigraphy could be used as a more effective dating tool than paleomagnetism and stable isotope chemostratigraphy during intervals such as the past 35 m.y., where $^{87}\text{Sr}/^{86}\text{Sr}$ has been rising steadily and rapidly, presumably due in large part to the Alpine–Himalayan orogeny (Edmond 1992) and/or Antarctic glaciation (Zachos et al. 1999).

Subsequent work on the seawater strontium isotope curve has involved focused efforts to produce high-resolution records through specific time intervals (e.g., De Paolo and Embry; Koepnick et al. 1990; Paytan et al. 1993; Shields et al. 2003), comprehensive Phanerozoic compilations from well-constrained and well-preserved samples (McArthur 1994; Veizer et al. 1999), and Precambrian compilations (Shields and Veizer 2002), most specifically for the Neoproterozoic (1,000–541 Ma), which shows changes comparable to the Phanerozoic (Shields 2007; Halverson et al. 2007; Fig. 1). Strontium isotope chemostratigraphy has proven particularly valuable in the Neoproterozoic, where lack of biostratigraphic constraints and consequent poor age control necessitate alternative dating methods.

Sample Selection and Diagenetic Considerations

As Wickman (1948) noted, the best materials for strontium isotope chemostratigraphy are minerals that precipitated from seawater. Many different materials have been explored and analyzed as proxies for seawater composition, including both aragonite and calcite bulk rock, shells, otoliths (fish ear bones), other biogenic and inorganic CaCO_3 precipitates, phosphatic material such as conodonts, and sulfates, namely, evaporite minerals (e.g., CaSO_4) and barite (BaSO_4). Due to the relatively high Sr concentration in primary aragonite (up to 1 wt%), originally aragonitic tests and shells (and to a lesser extent early marine cements) may be good targets for Sr isotope analyses. However, primary aragonite is unstable in the diagenetic realm and rare in the geological record. Furthermore, the type of materials available for strontium isotope stratigraphy is heavily dependent on geological age. Calcitic foraminifera tests recovered from deep sea cores have proven to be well suited for the Cenozoic record (McArthur et al. 2012), whereas brachiopod shells (Veizer et al. 1999) and belemnite guards (Jones et al. 1994) are among the most robust proxies for the Mesozoic and Paleozoic eras.

The paucity to absence of biogenic carbonates in Cambrian and older strata necessitates the use of bulk rocks for strontium isotope analyses. Conveniently, seawater and calcite contain only trace amounts of Rb; unfortunately, carbonate sediments also typically contain an acid insoluble (detrital) component, resulting in a degree of ingrowth of ^{87}Sr from detrital ^{87}Rb , mostly from clays. Coupled with loss of Sr during diagenesis, this can result in significantly elevated $^{87}\text{Sr}/^{86}\text{Sr}$ values in the carbonate fraction, even in carefully processed carbonate samples. Techniques are available for correcting for radiogenic ^{87}Sr ingrowth (e.g., McArthur 1994); however, where possible, low-Rb carbonates should be targeted for Sr isotope stratigraphy. Analyzing multiple samples from the same or closely spaced stratigraphic horizons is also useful in determining the pattern of alteration of $^{87}\text{Sr}/^{86}\text{Sr}$ during diagenesis (Banner and Hanson 1990; McArthur et al. 2012) and constraining the most likely seawater composition, which is typically assumed to be less than or equal to the lowest $^{87}\text{Sr}/^{86}\text{Sr}$ value.

The crystal lattice of dolomite, a common secondary carbonate mineral, does not accommodate the relatively large Sr^{2+} cation. Hence, dolostones, which comprise a significant fraction of the stratigraphic record, have sparingly low Sr concentrations (typically less than 100 ppm), making them highly prone to isotopic overprinting and in most cases unsuitable for strontium isotope stratigraphy. Other carbonate minerals, such as ankerite and siderite, typically form authigenically and hence are also poor proxies for seawater Sr isotope composite.

Analytical Techniques

Sample preparation and analyses for Sr isotopes on carbonate minerals (and other seawater precipitates) involve four steps: sample selection, sample cleaning and dissolution, chemical separation, and measurement of isotope ratios by mass spectrometry. Because only samples with minimal Rb contents consistently yield reliable data, only Sr isotope ratios (and not precise Sr or Rb concentrations) are typically measured for Sr isotope stratigraphy, hence eliminating the requirement to add an isotopic tracer solution, unless a radiogenic ingrowth correction is required:

1. Sample selection is performed based on a combination of petrographic and geochemical prescreening. Those samples showing the least recrystallization and overprinting by secondary

Fig. 3 A. The LOWESS fit Sr isotope curve for the time interval 200–140 Ma ago (Jurassic stages in *blue* and *gray*: *Aal* Aalenian, *Bj* Bajocian, *Bt* Bathonian, *Cal* Callovian, *Kimm* Kimmeridgian. Cretaceous Berriasian stage is in *green*), from McArthur et al. (2012). The *red* line is the LOWESS fit, and the *blue* lines mark the upper and lower 95 % confidence intervals. *Dashed* line at $^{87}\text{Sr}/^{86}\text{Sr} = 0.70720$ demonstrates the nonuniqueness of this value during the Jurassic, where it occurs during four distinct stages. B. Inset is a zoom-in of the interval from 170 to 169 Ma. If a sample with a Sr isotope composition of 0.70720 is known to be Bajocian in age (e.g., based on biostratigraphy or other chemostratigraphic data), then an age can be determined by comparison with the reference curve. In this case, a value of 0.70720 yields an age of $169.60 \pm \sim 0.04$ Ma (note that the error does not factor in uncertainty related to the calibration of the time scale)

cements, relatively high Sr/Rb ratios (or in the absence of Rb data, high Sr/Ca ratios), and low detrital component are best suited for Sr isotope analyses.

2. Sample dissolution is usually performed in a dilute acid such as weak acetic acid, which minimizes partial dissolution of the non-carbonate fraction. In order to further reduce incorporation of detrital strontium, it is common to pre-leach sample powders in ammonium acetate, which removes loosely bound Sr ions (Bailey et al. 2000). A prewash with methanol (McArthur et al. 2006) is also effective in removing clays from a sample powder, reducing the potential for leaching of detrital strontium during sample dissolution.
3. Dissolved samples are passed through an ion exchange resin (e.g., Eichrom™ Sr-spec resin) to separate Sr from other ions (see also entry on ► [Chromatography](#)), most importantly Ca and Rb, which can greatly affect Sr isotope measurements.
4. Traditionally, Sr isotope analyses have been performed by solid source, thermal ionization mass spectrometry (TIMS; see also entry on ► [Mass Spectrometry](#)). Measured $^{87}\text{Sr}/^{86}\text{Sr}$ values are corrected against an international standard, usually NIST (NBS) 987, with an accepted $^{87}\text{Sr}/^{86}\text{Sr}$ value of 0.710248. Reproducibility is commonly as good as ± 0.000005 (2σ). Strontium isotope

ratios may also be measured in solution or by laser ablation on a multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS). These techniques are faster, and laser ablation has the advantage that it does not require time-consuming chemical separation. However, they also yield less precise results than TIMS, although reproducibility as low as ± 0.00001 (2σ) has been achieved in solution mode (e.g., Balcaen et al. 2005). Similar precision and accuracy has not yet been realized by laser ablation MC-ICP-MS, but the technique is increasingly applied to high spatial resolution analyses of media such as fish otoliths, bones, and teeth where the high precision provided by TIMS analysis is not required (Copeland et al. 2010).

The Strontium Isotope Seawater Curve (1.0–0 Billion Years)

Since Burke et al. (1982) published their record of Phanerozoic seawater $^{87}\text{Sr}/^{86}\text{Sr}$, a great deal of work has gone both into developing high-resolution records for specific intervals of the Phanerozoic (e.g., Koepnick et al. 1990; Fig. 3) and in producing compilations of the highest-quality and best dated samples (Veizer et al. 1999; McArthur et al. 2001). The most comprehensive compilation of Phanerozoic $^{87}\text{Sr}/^{86}\text{Sr}$ data is found in the database of McArthur et al. (2001), which has been progressively updated (e.g., McArthur and Howarth 2004; McArthur et al. 2012), and now comprises over 4,000 data points from some 50 sources (McArthur et al. 2012). The construction of such a record requires the application of age models to specific data sets, the integration of these data sets, and a technique for fitting a curve to the data, which can then be used to calculate an age and appropriate error (see Howarth and McArthur 1997, for detailed description of data treatment and analysis for the Phanerozoic seawater Sr curve shown in Fig. 1). For the relatively well-dated Phanerozoic record, age models are reasonably robust and there exist high-resolution records, resulting in typical 95 % confidence intervals about the best-fit curve of 0.00001–0.00004 (McArthur et al. 2012).

The most complete database for Precambrian strontium isotopes is from Shields and Veizer (2002). However, the age constraints on Precambrian samples are deficient, and the quality of data is lower and more difficult to verify than for the Phanerozoic. Here, we include only data from 1.0 billion years onward because the pre-1.0 Ga record is poor and shows only limited change, in contrast with the 1,000–485 Ma Sr isotope record, which has been extensively studied and shows significant variability. Because the resolution and quality of the data from this time interval is low, rigorous fitting techniques as used for the Phanerozoic record are not yet applicable.

The Proterozoic–Phanerozoic strontium isotope seawater curve (Fig. 1) reveals many striking features. The first-order trend is one of increasing $^{87}\text{Sr}/^{86}\text{Sr}$, which results from the progressive decay of ^{87}Rb (Wickman 1948; Shields 2007). The second-order pattern is one of peaks at present and c. 500 Ma ago and troughs at about 180 and 1,000 Ma ago, which may reflect the cycle of supercontinental breakup and assembly (Halverson et al. 2007). Superimposed on this pattern are prominent fluctuations, some by as much as 0.001, over intervals of a few to 25 Ma, many of which closely correspond to tectonic events.

The main parameters controlling the seawater Sr isotope composition are the magnitude of the seafloor hydrothermal flux (both mid-ocean ridge volcanism and off-axis alteration of the seafloor) and continental weathering and their respective $^{87}\text{Sr}/^{86}\text{Sr}$ values. The composition of the seafloor flux (≈ 0.7037 ; Banner 2004) is approximately fixed by mantle composition, whereas the $^{87}\text{Sr}/^{86}\text{Sr}$ of continental weathering is presently ≈ 0.712 (Fig. 2) but presumably varied considerably through time. Because the residence time of Sr in the oceans is ~ 5 Ma and there are no plausible

mechanisms to increase or decrease the flux into or out of the oceans rapidly, changes in $^{87}\text{Sr}/^{86}\text{Sr}$ are steady state (i.e., gradual; see also entry on ► [Marine Isotope Stratigraphy](#)). In principle, changes in any one of the four major influx parameters (Fig. 2) can drive a change in seawater $^{87}\text{Sr}/^{86}\text{Sr}$, but due to the large isotopic difference between the hydrothermal and continental weathering sources, many researchers invoke changes in the relative contribution of these two fluxes to explain changes in seawater $^{87}\text{Sr}/^{86}\text{Sr}$. On the other hand, although the continental flux is buffered by the weathering of marine carbonates, the huge variations between different rivers (Gaillardet et al. 1999) suggest that the continental weathering flux should have changed substantially through time as a result of paleogeographic evolution of the continents and paleoclimate.

Use as a Geochronological Tool

Given a reference seawater $^{87}\text{Sr}/^{86}\text{Sr}$ curve, dating a marine rock or sediment of poorly constrained age may be accomplished by comparing its strontium isotope composition to a reference curve. However, the effectiveness of this tool is contingent upon the age and available age constraints on that sample, whether or not there are strontium isotope data from overlying or overlying strata, and the robustness of the curve. For example, a marine carbonate sample that is known only to be Jurassic or early Cretaceous in age and has an $^{87}\text{Sr}/^{86}\text{Sr}$ value of 0.70720 could equally be Pliensbachian (190.8–182.7 Ma), Toarcian (182.7–174.1 Ma), Bajocian (170.3–168.3 Ma), or Berriasian (145.0–139.4 Ma) in age (Fig. 3A). However, if the stage of the sample is known through biostratigraphy or other chronostratigraphic constraints, then the age can be specified more precisely (Fig. 3B), with the precision being a measure of the confidence interval for the Sr isotope curve at that age (Fig. 3) and the uncertainty in the age model upon which the reference Sr isotope curve is constructed (McArthur et al. 2012).

In the absence of additional age constraints that eliminate some of the possible matches between the sample and the reference curve, it helps to match both the absolute value and stratigraphic (i.e., temporal) trends. For example, if multiple samples from different stratigraphic levels are analyzed from the section containing the original sample of interest, then these can be used to determine the trajectory in $^{87}\text{Sr}/^{86}\text{Sr}$. If the samples show a trend of decreasing $^{87}\text{Sr}/^{86}\text{Sr}$ up-section (i.e., in progressively younger rocks), then this pattern eliminates either a Toarcian or Berriasian age, both of which correspond to intervals of increasing $^{87}\text{Sr}/^{86}\text{Sr}$ (Fig. 3A). Whereas the slope of the declining trends ($d[^{87}\text{Sr}/^{86}\text{Sr}]/dt$) differs between the Pliensbachian and Bajocian, it would be virtually impossible to use the distinction alone in a poorly dated section of strata to discriminate between these two ages. Rather, a more complete $^{87}\text{Sr}/^{86}\text{Sr}$ profile that captured, for example, the late Pliensbachian trough (0.707075) or the continued decline to $^{87}\text{Sr}/^{86}\text{Sr}$ values lower than 0.707075 in the Bathonian (Fig. 3) would be required. Alternatively, additional chemostratigraphic data such as carbonate carbon isotopes or sulfate sulfur isotopes (see entry on ► [Marine Isotope Stratigraphy](#)) or magnetic polarity data may provide sufficient constraints to narrow down the appropriate age for the 0.70720 sample.

Other Applications

The seawater strontium isotope curve has other useful applications in stratigraphy. By comparing the Sr isotope trend of a given succession of strata to the reference curve, sediment accumulation rates can be reconstructed. This application is most useful where the rate of change in $^{87}\text{Sr}/^{86}\text{Sr}$ is

high and of limited to no use where the rate of change is low or effectively nil (McArthur et al. 2012). Strontium isotopes are also useful for detecting and quantifying breaks in the stratigraphic record. Because seawater Sr isotope composition evolves gradually, any abrupt shifts within strata must record either a depositional hiatus (diastem) or an erosional disconformity. Again, this application works best where the rate of change in $^{87}\text{Sr}/^{86}\text{Sr}$ is high, in which case the offset in $^{87}\text{Sr}/^{86}\text{Sr}$ across a stratigraphic boundary can be used to approximate the amount of time missing at that stratigraphic level.

Summary and Conclusions

Strontium isotope stratigraphy has important applications as a chronostratigraphic tool. The basis for this dating method is the construction of a reference seawater strontium curve against which undated or poorly dated samples can be compared. The ability to date a given sedimentary sample or interval of strata depends on several factors: (1) the reliability of that sample as a proxy for seawater composition and the protocol by which it is analyzed, (2) independent constraints on the approximate age of that sample, and (3) the precision of both the age model and the Sr isotope data upon which the appropriate reference seawater Sr isotope curve has been constructed. A high-precision Sr isotope curve now exists for the interval from the Ordovician through the present (McArthur et al. 2012), and a lower-resolution and as yet poorly age-calibrated record for the Neoproterozoic–Cambrian is available (Fig. 1). The reliability of strontium isotope stratigraphy as a dating tool decreases with increasing age; however, its importance increases with older rocks because other dating methods are rare or less reliable. For example, in the absence of a robust biostratigraphy for Precambrian strata, strontium isotope stratigraphy will play an important role in defining the geological time scale for these older rocks.

Definitions

Cosmic rays are high-energy (10^4 to 10^{20} eV) particles composed mostly (90 %) of atomic nuclei but with some photons (gamma rays), electrons, and positrons. The majority (90 %) of the atomic nuclei are protons (H nuclei), the rest are alpha particles (He nuclei, 9 %) and nuclei heavier atoms (1 %). Two major sources of this **primary cosmic radiation** are the Sun whose flux peaks at ~100 MeV (solar cosmic rays, **SCR**) and our galaxy, the Milky Way, with the flux peak between 300 MeV and 1 GeV (galactic cosmic rays, **GCR**). We believe GCR is produced primarily in supernova events (an inference suggested by the excess over cosmic abundance of heavy nuclei).

Secondary cosmic radiation (or “secondaries”) refers to the cascade of particles produced by the interaction of primary cosmic rays with the atmosphere and the surface of the Earth. Because of the high energies of the incoming particles, a wide spectrum of hadrons, mesons, and leptons are produced. The lifetimes of many of these secondary particles are so short that they decay in a shower of lighter particles before they can interact with another atom of the material through which they are passing, but others do interact, producing yet another cascade. Ultimately, the flux is dominated by the longer-lived particles and by the particles with small interaction cross sections. By the time the primaries have passed through 10 % of the atmosphere, the secondary flux is predominately pions, kaons, protons, neutrons, muons, electrons, positrons, and gamma rays (photons). These secondaries will produce larger nuclei (cosmogenic nuclides) in the atmosphere and minerals.

Cosmogenic nuclides are produced through any interaction of primary or secondary cosmic radiation with matter. While some notable cosmogenic nuclides (isotopes) are produced from SCR (e.g., atmospheric radiocarbon is produced from low-energy (thermal) *neutron capture* by nitrogen: $^{14}\text{N}(\text{n}, \text{p})^{14}\text{C}$), the majority of TCN production is through *spallation* of a target nucleus which requires GCR primaries or secondaries with sufficient energy to exceed the binding energy of the target nucleus (a minimum of >3 MeV per target nucleon). Cosmogenic nuclides need to be distinguished from radiogenic and nucleogenic nuclides. A **radiogenic nuclide** is a daughter product of a radioactive decay (fission, beta, alpha). For U-dating methods or (U–Th)/He thermochronology, ^{234}Th + ^4He are radiogenic products of the α -decay of ^{238}U . A **nucleogenic**

*Email: john.gosse@dal.ca

nuclide is produced when an energetic radiogenic particle interacts with another nucleus just after decay of its parent. For example, ^{10}Be can be produced in a lithium-rich mineral via $^7\text{Li}(\alpha, p)^{10}\text{Be}$.

Cosmogenic nuclide dating uses the accumulation, production, or decay of cosmogenic nuclides to determine the exposure history of near-surface samples (top tens of meters on Earth or top hundreds of meters in space). This can be accomplished by measuring a cosmogenic isotope that has been produced in situ in a mineral on a rock surface or that has been produced in the atmosphere and subsequently accumulated in a soil. For instance, the concentration of ^{10}Be accumulated in a saprolite will depend on the flux of ^{10}Be in precipitation and dust delivered to the soil, the abundance and type of clay that holds the ^{10}Be , and the duration that the soil is at the surface. In addition to exposure ages, the method can determine whether a sample was at the surface or beneath it, whether the sample's position was stable or eroding, and whether the sample's surface history was interrupted by periods of burial. Examples of applications of cosmogenic nuclides that are produced in situ, but not in Earth's lithosphere, include surface exposure dating on Martian (Farley et al. 2014) and lunar surfaces (Drozd et al. 1974) and the size and exposure history of meteorites (Eugster et al. 2006). Cosmogenic nuclides produced in the atmosphere include ^{14}C (thermal-neutron capture by N). Radiocarbon dating has been widely applied for dating objects of importance in defining geologic and archaeologic chronologies; in testing the authenticity of objects of art, or worship, or historic significance; and, on even shorter time scales, in studying the inception and progress of disease in a living organism. ^{14}C has been used to study atmospheric mixing, verify the global circulation model of the oceans, and follow the fate of anthropogenic carbon in the biosphere and oceans. ^{36}Cl produced in the atmosphere by cosmic ray-induced spallation of argon has been used primarily by hydrologists to study the recharge histories of hydrologic systems. ^{10}Be and ^7Be produced in the atmosphere have been used to estimate ages of soils and ground ice (e.g., Gilichinsky et al. 2007) or rates of erosion of catchments (Brown et al. 1988) and study the behavior of aerosol deposition and air mass mixing.

Broadly, there are three types of systems that are dated using cosmogenic nuclides: (1) those in which the cosmogenic nuclide is produced in situ in a solid, e.g., ^{10}Be in rock; (2) closed systems in which the in situ production has stopped because of the complete shielding of a sample from cosmic rays, e.g., $^{26}\text{Al}/^{10}\text{Be}$ in deeply buried quartz; and (3) a now-closed system that formerly was in equilibrium with a reservoir that had a constant or known concentration of a cosmogenic nuclide, e.g., ^{14}C in *any* biogenic material; the reservoir is either the atmosphere or ocean.

This entry treats the open system and closed system (1 and 2) applications of nuclides specifically produced in exposed minerals near Earth's surface, to determine an exposure age of a surface, burial duration of minerals, or erosion rate of surfaces and catchments (Lal 1991). The term **terrestrial in situ cosmogenic nuclide (TCN)** exposure history describes this method, which utilizes a growing knowledge of how production rates spatially and temporally vary on Earth owing to variations in the geomagnetic field and atmospheric shielding. TCN methods are distinguished from methods using meteoric cosmogenic nuclides, even when the latter are absorbed by clays in soil and marine sediments or accumulated in various water reservoirs (e.g., ice sheets, groundwater). The term **CRN** excludes the stable cosmogenic nuclides (e.g., ^3He , ^{21}Ne , ^{38}Ar), **SED** can be achieved with other dating methods (e.g., luminescence), and **CRE** dating can be conducted on lunar and other planetary surfaces.

The TCN dating method is a *numerical dating method*. Currently the TCN production rates have been calibrated against other dating methods owing to the difficulty of obtaining precise cross sections for the production of each isotope through different interaction pathways. This would suggest that it is calibrated, such as lichenometry or the geomagnetic secular variation dating method. However, with improvements in our understanding of the temporal and spatial variations

in the geomagnetic field, cosmic ray interactions, nuclear cross sections, production rates, and depth profile shapes are becoming reliably predicted by theory (Masarik and Reedy 1995; Argento et al. 2013). In this sense, the TCN dating method is a numerical, *not calibrated*, method. The TCN method is distinct from cosmogenic dating methods based on correlation. For instance, meteoric cosmogenic nuclides measured in time series media – such as ^{10}Be in glacier ice (Beer et al. 1987) or marine sediment (Morris et al. 2002) – can provide a reliable method for correlating undated records to meteoric cosmogenic nuclide records in independently dated cores.

Introduction

TCN exposure methods are used to determine the duration of exposure to cosmic rays, duration and degree of shielding from cosmic rays, and rate and style of erosion, on or near Earth's surface. The premise is that the measured concentration of TCN is proportional to the duration that the mineral has been exposed to cosmic rays (Fig. 1) and, in the case of a radioactive TCN in a shielded sample, how much time the concentration has decayed.

Depending on the energy and type of incident cosmic ray particle and target nucleus, cosmic ray interactions produce a variety of secondary particles over a wide energy spectrum, including gammas, electrons, kaons, pions, muons, neutrons, protons, deuterons, tritons, ^3He nuclei, alphas, and heavier nuclides. It is the heavier nuclides that are of interest. However, to be useful for exposure dating, the TCN should:

- Be stable or have suitably slow decay rates
- Be more abundant than the radiogenic or nucleogenic species in the target mineral
- Have in situ production rates that yield extractable concentrations that can be resolved against its elemental isotopes
- Be precisely measurable considering blanks, detection limits, and isobaric interferences

Fig. 1 Gradual buildup of four TCNs in quartz at sea level high latitude. Black, ^{14}C ; green, ^{21}Ne ; blue, ^{10}Be ; and red, ^{26}Al . Continuous production by spallation only, with rates according to Borchers et al. (submitted) and Kober et al. (2011). Solid lines represent surfaces with zero erosion. Constant continuous erosion of 5 and 10 mm ka^{-1} shown with dashed and dotted curve for ^{14}C

- Be produced in stable, chemically resistant minerals that are common and have low thermal diffusivities for noble gases at surface temperatures

This greatly reduces the number of useful particles, and currently only 6 TCNs are widely used: ^3He , ^{10}Be , ^{14}C , ^{21}Ne , ^{26}Al , and ^{36}Cl (Table 1). The probability for cosmic ray interaction – cross section, measured in barns – takes into account the type and energy of the incident secondary and target nuclei. Thus, each TCN is produced at a unique rate, depending on the energy of the cosmic radiation, the type of interactions of which there are five (spallation, thermal and epithermal neutrons, and interactions of negative and fast muons), and the chemistry of the mineral. Although quartz is the most commonly used mineral, other minerals include calcite, feldspar, garnet, hornblende, magnetite, olivine, pyroxene, and sylvite. With the general exception of quartz, the chemical composition of each mineral should be measured to determine the abundance of suitable target nuclei for each of the five interactions. Quartz is unique in that its composition is stoichiometric, eliminating the need to analyze its chemical composition to determine the different production rates. For instance, ^{10}Be is produced in quartz from spallation and muonic interaction on Si and O at a rate of about 4 atoms $\text{g}^{-1} \text{year}^{-1}$ at sea level, high latitude, under current atmospheric and magnetic field conditions. Until recently, even whole rock samples have been analyzed for ^{36}Cl , ^{10}Be , and ^{14}C , giving the possibility that any lithology can be used if the TCN production rates for the specific rock composition can be determined. Thus, every TCN-mineral system is a unique clock. Ratios of multiple TCN can be measured in a single mineral (e.g., ^{10}Be , ^{14}C , ^{21}Ne , and ^{26}Al in quartz, Fig. 1) or in the same rock (^{36}Cl in feldspar and ^3He in olivine in basalt).

The TCN exposure methods differ from other dating methods. Both radioactive and stable (noble gas) isotopes can be used. The concentration of the isotopes is generally depth dependent, unlike other radiometric chronometers which are dependent on the parent isotope abundance. The technique is not temperature dependent as is the case for thermochronometry and amino racemization. Unlike most geochronometers, the TCN method is not necessarily restricted to specific minerals with a certain isotopic abundance, although production rates are currently well known for relative few minerals.

Table 1 Commonly used terrestrial cosmogenic nuclides

Nuclide	ET	ATM	Half-life (ka)	Isotope	Isobar	TCN analysis	TCN production mechanisms	Target minerals
^3He	•		Stable	^4He	^3H	NGMS	nf	Ol
^{10}Be	•	•	1,390	^9Be	^{10}B	AMS	nf, μ	Qtz
^{14}C		•	5.73	$^{12/13}\text{C}$	^{14}C	AMS	nf, μ , nt	Qtz
^{21}Ne	•		Stable	$^{20/22}\text{Ne}$		NGMS	nf, μ	Qtz
^{26}Al	•	•	720	^{27}Al	^{26}Mg	AMS	nf, μ	Qtz
^{36}Cl	•	•	300	$^{35/37}\text{Cl}$	^{36}S	AMS	nf, nt, μ	K, Ca-rich

Notes

Cosmogenic $^{37-38}\text{Ar}$ is not listed as it is not widely used as a TCN owing to difficulties in isolating it from the radiogenic components

ET, ATM: these nuclides are also measured in extraterrestrial and atmospheric/meteoritic targets

Isobar: listed are the most important isobaric interferences; recent isobaric separation innovations have greatly reduced the impact of isobars on low-level TCN measurements

Production pathways: nf, spallation by fast neutrons; nt, thermal (and epithermal) neutron capture; μ , fast and negative muonic interactions

Target minerals: only the most commonly utilized minerals are listed. For ^{36}Cl and $^{37-38}\text{Ar}$ feldspar separates are now used more than whole rock

Examples of TCN Exposure and Burial Dating

Details of the measurement and interpretation of TCN are provided below. Table 2 provides an indication of the wide range of applications of the method. Currently the most widely used application of TCN methods is exposure dating of glacial boulders for moraine chronologies, followed by the application of TCN to provide age control on alluvial strain markers for fault kinematics, and catchment average erosion rates.

Range of Applicability

The applicable range for TCN dating crosses seven orders of magnitude – more than any other dating method. Theoretically, the lower limit of the surface exposure dating method is $\sim 10^0$ years. While exposure ages of years have been determined, the technique is practically limited by the difficulty of measuring low concentrations (i.e., few hundreds of atoms per gram of mineral, requiring a large

Table 2 Examples of applications of TCN methods

Method	Landform/material	Purpose/test
Exposure dating	Lava surface	Eruption age or recurrence rate
	Bedrock fault scarp	Variation in slip rate with time
	Landslide scarp face	Acceleration of mass movement
	Erratics on moraine, esker, or plain	Timing of deglaciation, retreat rate
	Boulders on alluvial fan	Age of strain markers for fault kinematics
	Boulders on a beach	Isostatic uplift rate or tilt rate of raised shorelines
	Impact ejecta	Age of impact
	Bedrock mountain peaks, tors	Age of formation, timing of last glaciation
	Precariously perched boulders	Timing of seismicity for a given acceleration
	Overturned boulders	Timing of last major flood event
	Colluvial blocks	Timing of last seismic shaking
	Submarine cobble on continental shelf	Duration of shelf exposure
	Debitage, quarried tools	Timing of human occupation
Depth profile dating	Multiple sand samples in a terrace	Stream incision rate, age of strain marker
	Multiple samples in raised delta foresets	Relative sea-level curve, timing of marine limit
Burial dating/ isochron dating	Sediment in caves	Burial age of associated fossils, stream piracy
	Lava stack	Eruption recurrence rate
	Sediment buried under sediment	Age of paleoecological, paleontological, or anthropology records
	Cobbles buried by water	Duration of transgression
	Bedrock or sediment in glaciated area	Duration of cold-based ice cover
Erosion rate	Single rock surface	Outcrop-scale maximum constant erosion rate
	Single outcrop with TCN at saturation	Outcrop-scale average constant erosion rate
	Modern stream sediment	Average erosion rate for catchment above sample
	Older fluvial sediment	Paleo-erosion rates of catchment above sample
	Sediment sample	Erosion rate of surface with short-lived TCN
	Multiple samples in a depth profile	Erosion rate of sediment surface
	Two adjacent samples at different depth	Episodic erosion rate on glaciated summits
Paleoaltimetry	Single lava surface of known age with large vertical offset	Rate of offset
	Rapidly uplifted surface	Rate of uplift using atmospheric depth-dependent ratio of TCNs

sample mass) and our knowledge of production rate controlling factors such as atmospheric dynamics and the geomagnetic field variations over such a short integration time. Although the stable noble gas cosmogenic isotopes do not decay and have low thermal diffusivities in selected minerals at the Earth's surface, an effective upper dating limit on Earth is 10^7 years (e.g., alluvial surfaces in the Atacama Desert, Dunai et al. 2005). This is because the concentration of cosmogenic nuclides typically decreases with depth and because all surfaces on Earth over such long exposure durations will experience erosion. The applicable range for burial dating with ratios of TCN is narrower because short periods of shielding cannot be distinguished from the effects of erosion on the ratio.

The range of erosion rates over which the technique is applicable is narrow and depends on the approach, isotope-mineral system, and measurement precision. Surface erosion rates of continually exposed bedrock approaching 0.01 mm ka^{-1} can be determined with analytical precisions ($\sim 3\%$) and are usually averaged over a wide exposure time. Faster erosion rates, up to a maximum of 10^3 mm ka^{-1} for rock, may be resolved in the rare instance that the erosion rate is constant over much shorter exposure durations. Only recently has the TCN method been able to establish rates of the complex situation of nonconstant episodic erosion.

The TCN dating method extends beyond the normal limits of common Quaternary dating methods such as radiocarbon (5×10^4 years) and luminescence (10^5 years). Therefore, the technique provides a useful bridge between Quaternary and older dating methods. Furthermore, its ability to determine erosion and burial histories over the past 10^7 years can support exhumation models based on thermochronology.

Historical Developments

While the TCN dating method became established in the mid-1980s, the theory of the geochronometer was developed much earlier. Following the discovery of X-rays and radioactivity at the turn of the nineteenth century, experiments were undertaken to establish how high above Earth's surface atmospheric ionization would continue. As observation heights increased from towers to balloon experiments more than 5,000 m high in the atmosphere, it became apparent that above a few hundred meters the ionization rate actually increased with height and that the radiation did not diminish at night or during an eclipse. The demonstration of a non-terrestrial and nonsolar radiation (ionization with constant day and night and during an eclipse, Hess 1912) initiated a new field of physics. Two decades later, the first cosmic "radioelement" measured in rock was protactinium in eucolite and eudialyte, collected from surface outcrops in Greenland. Grosse (1934) carefully demonstrated that the amount of protactinium from the already well-established U-series decay rates was more than 3 % higher than the parent activity could explain. He indicated that a better understanding of the interaction of cosmic rays with matter and cosmic radiation variation with time was necessary to fully understand the production of cosmic radioelements. Knowledge of cosmic ray flux and interactions continued only through measurements of cosmogenic nuclides at higher concentrations in meteorites, lunar samples, and meteoric samples (tree rings, manganese nodules, ice sheets) and sophisticated transport codes capable of simulating particle interactions at various energies and magnetic field (Reedy et al. 1983). A current and very comprehensive review by Olive et al. (2014) provides the state of knowledge of the particle physics and cosmology underlying the theory.

Measurement of TCN lagged the theory. The low production rate of cosmogenic nuclides on Earth's surface even at mountain elevation (hundreds of atoms per gram of mineral per year) resulted

in few successful measurements of TCN (Davis and Schaeffer 1955; Hampel et al. 1975) until significant improvement in isotope mass spectrometry. Unlike radiocarbon dating (based on the decay of ^{14}C produced in atmosphere by cosmic rays and invented by Willard Libby in 1948), application of TCN methods has only been practical since the advent of improved spectrometry of noble gas isotopes and ultimately accelerator mass spectrometry (AMS) in 1977. The technical difficulty lies in the accurate measurement of an extremely small number of atoms, typically 10^6 to 10^8 in a sample that might range from a few milligrams ($\sim 10^{19}$ atoms) to a kilogram of material ($\sim 10^{25}$ atoms). Even after extracting and concentrating the chemical moiety of interest, say aluminum for ^{26}Al measurements, the isotopic ratios are still daunting, $<10^{-14}$.

During an experiment in which atmospheric ^{10}Be (half-life 1.39 Ma) was used as a radioactive tracer to prove that pelagic sediments from the ocean floor were carried through the subduction zone, and ultimately incorporated in the lavas erupted by arc volcanoes, Brown et al. (1982) obtained high concentrations (1×10^6 atoms g^{-1}) of ^{10}Be in the Columbia Plateau basalt. The Columbia Plateau basalt had been chosen as a control sample: since it was produced by hot-spot volcanism which has no connection with subduction, sediments, or any other “surface” material, it was expected to be a blank ($<10^2$ atoms g^{-1}). All other samples from hot-spot volcanism in Hawaii and Iceland had been blank. The significant difference between the Columbia Plateau sample and these other samples was that the other samples were collected within a year of their eruption, sometimes days, while the Columbia Plateau sample had lain subaerially exposed for 14 Ma. It was first thought that the ^{10}Be contamination might be meteoric ^{10}Be , brought to the basalt by rain. But sequential etching of the surface proved that the “contamination” was distributed uniformly throughout the sample. The only remaining possibility was that the ^{10}Be was produced in situ as the sample lay on the surface. A quick calculation showed it was possible. This was the first measurement of an in situ-produced terrestrial cosmogenic nuclide with modern methods. Shortly after, five papers in 1986 announced the birth of TCN exposure history and erosion methods (Craig and Poreda 1986; Klein, et al. 1986; Kurz 1986; Nishiizumi et al. 1986; Phillips et al. 1986). The number of different applications of the TCN method has continued to grow (Table 2; for reviews, see Lal 1991; Gosse and Phillips 2001; Dunai 2010; Granger et al. 2013).

Since Lal’s seminal 1991 paper, the number of parameters considered when interpreting the TCN data has increased, and uncertainty in their values has improved. During the last three decades, the community has benefitted from over a hundred studies from both individual and group efforts to improve sampling strategies, isotope geochemistry procedures, our knowledge of production rate through the atmosphere and lithosphere, and our capacity to process the data. The community shared a number of different calculators – e.g., CHLOE for ^{36}Cl ages, erosion rates, and depth profiles (Phillips and Plummer 1996), CosmoCALC for ages with any of the TCN (Vermeesch 2007), and a Bayesian-like Monte Carlo-based calculator for depth profile dating (Hidy et al. 2010). The most significant development began in the mid-2000s, when two multinational programs were funded for the primary purpose of improving our knowledge of TCN systematics. CRONUS-Earth was funded by the US National Science Foundation and CRONUS-EU was funded by the European Union. Early in the process, an online calculator was provided by members of the CRONUS-Earth group (Balco et al. 2008). Over the last decade, important data gaps were filled and improvements in our understanding were made in nuclear cross sections, radioactive decay rates, muonic interactions, spatial scaling of production rates, temporal variations in production rates, and a more robust assessment of error. The results of these programs have been recently published or submitted (Phillips et al. 2014 submitted). One major improvement is the manner in which the secondary flux is scaled through the atmosphere and the changing geomagnetic field (Lifton et al. 2014). An updated CRONUS online calculator is available at <http://web1.ittc.ku.edu:8888/>. Currently there

remains a lack of consensus regarding some aspects of the computation used in this and other calculators and the values of some of the parameters chosen, particularly the production rates. Although the CRONUS programs have ended, efforts to improve the TCN methods continue.

TCN Dating Systematics

TCN Production Pathways

At the base of the atmosphere, the most abundant secondaries capable of producing TCN are neutrons and muons. Other secondaries either lack energy, have rapid decay rates, are uncommon, or are absorbed so quickly in the atmosphere that they generate TCN at a much lower rate. TCN are produced in exposed minerals by three main interactions: spallation by high-energy neutrons, capture of thermal or epithermal neutrons, and muonic interactions.

At the base of the atmosphere, at sea level, the most abundant cosmic ray is muons with an average energy of 4.2 GeV. They have a vertical flux of $\sim 70 \text{ m}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$ (for momentum $> 1 \text{ GeV c}^{-1}$); incident on a horizontal surface, the equivalent flux is $\sim 1 \text{ cm}^{-2} \text{ min}^{-1}$. Nucleons are the next most abundant: the integral vertical intensity of protons above 1 GeV c^{-1} is $\sim 0.9 \text{ m}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$ and for neutrons $\sim 0.45 \text{ m}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$. Other components of the flux including the electromagnetic pions and kaons play a little role in the production of TCNs.

Spallation

A spallation reaction occurs when a low-mass (e.g., neutron, proton) energetic ($> 30 \text{ MeV}$) particle interacts with a nucleus. The interaction causes an intranuclear or hadronic cascade that at first evaporates neutrons and protons and other light nuclei and then may eventually result in the breaking apart (fission) of the target nucleus. In general, the most probable products have masses close to the target nucleus or close to the projectile. All TCNs are produced by spallation, and it is the dominant production pathway for TCN within the upper $1,000 \text{ g cm}^{-2}$ ($\sim 4 \text{ m}$) of the lithosphere.

Thermal and Epithermal Neutron Capture

Neutron capture occurs when a slow neutron is absorbed by a nucleus to create a nucleus with a mass of one amu larger. Fast neutrons lose their energy through momentum transfer during elastic collisions with nuclei. Epithermal neutrons (0.1 MeV to 0.5 eV) and thermal neutrons ($< 0.025 \text{ eV}$) can be captured by a nucleus. The resulting nucleus is generally unstable and it decays by the immediate emission of a proton, or beta decay. Excited nuclei relax by emission of a gamma. While thermal-neutron capture is possible by many nuclides, the only cosmogenic nuclides that are produced significantly by thermal-neutron capture are $^{14}\text{N}(\text{n}, \text{p})^{14}\text{C}$, $^{35}\text{Cl}(\text{n}, \gamma)^{36}\text{Cl}$, and $^{40}\text{Ca}(\text{n}, \gamma)^{41}\text{Ca}$.

Muonic Interactions

Muons (leptons that are $207\times$ more massive than electrons) are produced in cosmic ray showers from the decay of mesons and comprise more than eighty percent of the non-electromagnetic cosmic ray flux at Earth's surface. However, like other leptons, they do not interact through the strong force and thus their penetration is much greater than neutrons. Despite their short half-life (10^{-6} s) and their relatively small contribution ($< 2\%$) to total TCN production at the lithosphere surface, slow negative muons (e -folding length $\Lambda \sim 1,300 \text{ g cm}^{-2}$, Heisinger et al. 2002a) and fast muon ($\Lambda \sim 4,320 \text{ g cm}^{-2}$, Heisinger et al. 2002b) are the dominant production pathways at depths greater than 4 m in rock ($> 1,000 \text{ g cm}^{-2}$). For comparison, the Λ for fast neutrons is $\sim 145 \text{ g cm}^{-2}$. Muon

contributions to TCN production are therefore important when applying TCN burial dating methods or when samples are collected from rock or sediment depths greater than 1 m.

TCN Production

Exposure duration (t) of a basalt boulder on a moraine is determined by the measurement of the TCN concentration in a target mineral, such as ^3He in pyroxene:

$$t = \frac{C_{meas} - C_i}{P_{T,t,0}} \quad (1)$$

where C_{meas} is the measured abundance of ^3He per gram of pyroxene, C_i is any concentration of ^3He that is either non-cosmogenic or in situ cosmogenic ^3He produced prior to the deposition of the boulder on the moraine (i.e., “inherited concentration”), and $P_{T,t,0}$, the total production rate at the surface, is the time-integrated sum of all cosmogenic nuclide production pathways for ^3He in pyroxene at the surface for the particular time, in atoms $\text{g}^{-1}\text{a}^{-1}$.

The state of knowledge of production rates and how they scale spatially and temporally is rapidly improving (Lifton et al. 2014; Phillips et al. 2014 submitted). Site-specific time-integrated production rates have been determined (calibrated) by measuring TCN concentrations in minerals with simple exposure histories over an independently determined duration (C_i is considered zero or is measured). The sum of production rates from the different cosmogenic nuclide interactions (fast neutrons, P_{nf} ; thermal neutrons, P_{nt} ; epithermal neutrons, P_{ne} ; negative muons, $P_{\mu n}$; and fast muons, $P_{\mu f}$) depends on the nuclide-target system, location, environmental factors, and the particular part of Earth’s geomagnetic field and atmosphere history corresponding to the exposure period. For reference, the calibrated TCN production rates are scaled to sea level, high latitude, under today’s geomagnetic and atmospheric conditions (e.g., ^{10}Be is produced in quartz at ~ 4 atoms $\text{g}^{-1}\text{year}^{-1}$). Thus, first-order (up to two orders of magnitude) adjustments to the reference production rate may be required to account for spatial variability in atmospheric and geomagnetic controls on the cosmic ray flux to any location on Earth.

Earlier simplifications with a symmetric standard atmosphere and dipolar magnetic field have now been replaced by more sophisticated models for both. In general, lower magnetic field strength will result in a higher production rate and a softer (lower average) secondary energy spectrum that will not penetrate as far. Sites at higher geomagnetic latitudes have higher surface production rates. The flux of each type of secondary decreases with penetration through the atmosphere, so production rates decrease with atmospheric depth. Atmospheric shielding is a greater control than geomagnetic field effects (except during reversals) so the highest production rates are at mountain tops.

The intensity and geometry of the geomagnetic field and the distribution of atmospheric mass has changed with time. The effects can cause changes of $>25\%$ over several millennia for a given site. Periods with higher paleointensities had lower instantaneous TCN production rates. During colder periods when the atmosphere contracted, production rates at high altitudes were less shielded. Such temporal variation in production is clearly evident from the variation in abundances of atmospheric ^{14}C or ^{10}Be abundances recorded in ice sheets or marine sediments. Fortunately, unlike the instantaneous effect of these changes on atmospheric cosmogenic nuclide production used for radiocarbon dating, terrestrial in situ production is integrated over the entire exposure duration, so TCN dating is not as sensitive to short-term high-amplitude geomagnetic or atmospheric variations.

Other first-order adjustments are needed to account for the decrease in production as the average energy of each type of secondary flux decreases with mass depth z (g cm^{-2}) through rock:

$$P_{z,nf} = P_{0,nf} e^{-z/\Lambda_{nf}} \quad (2)$$

where P_0 is the surface production rate and Λ_{nf} is the effective e -folding attenuation length for fast neutrons at that depth. While the concentration of TCN produced from spallation by fast neutrons generally follows this simple exponential, thermal-neutron capture interactions do not. Owing to the moderating effect of water (water vapor in air, pore water in rock or sediment, snow cover) on thermal neutrons, initially there is a reduced thermal and epithermal neutron flux in the upper 60 g cm⁻² of rock or sediment until the flux re-equilibrates with the exponentially attenuating fast neutron flux. Unlike spallogenic TCN, the highest concentration of thermal-neutron capture TCN occurs a few dm below the surface.

Second-order adjustments to the production rate may be negligible or significant. These include corrections for erosion or exhumation of the samples, cover by snow, water, ice, loess, or colluvium (shielding the surface from fast neutrons); geometry of the sampled surface; partial shielding by vegetation; elevation changes due to isostatic, tectonic, or surface processes; and partial shielding of cosmic ray secondaries due to topography.

Laboratory and Field Considerations

The field and laboratory procedures will depend on the objective of the study. Choices of TCN will mainly depend on the abundance of target minerals with known production rates, the radionuclide half-life, and whether or not multiple nuclides or a particular production pathway is sought.

There is no standardized list of field observations for TCN methods, partly because the types of TCN applications vary widely. Table 3 includes most of the important observations that will be needed to calculate an age or erosion rate, adjust for complexities in exposure history, interpret the data, and evaluate uncertainty. The number of samples necessary will depend on many factors. If inheritance is possible (e.g., due to exposure prior to the exposure period of interest), concordance of three or more surface exposure ages may be required to establish if inheritance is negligible, or subsurface samples in sediment collected in a depth profile may be needed to adjust for the average inheritance of a sediment.

While the physical and chemical processing required will vary with the isotope-mineral system, the objective is the same: provide a pure and representative target with sufficient TCN concentration to obtain the desired precision. Mineral isolation processes after cleaning, crushing, grinding, and sieving include froth flotation; magnetic, electrostatic, heavy liquid, air abrasion; and differential leaching with hydrofluoric, hexafluorosilicic, or hot phosphoric acid. For the noble gas measurement, no future chemistry may be required on the <100 mg of target mineral. For AMS, extracting and concentrating the radionuclides after dissolution is achieved with isotope dilution (spiking) followed by dissolution, ion chromatography, and pH-controlled precipitation, yielding BeO, Al₂O₃, AgCl, or other targets which are mixed with a pure metal to enhance sputtering in the AMS source. Masses between 2 and 200 g will be needed, depending on the concentration. Extraction of ¹⁴C is by thermal extraction of ¹⁴C in the presence of ultrapure O and can be in graphite or CO₂ gas. Most extraction methods require less than 10 g of quartz. Some elemental analyses of the naturally abundant isotope or a measurement of target nuclei abundances, radiogenic and nucleogenic sources, or neutron moderators is usually required.

Table 3 Field observations

Observation	Example	Comment
Latitude	-72.4472°	Convention: south is negative; high precision is useful for site recovery
Longitude	-130.3362°	Convention: west is negative; high precision is useful for site recovery
Elevation	3,232 m	Record method; evidence for surface elevation changes during exposure should be considered
Pressure	Varies	Used if atmospheric model does not adequately describe the time-averaged barometric pressure for the average temperature history
Bulk density	2.7 g cm^{-3}	Bulk density of the material sampled; if subsurface sampling, bulk density of the material above each sample must also be determined
Thickness	1.0 cm	Average thickness of the sample
Depth below top	0 cm or 10 g cm^{-2}	For surface samples, this is taken as 0 cm. For subsurface samples, the vertical distance between the landform surface and the top of the sample is recorded. Units vary with calculator
Surface slope	$19^{\circ} \rightarrow 235^{\circ}$	This is the dip and dip direction of the slope of the sampled surface. Generally dips less than 10° will have negligible foreshortening effects, unless there is considerable topographic shielding
Topographic shielding	235, 310, 40, 130, 170° 22, 13, 9, 17, 25°	Trend and plunge ($^{\circ}$) measurements taken at major topographic inflections in the skyline. This shielding becomes more critical with greater shielding (e.g., in a canyon) and with greater sampled surface slope
Sample height	130 cm; geometry	If the surface of the sampled landform is above the local ground level, such as a boulder top, it may be useful to provide the entire geometry (L, W, H) when considering neutron loss
Snow shielding	100 cm for 3 months, 50 cm for 2 months, 0.25 g cm^{-3}	An estimate of the thickness and density of snow that may have covered the sampled surface. If the surface is above the local ground level, consideration for the sample height may be required
Geometry effects	30 cm from edge; 25 cm under an overhang that protrudes 80 cm from cliff	This is needed to compute effective attenuation lengths, compute thermal-neutron production rates, and evaluate neutron loss
Forest shielding	Temperate rainforest for majority of time	Record the type of forest and other vegetation cover. For boulders, this could account for 2 % to >9 % shielding of secondary cosmic ray flux (e.g., boreal forest or temperate rainforest). For subsurface samples, vegetation shielding could be even greater
Erosion	1 mm ka^{-1} ; 30 cm max	If known, indicate method or evidence (height of protruding quartz vein; striation; soil development; lichen cover; weathering features; measured). Units vary with calculator
Aggradation	50 cm	Gradual or episodic cover by loess, ash, colluvium, ice, water, and other material currently or previously existing that was added to the surface of the landform after exposure began
Sample type	Boulder; braided stream deposits	Describe lithology, sediment structures

(continued)

Table 3 (continued)

Observation	Example	Comment
Landform type	Broad moraine ridge; fluvial terrace	Provide stratigraphy information, e.g., Qf3. Describe where on the landform the sample was collected (subsurface samples under a longitudinal bar in the alluvial fan)
Sample method	Cutoff saw; chisel; hand dug pit	Indicate any difficulties, particularly if thickness is not constant
Inheritance	High catchment erosion	Note evidence of catchment erosion for sediments (e.g., alluvial fans); low rates may indicate a higher probability of inheritance, yielding older apparent ages or causing scatter among individual ages on a given landform
Volumetric water	5 % water content in soil	The volumetric water content, Q_v , is needed to account for moderation of the thermal and epithermal neutron flux through rock and sediment. Each sedimentary layer and soil horizon may need its own measurement
Soil properties	15 cm below the 30 m mixed zone	Information about the soil that can help constrain erosion rate (e.g., a local catena, or evidence that the soil has been truncated); evidence that the samples were collected below any zone of cryoturbation or bioturbation; consideration that a soil horizon may have gradually altered the bulk density and moisture properties over time
Exhumation of the surface	Cobble may have been frost heaved, or till may have been eroded	Boulders and small clasts may have moved vertically in the sediment and been completely exposed for a shorter time than the actual landform. Exhumation by frost heave or denudation of the landscape should be noted

TCN Applications: Dating of Surfaces and Sediments with Simple Exposure Histories

Exposure dating has been conducted in just about every landscape element to address questions relevant to classical geomorphology, landscape responses to climatogenic and tectonic change, kinematics of brittle and ductile deformation, and applied science regarding geohazard risks associated with seismicity, volcanism, mass wasting, aridity, and sea-level change. Various combinations of isotopes and sampling strategies can reduce the degrees of freedom in constraining the factors that control the calculation of an exposure or burial age.

Single-Nuclide Surface Exposure Dating

A simple exposure age on a surface that is not eroding can be determined with a stable or radionuclide with decay constant λ :

$$t = -\frac{1}{\lambda} \ln \left(1 - \frac{C\lambda}{P} \right) \quad (3)$$

However, if the surface experienced a constant erosion or aggradation during the equation, it is more complicated. Constant erosion and aggradation can be treated explicitly. As the absorption of the cosmic ray secondaries with mass is well known, we are not required to sample at the surface. An approximation for the concentration of a nuclide in a rock at depth z (cm) with an erosion rate ε (cm a^{-1}) was provided by Lal (1991)

$$C_{(z,t)} = \frac{P_{(t,0)}}{\lambda + \frac{\rho\varepsilon}{\Lambda}} e^{-\frac{\rho\varepsilon}{\Lambda}t} \left(1 - e^{-\left(\lambda + \frac{\rho\varepsilon}{\Lambda}\right)t}\right) + C_{(z,inh)}e^{-\lambda t} \quad (4)$$

The latest CRONUS calculator ([Borchers et al. submitted](#)) iteratively seeks an exposure time with a set of equations that allow production rates through the five interaction pathways to vary over the exposure period, simultaneously considering changes in effective attenuation lengths during erosion. If erosion rate is known and constant, exposure age can be solved. However, if the erosion rate is uncertain or appears to be episodic, the normal protocol with a dominantly spallogenic TCN is to assume $\varepsilon = 0$ to obtain a minimum exposure age for the surface. If the inherited concentration ($C_{(z,inh)}$) is also not negligible, but erosion is zero, the exposure age would be a maximum age. The exposure age cannot be constrained with one isotope (maximum nor minimum limit) if both inheritance and erosion are nonzero. However, if single-nuclide exposure ages from multiple, spatially distinct samples from the same landform are identical, then it may be possible to suggest a negligible inheritance in all samples.

Multiple Nuclide Surface Exposure Dating

To overcome the difficulty related to erosion, two nuclides can be measured in the same rock surface. If the surface has been exposed and eroding at a steady state for a long time, the concentration of radionuclides will reach a dynamic equilibrium where loss due to decay is matched by the production according to the above equation. A short-lived radionuclide that has reached its saturation concentration C^* for a given erosion rate over sufficient time can be used to determine the erosion rate (Lal [1991](#)):

$$\varepsilon = \frac{\Lambda}{\rho} \left(\frac{P}{C^*} - \lambda \right) \quad (5)$$

The surface exposure time can be determined by adjusting the unsaturated concentration of a second nuclide for this erosion rate. Alternatives to the saturation approach include a combination of a TCN with a significant thermal-neutron capture production rate (e.g., ^{36}Cl) and a spallogenic isotope (e.g., ^{10}Be). The thermal-neutron loss near the surface will cause the concentration to increase with erosion, while the spallogenic nuclide will decrease for the same erosion rate. Their erosion-adjusted ages will converge provided that erosion rate is not too fast and that sufficient ^{35}Cl is in the mineral.

The two-isotope approach can also solve exposure age and erosion rate simultaneously for two radionuclides without the need for saturation or thermal-neutron production (Fig. 2). However, the $^{26}\text{Al}/^{10}\text{Be}$ ratio plot (Nishiizumi et al. [1986](#)) reveals a narrow banana-shaped steady-state island and therefore requires very high precision to establish erosion and exposure age. Phillips et al. ([1997](#)) have suggested that the $^{10}\text{Be}/^{36}\text{Cl}$ may have the advantage of being more sensitive for experiments requiring simultaneous solutions of exposure age and erosion rate. Ratios of a noble gas and radionuclide have also been used, and a three-isotope approach may have the advantage of a reduction of a degree of freedom. The multi-isotope approach may also simplify the requirement to know how production rates have changed with time if, in some circumstances, the amount of variation is the same for all measured isotopes in the same sample.

Fig. 2 $^{26}\text{Al}/^{10}\text{Be}$ versus ^{10}Be plot. Production systematics as per Balco et al. (2008) for the Lal (1991) and Stone (2000) time invariant scaling model, initial ^{10}Be production rate of 4.9 atoms g^{-1} and surface $^{26}\text{Al}/^{10}\text{Be}$ of 6.75, and muogenic production from negative and fast muons (Heisinger et al. 2002a, b). Plot and sample represent a surface of 30 m depth under gravel with 1.9 g cm^{-3} density. The thick red upper curve represents the history of a sample that experienced continuous exposure with no erosion (exposure duration in Ma increases to the right). Ratios plotting within the shaded field (“steady-state erosion field” (Lal 1991)) have experienced erosion or minor burial (curves indicated for 0.1 and 1.0 mm ka^{-1} constant and continuous erosion). Samples plotting below the shaded field have experienced a complicated exposure history in which an exposure was by at least interrupted one burial event. Even at 30 m, the shielding is not complete because of muogenic production. The duration of burial indicated by the thin blue curves ranging from 0.25 to 8 Ma represents the burial age for a single even or a minimum estimate of burial duration if multiple burial events have occurred, as in cyclic glacial cover. The hypothetical sample shown with 1σ error ellipse could be interpreted to represent a minimum exposure duration of 0.2 Ma and minimum burial duration of 2 Ma. However, it is possible that the sediment was buried and reexposed many times, so the total time represented would be greater than 2.2 Ma. If an amalgamated sediment had a depressed initial ratio (owing to complex exposure prior to final deposition), then the burial age would overestimate the timing of the last burial event

Exposure Dating of Sediments

The difference between dating the exposure age of a rock surface and dating the depositional age of a sediment is that each grain of the allochthonous sediment will have a different C_{inh} which must be considered in the calculations. There are many approaches to dating a sediment (see Gosse 2012 for a review). If the objective is to determine the age of a cut or fill alluvial terrace surface, a fan or delta surface, moraine, or mass wasting deposit, it is possible to date large boulders (reducing the effect of snow or loess cover and exhumation) or cobbles and pebbles on the surface. As in dating a bedrock surface, a single-nuclide age on a clast (or amalgamation of clasts) on the surface of a deposit requires knowledge of erosion (or aggradation) history and inheritance.

Erosion of the surface can be determined by different TCN approaches as discussed above. An alternative approach is to use subsurface samples. The concentration versus depth profile through a rock or sediment is controlled by erosion rate. The faster the erosion rate, the steeper the profile until ultimately only a fast muonic attenuation would be measured. Unfortunately, constant erosion rates on Earth are generally not that fast, so most measured depth profiles will be dominantly controlled by the simple e -folding length for a fast neutron. Therefore, a single spallogenic nuclide cannot establish a unique erosion rate or exposure age. However, a depth profile for a single TCN with

sufficient thermal-neutron capture production (e.g., ^{36}Cl) can provide this uniqueness. Alternatively, two TCNs can be measured in the same profile to solve for erosion rate and age (Mercader et al. 2012).

The C_{inh} in sediment clasts is equally problematic. If not treated, the apparent exposure age will overestimate the actual timing of deposition. There are many approaches, each with assumptions that may be validated in certain scenarios. One option is to measure the exposure age for many samples on the surface of the deposit and assume that all clasts have been eroded similarly. If there is no variability among ages, then it may be possible to interpret that inheritance is negligible, as it is very unlikely that all clasts would have the same inheritance if the C_{inh} was a significant component of the total concentration. This is often the case where sediment is eroded from glaciated catchments or regions with otherwise very high erosion rates. In regions where the sediment is sourced from a catchment that has not been rapidly eroded, determining the C_{inh} is necessary. One option is to measure a sample that is essentially shielded from cosmic rays (e.g., $>4,000 \text{ g cm}^{-2}$ deep) for long exposure to muons (Brown et al. 2002) and assume that the sediment at shallower depths have the same C_{inh} . This assumption would only be true in special cases where, for instance, the sediment flux from the catchment remained constant over that entire thickness. A similar approach that uses the TCN concentration in modern stream sediment as an indication of C_{inh} is similarly invalid for many catchments in which millennial-scale climate variations have changed catchment erosion rates. A better and more widely used treatment of inheritance in alluvium (Anderson et al. 1996) uses the TCN concentration in at least four subsurface samples of amalgamated clasts along a depth profile. The profile will reveal the time-integrated concentrations from the different interaction pathways as the rock is advected toward the surface due to erosion. The exponential decrease in concentration will trend toward zero with depth if there is no inheritance. However, if C_{inh} is nonzero, the concentration versus depth curve will be asymptotic along the depth axis. The offset corresponds to the C_{inh} and can be subtracted from the measured concentration to solve for erosion or exposure age. Hidy et al. (2010) showed that amalgamations of hundreds of thousands of sand clasts provide a more precise solution than dozens of pebbles (pebbles seem to work in rapidly eroding catchments, whereas many more sand grains are necessary to characterize the average C_{inh} where catchment erosion rate is low, and C_{inh} is high and more variable).

Burial Dating

When rock or sediment is buried and effectively shielded from any secondary cosmic ray flux, the concentration of TCNs in the buried minerals will change according to their decay rate. The noble gases will remain constant (assuming no unaccounted diffusion) and radionuclides with faster decay rates will decrease faster. The change in the ratio of the concentration of two (or more) different TCNs in the same sample, as long as one is a radionuclide, depends on burial duration, erosion rate, and depth. Burial dating has been contributed to many different disciplines:

- Glaciology and paleoclimatology: burial of bedrock by one or more episodes of glacier cover (e.g., Nishiizumi et al. 1991)
- Anthropology and archaeology: sediment and associated human fossils that were shielded in caves (e.g., Shen et al. 2009)
- Geomorphology and paleontology: fluvial terraces and alluvial back to the Pliocene (e.g., Rybczynski et al. 2013)

Simple Burial Dating with Two Isotopes

In the simplest case of a surface that had build up over exposure time (t) interrupted by a single period of complete shielding from cosmic rays (t_b), the burial duration can be determined using two TCNs with different mean lives (τ) in the same sample:

$$t_b = -\frac{\tau_{\text{short}}\tau_{\text{long}}}{\tau_{\text{long}} - \tau_{\text{short}}} \ln\left(\frac{P_{\text{long}}(t, z, \varepsilon)C_{\text{short}}}{P_{\text{short}}(t, z, \varepsilon)C_{\text{long}}}\right)$$

where C is the measured concentration and $P_{(t,z,\varepsilon)}$ is the sum of the time-averaged production rate over the time of exposure for a given depth and erosion rate for the short- or long-lived isotope (Granger and Muzikar 2001). In this simple scenario, such as burial of a lava by another thick lava, there $C_{\text{inh}} = 0$ atoms g^{-1} and $\varepsilon = 0$ cm a^{-1} . Even if the initial exposure duration is not known, the pre-burial and burial durations may be solved if the ratio of the two isotopes fall below the steady-state island in a ratio plot (e.g., $^{26}\text{Al}/^{10}\text{Be}$ vs. ^{10}Be , Fig. 2), erosion is assumed negligible, and the surface or sediment had never experienced a previous burial (or storage) event. This method requires two isotope measurements in only one sample. It assumes that burial was complete and instantaneous; otherwise, production during partial exposure at varying depths with time will need to be considered.

Isochron Burial Dating

Balco and Rovey (2008) provided an isochron solution for the common instance where a surface or sediment has undergone previous burial episodes. In these cases, the initial ratio of the isotopes measured in a sample does not correspond to the concentration for the production ratio $\left(\frac{P_{\text{short}}(t, z, \varepsilon)}{P_{\text{long}}(t, z, \varepsilon)}\right)$.

Instead, prior burial durations will cause the concentration ratio to be lower at the beginning of the last burial episode. If ignored, the calculated burial duration will overestimate the burial age. By using an isochron approach (Fig. 3), the concentration ratio prior to the last burial episode does not need to be known. The isochron approach requires that multiple samples are collected in the buried rock or sediment and that the concentrations of the TCN in each sample are different but that the ratio of the two TCN samples is the same. One option is to collect samples within a short (<1 m) depth profile interval below the burial contact. In this case the concentration for each TCN will diminish with depth if the buried minerals were exposed prior to burial. The greater the pre-burial exposure time, the greater the differences in concentration in the samples. However, the ratio of two spallogenic nuclides will be approximately constant over this short and shallow interval. For instance, on a $^{26}\text{Al}/^{10}\text{Be}$ isochron plot, the initial slope will be close to the production ratio (~ 6.75). During burial, the isotopic ratios will decrease at a rate proportional to their concentration, so the slope of their concentrations will decrease. The slope is proportional to the burial duration. In instances where exposure prior to burial was short (e.g., if eruption recurrence intervals were short) or there is no evidence of a paleosol because of significant erosion prior to burial, there are other options for obtaining multiple samples with different concentrations. For instance, there is a well-documented grain size dependency on concentration in sediments where deep-seated landsliding has occurred (Brown et al. 1995), so ^{26}Al and ^{10}Be concentrations in different grain size fractions from a single sample may be sufficiently distinct to define a ^{26}Al versus ^{10}Be slope.

In the instance that multiple burial events have occurred, such as on a glaciated summit, different approaches have been used to constrain the possible burial history. The approaches use a combination of burial dating with two or more TCNs and an independent record of glaciation, such as an ice volume time series from a marine or ice sheet record. A recent approach reported by Margreth

Fig. 3 Concept of TCN burial isochron dating (Balco and Rovey 2008), illustrated using a $[^{26}\text{Al}]$ - $[^{10}\text{Be}]$ plot. The ratio of samples collected from a continuously exposed soil (never buried) will plot on the *solid blue curve* depending on depth and exposure duration. *Blue dashed curves* represent sediment in a paleosol that was buried once (continuously) for the indicated duration. *Red curves* are defined by samples collected at different depths in sediment that had previously experienced burial and was redeposited and weathered in the modern paleosol. The initial ratios of the red samples in the paleosol would be less than the production ratio of the isotope pair (6.75 in the case of $^{26}\text{Al}/^{10}\text{Be}$). The slope and position of the isochrons solve for initial ratio and burial duration simultaneously

et al. (submitted) used the ratio of two radionuclides in two nearby surfaces, but one has been more recently plucked than the other. Considering periodic burial by ice, and even subaerial and episodic subglacial erosion, the concentrations and ratios help constrain the long-term (millions of years) fraction of ice-free time.

TCN Applications: Erosion Rates

While erosion can contribute significantly to the uncertainty of exposure ages, the dependence of concentration on erosion increases the value of the TCN method. The TCN method can provide a direct estimate for erosion rate of local surfaces to large catchments. Erosion rates on bedrock surfaces have provided a means to establish background rates for comparison with recent erosion rates during the Anthropocene, or longer-term rates determined by thermochronology, or relief generation from the difference between valley and summit erosion rates.

In most applications of TCN erosion rate analysis, the overriding assumption is that the erosion was continuous and constant over the entire exposure duration. A single concentration in one sample on a surface constrains erosion (Eq. 5) if the radionuclide has reached its saturation concentration C^* . Saturation can be achieved more easily by using a short-lived isotope (e.g., ^{14}C) on a rapidly eroding surface (e.g., a sloped surface on a sediment, Fig. 1). If the objective is to obtain an estimate of erosion over a longer time period than recorded by a short-lived TCN, but the C^* for the longer-lived isotopes has not been attained, then the erosion rate determined from Eq. 5 will be an estimate of the maximum erosion rate permitted to achieve the measured concentration. Multiple nuclides measured in one sample can provide the exposure duration and erosion rate of that surface (e.g., Nishiizumi et al. 1991; Phillips et al. 1997).

It is also possible to apply Eq. 5 to estimate the denudation rate of an entire catchment. While the approach was first conducted using meteoric ^{10}Be absorbed on regolith delivered to streams (Brown et al. 1988), the method now uses the lower concentrations of in situ TCN in the same sediments (Brown et al. 1995; Granger et al. 1996). The approach assumes that at each location in a catchment, the concentration at the surface has reached saturation. However, instead of tagging the C^* and therefore ε at every surface in the basin, the hillslope processes and streams will deliver a flux of sediment that is scaled with the erosion rate of the upstream slopes. Thus, one sample of modern stream sediment provides an estimate of basin-average erosion rate for all catchment surfaces above that point. A basin TCN production rate can be calculated by taking the average of production rates for each pixel in the DEM; scaled for latitude, longitude, and elevation; and adjusted for topographic shielding, vegetation, and other factors. The basin-average erosion rate method relies on the constant delivery of sediment from all surfaces in the catchment and assumes a homogeneous distribution of the mineral of choice. Special approaches are required if some areas of the catchment are not eroding or have no target mineral of the selected grain size. The duration over which the erosion rate is applicable depends on the radionuclide decay rate and the erosion rate of the catchment (faster rates reduce the averaging time).

It is also possible to determine the paleo-erosion rate of a basin (Schaller et al. 2002; Hidy et al. 2014). Instead of using modern sediment, it is necessary to sample sediment stored in the catchment that was deposited at the time of interest. In order to obtain the average depositional concentration (C_{dep}) for a given time in the past, we determine the inherited concentration (C_{inh} , e.g., with a depth profile) and compensate for the concentration lost to decay over the time since deposition. Time since deposition may be determined with TCN methods or independently with a different dating method. The method assumes that any changes in catchment elevation, relief, area, or target mineral abundance with time are negligible or known.

Uncertainty and Assumptions of TCN Exposure Ages and Erosion Rates

Arguably more than any other dating method described in this encyclopedia, the TCN dating method is more sensitive to sample and environmental context. For this reason, it is challenging to establish a rigorous analysis of total uncertainty in an exposure age, burial age, or erosion rate (Borchers et al. submitted). There is no consensus on whether or not 1σ or 2σ uncertainties shall be reported. In some instances involving Monte Carlo approaches, the only fits obtainable are at the 3σ level and that error is not reduced to a lower confidence level.

Internal random errors affect the precision of the measurement. These include (i) AMS or MS precision (typically based on a Poisson distribution, averaging 2–3 % 1σ), (ii) uncertainty in the spike or carrier concentration (generally better than 2 % 1σ), and (iii) contribution to the measurement of the process blank, calculated by considering what fraction of the sample measurement was contributed by the process (usually <1 % except for very low-level measurements). As ^{36}Cl requires elemental analysis of potential target elements, and thermal-neutron absorbers and producers, the uncertainty in ICP, ICP-MS, or XRF measurements is also incorporated.

The principal external error is uncertainty in the scaled and time-averaged production rate. Balco et al. 2008 recommended approximately 10 % 1σ uncertainty, and it is unclear if the production rate uncertainty has improved for each TCN since then.

Most publications do not consider the other sources of error that relate to the various environmental conditions that affect production rate or add complexity to the exposure and burial history. In the newest CRONUS-Earth online calculator, uncertainties for all of the required input parameters

are requested, including uncertainty in the shielding factors for snow, vegetation, geometry, topography, and effective attenuation lengths. Hidy et al. (2010) also incorporated the stochastically or normally distributed uncertainties in bulk density and inheritance in evaluating error for depth profile ages and erosion rates. Still typically non-quantified are errors associated with surface uplift, erosion, episodic erosion, burial and aggradation, exhumation, mixing, and other factors.

Numerous comparisons of TCN surface exposure ages of rock surfaces and sediments and other dating methods have been published, and summaries of recent interlaboratory comparisons and duplication measurements have been reported in Jull et al. (2013) and Phillips et al. (2014 submitted). These include alluvial depositional ages against OSL in the same section, erratic boulder exposure ages against calibrated radiocarbon ages, and exposure ages on lava dated with $^{40}\text{Ar}/^{39}\text{Ar}$.

Assumptions Common to Many TCN Dating Applications

- The TCN production rate is known for a given production pathway. This is the major source of uncertainty in the dating method. The production rate varies as a function of (i) temporal and spatial variations in dipole and non-dipole magnetic field controls on the GCR flux to the atmosphere (Lal 1991; Lifton et al. 2014), (ii) temporal and spatial variations in atmospheric shielding of GCR and secondaries (Lal and Peters 1967; Stone 2000; Staiger et al. 2007), and (iii) depth below the surface because of attenuation of the cosmic ray flux through different interactions that depend on the energy spectra and type of secondary and the chemistry of the mineral matter.
- All cosmogenic, radiogenic, and nucleogenic pathways are recognized. For TCN exposure dating the primary cosmogenic production pathways are spallation, capture, and muonic interactions (Lal 1991; Gosse and Phillips 2001).
- Any initial TCN concentration prior to the exposure of interest is negligible or can be determined independently, e.g., with depth profiles through sediment (Anderson et al. 1996).
- The cosmic ray flux is constant. The uncertainty in this assumption has not been well established (e.g., Wieler et al. 2013).
- TCN concentrations are measured accurately. While the majority of modern measurements with noble gas mass spectrometers or accelerator mass spectrometers (AMS) average 2–4 % 1σ precision for some TCN (Vermeesch et al. 2012; Jull et al. 2013), the actual range of internal measurement precisions evaluated by duplicates and interlaboratory comparisons can be larger. Low TCN concentrations due to small sample mass, low production rate, short exposure time, or long burial time will increase uncertainty because of counting statistics (Poisson distribution), the uncertainty in blank correction (by nature, the process blanks will have poor counting statistics), spectrometry detection limits, and, in the case of AMS, normalization with standards with TCN abundances that are more than two orders of magnitude greater than the low-level samples.
- No unaccounted surface processes have influenced the exposure or erosion history of the minerals being dated. For instance, there is negligible or known effects of (i) erosion of the rock surface (Gillespie and Bierman 1995); (ii) shielding and the moderating effects of snow (Gosse and Phillips 2001; Zweck et al. 2013; Delunel et al. 2014), soil moisture (Dunai et al. 2014), ice, or forests and vegetation (Plug et al. 2007); (iii) exhumation (Putkonen and Swanson 2003); and (iv) movement of the dated material by tectonics, isostasy, mixing, or rotation during exposure.

Radiocarbon Dating of Marine Carbonates

Quan Hua*

Australian Nuclear Science and Technology Organisation, Kirrawee DC, NSW, Australia

Definition

Contaminant: Carbon-containing materials that do not originally belong to the sample.

Pretreatment: A process applying physical and chemical treatments to remove contaminants.

Contamination and Sample Pretreatment

Marine carbonates such as shells and corals mainly consist of aragonite. Before samples are processed for radiocarbon dating, all contaminants must be removed; otherwise the determination of correct radiocarbon ages may not be achieved. Contaminants are derived from the surrounding environment if samples were buried in soils or sediments (e.g., secondary carbonates derived from groundwater and recrystallization of sample carbonate due to chemical exchange between the sample and the surrounding environment). These carbonate contaminants are mostly in the form of calcite. Contaminants can also be conservation materials in the case of museum specimens. Contamination cannot always be seen by naked eye. In such cases, samples should be screened for secondary carbonates and recrystallization and diagenetic alteration using X-ray diffraction, thin-section examination (McGregor and Gagan 2003), or scanning electron microscopy (Webb et al. 2007; Nothdurft and Webb 2009).

If the outer layers of carbonate samples are contaminated by secondary carbonates, the outer surface of the samples is usually cleaned physically by abrasion or sandblasting and/or chemically by acid etching. Routine pretreatment of shell samples involves removal of the outer 20 % (by weight) of the samples by acid etching (Walker 2005). If contamination appears not only in the outer layers but also in the inner layers of carbonate samples (e.g., recrystallization and diagenetic alteration), acid etching may not be useful. This pretreatment method may result in an increase of the proportion of diagenetic calcite in the samples because aragonite is more soluble than calcite in acid media (Douka et al. 2010). This means poorly preserved carbonate samples may not be adequate for ^{14}C dating. Recently, Douka et al. (2010) and Russo et al. (2010) have tried to separate original aragonite from diagenetic calcite of poorly preserved fossil shells and corals by density separation using lithium heteropolytungstate and bromoform, respectively. Their initial test results were very encouraging.

Pretreated samples free of contamination are converted to CO_2 by reaction with acid solutions (dilute HCl or 85 % H_3PO_4). The sample CO_2 is usually converted to benzene or graphite for radiocarbon analysis using radiometric and accelerator mass spectrometry (AMS) method, respectively (Walker 2005; Hua 2009; Sloss et al. 2013).

Fig. 1 The ^{14}C content in the surface waters of the Pacific Ocean for the period 1950–1984 recorded in corals. Error bars are 1σ (Adapted from Hua (2009))

Marine Reservoir Effect and Age Calibration

After its production in the atmosphere, radiocarbon is oxidized to $^{14}\text{CO}_2$. In this form, ^{14}C is transferred from the atmosphere to the surface ocean via air-sea gas exchange and then incorporated into the deep ocean. The residence time of carbon in the deep ocean is quite long (~ 800 – $1,000$ years), and during this time ^{14}C in deep ocean waters decays without replenishment from the surface. As a result, the deep ocean has a much lower ^{14}C content than that of the atmosphere, or materials drawing carbon from the deep ocean reservoir are much older than contemporaneous materials of terrestrial origin. For the surface ocean, the aging effect is smaller because the surface ocean, exchanging with both the atmosphere and the ^{14}C -depleted deep ocean, has a ^{14}C level intermediate between these two reservoirs. In other words, marine organisms living in the surface ocean (e.g., shells, corals, and planktonic foraminifera) appear older than contemporaneous terrestrial samples. The age offset between surface ocean and terrestrial samples, ~ 400 years on average, is known as the marine reservoir age (R). Marine reservoir effect is corrected during the process of age calibration.

As radiocarbon and calendar ages are not the same, the former ages have to be converted to the latter ones using an age calibration process. To calibrate a radiocarbon date for a surface ocean sample, one can use an internationally ratified terrestrial calibration curve (e.g., IntCal13 for the Northern Hemisphere (Reimer et al. 2013) or SHCal13 for the Southern Hemisphere (Hogg et al. 2013)) with a known value of R . Alternatively, one can use the current internationally ratified marine calibration curve Marine13 (Reimer et al. 2013) with a known value of regional offset from the global marine model age for that sample, defined as ΔR . The latter method is generally preferred. Databases of R and ΔR values for different regions are available online (e.g., <http://calib.qub.ac.uk/marine/> and <http://radiocarbon.ldeo.columbia.edu/research/resage2.htm>). Calibration of ^{14}C ages is undertaken using a computer program. Several programs are available online (e.g., CALIB at <http://radiocarbon.pa.qub.ac.uk/calib/>, OxCal at <http://c14.arch.ox.ac.uk/embed.php?File=oxcal.html>).

Dating of Recent Materials

Atmospheric nuclear weapon tests, mostly in the late 1950s and early 1960s, released a considerable amount of ^{14}C into the atmosphere, leading to an enormous increase in atmospheric ^{14}C concentration. Via air-sea exchange of CO_2 , ^{14}C levels in the surface ocean also increased significantly. This means bomb radiocarbon can also be used to date recent marine carbonate samples. However, unlike the simple zonal pattern of bomb ^{14}C in the atmosphere (Hua et al. 2013), the distribution of bomb ^{14}C in the surface ocean is sensitive to local and regional patterns of ocean circulation including horizontal advection and vertical transport such as ocean upwelling. In other words, ^{14}C levels in the surface ocean have local and regional characteristics such as those depicted in Fig. 1 for the Pacific Ocean. Therefore, recent marine carbonate samples from a particular location can accurately be dated only if a surface ocean bomb ^{14}C curve for such location/region, which serves as a radiocarbon calibration curve, is well determined. Based on Fig. 1, the highest dating accuracy can be achieved for marine organisms formed in the period from ~1960 to the mid-1970s, when there was a significant increase in surface ocean ^{14}C .

Advances in Dating of Marine Carbonates

Small quantity of materials required by the AMS method (tens of micrograms to a couple of milligrams of carbon; Hua 2009; Sloss et al. 2013) has advanced radiocarbon dating in general and dating of marine carbonates in particular. For example, depositional chronologies of reef islands are traditionally based on radiocarbon dating of bulk carbonate sediments using the radiometric or conventional method. However, Woodroffe et al. (2007) dated by AMS different skeletal components of carbonate sediments (corals, foraminifera, and gastropod shells) collected in a transect across Warraber Island in Torres Strait (Australia) and compared these AMS dates to those of corresponding bulk carbonate sediments. The authors found that gastropods appeared to be the youngest among the samples and concluded that ^{14}C dates on the most dominant skeletal organism (gastropods in this case) rather than those on bulk carbonate sediments should deliver reliable information on reef island evolution.

The ability to analyze microgram-sized samples by AMS also helped to answer one of the important questions on the study of reef islands: How quick after their death are skeletal organisms transported from reef flats, where they are produced, to deposit to build reef islands? This question becomes more important as climate change progresses. In this scenario, the oceans become more acidic due to their uptake of anthropogenic CO_2 ; therefore it is likely that the skeletal organisms are vulnerable and consequently the development of reef islands is unsustainable. Dawson et al. (2013) studied Raine Reef in northwestern Australia and dated individual foraminifera, the most dominant skeletal organism at Raine, at different locations including the reef flat and beaches. A surface ocean ^{14}C bomb curve for the study region derived from known-age corals was reconstructed to facilitate the dating of these recent foraminifera. The AMS results on pristine samples indicated that it took a short period of time (maximum of 13–27 years) to transport the samples from the reef flat to the island, over distance up to 2 km.

Another example of dating of small-sized carbonate samples is the use of bomb ^{14}C in the surface ocean to validate fish ages (Ewing et al. 2007; Andrews et al. 2011). This method was pioneered by Kalish (1993) when he showed a good comparison between ^{14}C values recorded in known-age otolith carbonate of a marine fish species and regional surface ocean ^{14}C records from corals of the Great Barrier Reef. In this application, the birth dates of fish specimens were first

estimated by counting annual increments visible in otolith thin sections. These dates were then checked or validated by comparing the ^{14}C content of the first annual otolith increment with a regional surface ocean ^{14}C bomb curve.

Difficulties in Dating of Marine Carbonates

The ^{14}C content in some shellfish species may not reflect that of dissolved inorganic carbon (DIC) of surrounding sea waters at the time of accretion of their calcium carbonate skeletons, leading to problems in radiocarbon dating of these species. Petchey (2009) attributed these issues to the dietary and habitat preferences of shellfish. In particular, deposit feeders consume detritus in areas dominated by limestone geologies containing much older carbon or digest younger carbon from a terrestrial source in areas influenced by local freshwater runoff. As a result, the ^{14}C ages of these shellfish samples are older or younger than the true ages, respectively. Dating of carnivorous shellfish is also problematic because of the uncertainty in their ^{14}C content, which is dependent on the carbon reservoirs of their prey. By contrast, suspension feeders, which consume suspended phytoplankton and seawater DIC, reflect the ^{14}C content of the surface ocean and are therefore considered as the most reliable shellfish for dating (Petchey 2009).

The ^{14}C content of organisms living in atoll lagoons and estuaries may also be different from that of open ocean waters. For shallow lagoons with limited exchange with open ocean waters, ^{14}C levels of lagoonal waters are strongly influenced by air-sea gas exchange and are therefore much higher than those of nearby open sea waters (Petchey 2009). Similarly, ^{14}C levels of estuarine waters reflect the interaction and mixing of terrestrial and marine carbons (Ulm 2002). The estuarine effect is significant where water circulation is restricted. Thus accurate dating of these organisms can be achieved only if R and/or ΔR values relevant to their environment are known.

Radiocarbon dating of surface ocean samples involves estimates of marine reservoir effect (R and ΔR). These values for a given location are generally assumed to be constant with time when calibrating marine ^{14}C ages. However, recent studies have reported large variability in the marine reservoir effect of several hundred to a couple of thousand years for various regions during the Late Glacial and Holocene (e.g., Siani et al. 2001; Bondevik et al. 2006; Yu et al. 2010; Ortlieb et al. 2011). These variations resulted from changes in ocean circulation and the carbon cycle associated with climate change. For these regions, if temporal variability in R and ΔR does not take into account when calibrating marine ^{14}C ages, the resultant calibrated ^{14}C ages may be erroneous. Ortlieb et al. (2011) reported high ΔR values for the northern Chile-southern Peru coast of up to 1,000 years during the period 7,000–10,000 cal years BP (early to mid-Holocene) in comparison with their modern value of 200–300 years. The authors showed that the calibrated ^{14}C ages during the early to mid-Holocene based on the constant modern ΔR value were older than the true calendar ages of up to 800–1,000 years.

Summary

Radiocarbon dating has widely been used to reconstruct chronologies for marine carbonates for the past 50 ka for studies in archaeology, earth sciences, paleoceanography, marine ecology, and Quaternary climate change. For example, radiocarbon-dated corals have been used to investigate changes in sea surface temperature and salinity, and variations in El Niño-Southern Oscillation through time. Radiocarbon dates on boring bivalves occurring in dislocated boulders and on

mollusk shells associated with gravel deposits along coast lines have also been employed to constrain the timing of tsunami events. In addition, radiocarbon dating of cultural shells has been used for the study of human occupation and colonization of Pacific atolls.

With the advent of AMS radiocarbon dating on microgram-sized samples, some radiocarbon applications are available (e.g., validation of fish ages by ^{14}C analysis of fish otoliths) or become more reliable (e.g., ^{14}C -based chronologies for the study of reef island evolution). However, the dietary and habitat preferences of shellfish, the lagoonal and estuarine effects, and possible temporal variations in the marine reservoir effect should be carefully considered when dating marine samples.

Radiocarbon Dating of Terrestrial Carbonates

Jeffrey S. Pigati*

U.S. Geological Survey, Denver Federal Center, Denver, CO, USA

Introduction

Terrestrial carbonates encompass a wide range of materials that potentially could be used for radiocarbon (^{14}C) dating. Biogenic carbonates, including shells and tests of terrestrial and aquatic gastropods, bivalves, ostracodes, and foraminifera, are preserved in a variety of late Quaternary deposits and may be suitable for ^{14}C dating. Primary calcareous deposits (marls, tufa, speleothems) and secondary carbonates (rhizoliths, fracture fill, soil carbonate) may also be targeted for dating when conditions are favorable. This chapter discusses issues that are commonly encountered in ^{14}C dating of terrestrial carbonates, including isotopic disequilibrium and open-system behavior, as well as methods used to determine the reliability of ages derived from these materials. Recent methodological advancements that may improve the accuracy and precision of ^{14}C ages of terrestrial carbonates are also highlighted.

Dating Terrestrial Carbonates

All materials that yield reliable ^{14}C ages have two common characteristics. First, the initial ^{14}C activity of a material must be in isotopic equilibrium with atmospheric ^{14}C at the time it was alive (for living materials) or precipitated (for nonliving materials). Second, it must behave as a closed system with respect to carbon after death or precipitation; that is, secondary (contaminant) carbon is neither added to nor exchanged with carbon that is original to the material itself. If both of these criteria are met, then the measured ^{14}C activity is a function of only two parameters: the initial ^{14}C activity of the atmosphere and the amount of time elapsed since the death of the organism.

The measured ^{14}C activity and age of the material are related by the familiar decay equation

$$A = A_0 e^{-\lambda t}$$

where A and A_0 are the measured and initial ^{14}C activities of the material, respectively; λ is the decay constant of ^{14}C ; and t is the time elapsed since death or precipitation. Conventional radiocarbon ages (incorrectly) assume that atmospheric ^{14}C activity is invariant through time ($A_0 = 1$) and are calculated using the Libby half-life for ^{14}C of $5,568 \pm 30$ years (Libby 1955). Radiocarbon ages can be converted to calendar year ages via calibration to account for temporal variations in the ^{14}C activity of the atmosphere that are known to have occurred (Reimer et al. 2013). Calibration also accounts for the differences between the Libby half-life and the Cambridge half-life for ^{14}C of $5,730 \pm 40$ years (Godwin 1962). If the equilibrium and closed-system

*Email: jpigati@usgs.gov

behavior criteria are met, and the calibration curves are accurate, then the calibrated age of a material should represent its true age in calendar years.

Isotopic Equilibrium

Organisms obtain carbon to build their shells or tests from up to four different sources: air, water, food, and rocks. The ^{14}C activity of these sources ranges from modern (atmospheric CO_2 , live plants, modern water) to ^{14}C -deficient (organic detritus, “old” water) to ^{14}C -free or “dead” (carbonate rocks, coal, some peat deposits). The influence that each of these sources has on the overall ^{14}C content of a shell or test depends on the relative proportion that they contributes to the total carbon pool. For example, if a gastropod obtains all of its shell carbon from air, live plants, and modern water, then the isotopic equilibrium criterion is satisfied and its shell may be suitable for ^{14}C dating. However, if the same gastropod consumed old organic detritus or peat, drank water that was deficient in ^{14}C , or ingested limestone and incorporated the dead carbon in its shell, then the isotopic equilibrium criterion would be violated and the resulting shell age would be too old. Common causes of isotopic disequilibrium in biogenic carbonates are discussed below in order to demonstrate the importance of identifying and quantifying the various sources that contribute carbon to the dated material.

Terrestrial Gastropods and the “Limestone Problem”

Terrestrial gastropods acquire carbon to build their shells from air, water, plants (live and decayed), and carbonate rocks (limestone, dolomite, soil carbonate). Respired CO_2 from the atmosphere is introduced to the bicarbonate pool in the gastropod’s hemolymph and passed along to the extrapallial fluid, from which the shell carbonate is ultimately precipitated (Wilbur 1972). Carbon from food sources (e.g., living plants, fungi, organic detritus) and water (dissolved inorganic carbon; DIC) is also incorporated into the extrapallial fluid and incorporated into the shell material (Balakrishnan and Yapp 2004). Estimates of the individual contributions of atmospheric CO_2 , plants, and water toward gastropod shell carbon vary considerably, but together, in the absence of limestone or carbonate rocks, they account for 100 % of the total input (Goodfriend and Hood 1983; Stott 2002; Romaniello et al. 2008).

In most environments, the ^{14}C activities of live plants and water sources are in equilibrium with atmospheric carbon, which is ideal for ^{14}C dating. However, gastropods also consume organic detritus (i.e., decaying plant litter), which potentially could cause their ^{14}C ages to be anomalously old. In most cases, however, the amount of time elapsed between the death of a plant, its incorporation into decomposition products, and consumption by gastropods is usually quite short, on the order of a few years, which would not affect the resulting ^{14}C ages significantly. Gastropods living in or around coal seams and peatlands are an exception, as they may have access to carbon that is hundreds or even thousands of years old. Similarly, gastropods living in areas of active volcanism, where ^{14}C -deficient carbon in plants may be present, can also yield ages that are much too old. Shell ages derived from gastropods living in these unusual settings should be evaluated carefully.

These exceptions aside, the primary concern with dating terrestrial gastropod shells is the “limestone problem.” A term coined by Goodfriend and Stipp (1983), the limestone problem refers to the fact that many gastropods scrape or abrade carbonate rocks and ingest the powder or granules which then dissolve in their stomach acid to produce CO_2 . As with carbon from other sources, the dead carbon from rocks is introduced to the hemolymph, passed on to the extrapallial fluid, and ultimately incorporated in the shell carbonate. Dead carbon from limestone can account for up to ~30 % of the total carbon in shells of some large terrestrial gastropods, which would cause apparent

^{14}C ages of the shell carbonate to be $\sim 3,000$ ^{14}C years too old (Tamers 1970; Goodfriend and Stipp 1983; Zhou et al. 1999; Pigati et al. 2004). Unfortunately, a simple correction factor that accounts for the limestone effect cannot be applied universally because the amount of old carbon incorporated by gastropods is highly variable, both between taxa and between populations of a single taxon living in different habitats (Goodfriend et al. 1999; Pigati et al. 2010). Thus, to be confident in ^{14}C ages derived from terrestrial gastropod shells, researchers should avoid dating gastropods that incorporate dead carbon from rocks altogether.

Aquatic Organisms and Hard-Water (or Reservoir) Effects

The ^{14}C activity of dissolved inorganic carbon (DIC) in springs and lakes can be lower than atmospheric values for two reasons: (1) interaction between ground water and carbonate rocks, and (2) isotopic decay of DIC that occurs as water molecules travel between areas of recharge and discharge. The magnitude of the local “hard-water” or “reservoir” effect can be highly variable, ranging from negligible to extreme. For water bodies that freely exchange carbon with the atmosphere, the ^{14}C activity of DIC should be in isotopic equilibrium with atmospheric carbon. On the other hand, the ^{14}C activity of ground water flowing through large carbonate aquifers can be very depleted, reaching values as low as $\sim 2\text{--}3\%$ of modern values (e.g., Winograd and Pearson 1976; Riggs 1984). Fully aquatic organisms, such as gill-breathing aquatic gastropods (subclass Prosobranchia), ostracodes, and foraminifera, acquire all of their carbon from aqueous sources, either directly from the water or indirectly from aquatic plants. Thus, the full magnitude of the local hard-water effect is passed on to shells or tests of these organisms. Lung-breathing aquatic and semiaquatic gastropods (subclass Pulmonata) obtain their shell carbon from both water and air and, therefore, are subject to partial hard-water effects. For these gastropods, the offset between true and apparent ages depends on both the magnitude of the local hard-water effect and the proportion of shell carbon derived from aqueous sources and the atmosphere.

Closed-System Behavior

Even if organisms avoid the limestone problem and hard-water effects, their shells or tests must remain closed systems with respect to carbon after death if they are to yield reliable ^{14}C ages. To do so, carbon atoms measured during the ^{14}C dating process must consist solely of those that originally resided in the shell or test. Biogenic carbonates that exhibit open-system behavior typically yield ^{14}C ages that are too young, and the magnitude of the error depends upon the degree of such behavior. Unlike limestone or hard-water effects, which result in discrepancies between measured and actual ^{14}C ages that remain constant over time, the impact of open-system behavior increases with sample age (Fig. 1). For example, if a gastropod shell that is 10,000 ^{14}C years old is contaminated by the equivalent of 1 % modern carbon, then the resulting age would be 9,730 ^{14}C years, a difference of only 270 ^{14}C years. In contrast, if a shell that is 50,000 ^{14}C years old is contaminated by modern carbon to the same extent, the apparent age would be only 35,540 ^{14}C years, a difference of 14,460 ^{14}C years!

Reliable or Not? Evaluating Carbonates for Potential Use in ^{14}C Dating

If terrestrial carbonates are to be used for ^{14}C dating, it is critical that they are evaluated repeatedly in different depositional settings, habitats, and climate regimes to determine if they meet the isotopic equilibrium criterion and behave as closed systems with respect to carbon during burial. Evaluations can be done using at least three different methods: (1) evaluating the ^{14}C content of

Fig. 1 Deviation from the true ^{14}C age for four scenarios: (1) closed-system behavior and no dead carbon (*thick solid line*), (2) closed-system behavior and 10 % dead carbon (*dashed line*), (3) open-system behavior equivalent to 1 % modern carbon contamination and 10 % dead carbon (*thin solid line*), and (4) open-system behavior equivalent to 1 % modern carbon contamination and no dead carbon (*dotted line*) (After Pigati et al. 2010)

modern specimens, (2) comparing ^{14}C ages of terrestrial carbonates with independent ages, and (3) analytical assessments.

Evaluating Modern Specimens

Evaluating modern specimens for the presence of old carbon from either limestone or hard water can be done with relative ease and minimal cost. Moreover, such evaluations provide worst-case scenarios because the influence of old carbon is most apparent in young/modern samples. In modern evaluations, the ^{14}C activities of live-collected specimens are measured by accelerator mass spectrometry (AMS) and compared against atmospheric values (Hua and Barbetti 2004). If old carbon from limestone or hard water is present, then the measured ^{14}C activity will be lower than the atmosphere. It is critical to perform such evaluations on the specific taxon of interest. For example, Goodfriend and coworkers found evidence of significant (10–30 %) old carbon in large (1–2 cm diameter) gastropods collected live in Texas and elsewhere in the southwestern United States (Goodfriend 1987; Goodfriend et al. 1999). In contrast, Pigati et al. (2004, 2010) examined the ^{14}C activities of small (<1 cm diameter) terrestrial gastropods collected live from limestone or carbonate terrains throughout North America. They found that nearly 80 % of the taxa analyzed did not show evidence of measurable limestone effects. Results from these studies show the importance of evaluating the specific taxon of interest rather than extrapolating results across taxonomic lineages.

Obviously, evaluating modern specimens is only possible if the taxa of interest are still living today, which is not always the case. Moreover, although modern evaluations usually give clear indication of whether old carbon is a problem in the material to be dated, researchers must assume that the results observed remain invariant over time. In general, this appears to be the case for terrestrial gastropods. Terrestrial taxa such as Succineidae, *Discus*, and a few other common small gastropods that appear to avoid limestone in modern settings also yield ages that are similar to independent ages in the fossil record (Pigati et al. 2013). Similarly, *Mesodon* shells are offset from

Fig. 2 (a) Independent and gastropod shell ages from a Holocene loess section in Wrangell-St. Elias National Park near Chitina, AK (Muhs et al. 2013b; Pigati et al. 2013). The independent ages consist of calibrated ^{14}C ages from well-preserved wood, and the shell ages are from Succineidae. (b) Independent and gastropod shell ages from loess deposits at Loveland, IA (Muhs et al. 2013a; Pigati et al. 2013). The independent ages consist of optically stimulated luminescence (OSL) ages, and the shell ages are from Succineidae

independent ages by the equivalent of $\sim 3,000$ ^{14}C years or more in both modern systems and the fossil record (Rakovan et al. 2013).

In aquatic environments, researchers can evaluate modern aquatic or semiaquatic organisms living near extant springs and lakes to determine the influence of potential hard-water effects, which are also assumed to be invariant over time. However, hard-water or reservoir effects in some hydrologic systems (mostly lakes) can vary significantly over time because of changes in the balance between hydrologic inputs, say, for example, between runoff and ground water. Thus, if there is reason to believe that the relative contributions of different inputs have varied in the past, then the results of modern evaluations may not be directly applicable to aquatic systems in the geologic record.

Comparison Against Known Ages

One of the best – and most difficult – evaluations to conduct is to compare terrestrial carbonate ages against independent ages to determine if the shells or tests remained closed systems after death. If the evaluations can be conducted for the same time period and environmental conditions represented in the geologic record of interest, then we can be reasonably confident in the results. However, establishing strong independent chronologies is often difficult and costly.

Thus far, there have been relatively few studies conducted in which terrestrial gastropod shell ages have been systematically compared against robust independent ages. Results from loess deposits in Alaska and the Great Plains demonstrate that shell ages (mostly from Succineidae) closely track independent ^{14}C ages derived from plant macrofossils and luminescence ages over the past 40,000 year or so (Fig. 2). Shell ages of terrestrial gastropods from soils and wetland deposits in the southwestern United States and Europe, as well as glacial deposits in the Midwest United States, are also indistinguishable from independent ages, which suggests that many small terrestrial

gastropod shells do, in fact, yield reliable ^{14}C ages for the fossil record, regardless of the local rock type, depositional setting, or climate regime (e.g., Preece 1991, 1994; Pigati et al. 2010, 2011).

Chronologies based on ^{14}C dating of aquatic carbonates can be compared to ^{14}C ages of vascular plant material or charcoal, as well as independently dated chronometric markers such as tephra layers, unique geochemical signatures (e.g., presence of industrialization by-products, anthropogenic indicators), or geomagnetic excursions. In ideal situations, researchers working in aquatic systems should use multiple tie points between the carbonates and independent ages to determine whether the local hard-water effect remained constant over time.

Analytical Assessments

Analytical tools, including scanning electron microscopy (SEM) images and X-ray diffraction (XRD), can be used to determine the nature and physical location of contaminants in terrestrial gastropod shells (Yates 1986; Rech et al. 2011). SEM images can show the position and physical structure of potential contaminants, especially if they are present on the surface of the material dated. However, if chemical exchange has occurred without concomitant morphologic alteration, then SEM imagery may not reveal the contaminants. XRD methods can detect the presence of calcite contaminants in aragonitic shell material, but in most cases the amount of calcite contamination must be at least ~1 % of the total to be detected reliably. If SEM or XRD techniques cannot be applied, then, at a minimum, the shells or tests of terrestrial and aquatic organisms should be broken and inspected under magnification to ensure that they are free of detritus before processing.

Methodologic Innovations

One of the primary assumptions in radiocarbon dating is that the carbon atoms isolated for dating consist solely of atoms that are original to the material itself (i.e., no contamination). Some terrestrial carbonates, such as ostracodes, have exceptionally high surface area-to-volume (SA/V) ratios, which increases the likelihood of chemical exchange with the atmosphere during pretreatment. Standard laboratory procedures for dating carbonate shells or tests often include etching the surfaces with dilute acid, which removes dust and other particulate contaminants. However, recent studies have shown that modern atmospheric carbon can be incorporated into ostracode tests by either surface adsorption or exchange during laboratory processing (Hajdas et al. 2004). Such contamination may not necessarily be removed during the etching process. Stepped-dissolution experiments using ostracode tests show that even after etching, younger carbon is preferentially released during initial acid dissolution steps (i.e., contaminants plus sample material), whereas older carbon is released in later steps, presumably all original to the sample (Zimmerman et al. 2012). These results imply that if the SA/V ratio of a material is high enough, contaminants can be missed by standard laboratory pretreatment protocols and the resulting ^{14}C ages would be too young. Although stepped-dissolution procedures can be time consuming, technically challenging, and expensive if multiple aliquots are measured by AMS, they may ultimately yield ^{14}C ages that are more accurate and precise than those obtained using standard methods.

Conclusions

Terrestrial carbonates encompass a wide variety of materials that can potentially be used for ^{14}C dating. However, issues related to isotopic disequilibrium and open-system behavior must be addressed before ^{14}C ages derived from these materials are considered reliable. Removing contaminating materials from terrestrial carbonates can be difficult because the contaminant species is often calcite, which may be the same as, or similar to, the sample material. For biogenic carbonates that are composed of aragonite, small amounts of calcite contamination may be detected using scanning electron microscopy or X-ray diffraction. In the fossil record, ^{14}C ages derived from terrestrial carbonates should be compared against ^{14}C ages of independent materials (ideally charcoal or plant macrofossils) in depositional settings and time periods that are similar to those in the geologic record of interest. If the terrestrial carbonates consistently meet the isotopic equilibrium and closed-system behavior criteria, then the materials should yield reliable ^{14}C ages. New methodological and technological innovations may improve the accuracy and precision of ^{14}C ages of terrestrial carbonates, which is particularly important as high-resolution chronologies are increasingly given high priority in paleoclimate and other studies.

Corals (Sclerochronology)

Kristine L. DeLong*

Department of Geography and Anthropology, Louisiana State University, Baton Rouge, LA, USA

Synonyms

[Coral chronometer](#); [Related to dendrochronology](#)

Definition

Sclerochronology: The study of the incremental layers contained in the hard parts or skeletons of organisms that form at regular intervals during the organism's life span. Sclerochronology is derived from the Greek words *sklero* meaning "hard," *khronos* meaning "time," and *logos* meaning "science of." Sclerochronology is related to dendrochronology or the study of annual growth rings in trees.

Coral: Corals are in the class Anthozoa of the phylum Cnidaria and include scleractinian or "stony corals," which form colonies of many individual polyps with an external skeleton or exoskeleton of calcium carbonate (CaCO_3), and non-stony corals or soft corals. Some stony corals contain incremental layers in their exoskeleton. Coral-based sclerochronological research is focused on stony corals yet recent research reveals that some soft coral species contain incremental layers (see Roark et al. [2006](#)).

Introduction

The general term of sclerochronology includes a diverse array of marine and terrestrial organisms, both extinct and extant, that produce hard structures with regular time intervals related to the organism's growth and/or environment. Such organisms include corals, molluscs, fish otoliths or "ear bones," coralline algae, sclerosponges, brachiopods, and bones of vertebrate animals with research expanding to other organisms (see Arnold and Jones [2007](#); Schöne [2010](#)). This description is focused on coral-based sclerochronology, in particular scleractinian corals, with descriptions of mollusc-based sclerochronology appearing in another entry.

The exoskeleton of scleractinian corals is composed of aragonite, a mineral form of calcium carbonate, deposited by the living coral polyps within the surface of the exoskeleton. The individual coral polyps calcify new skeleton thecal "walls" and dissepiment "floors," lifting up as new skeleton is created, similar to building a skyscraper. As the coral deposits its skeleton, it produces a high-density band and a low-density band each year while simultaneously recording environmental signals, such as water temperature and chemistry, in its skeleton (e.g., $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and Sr/Ca). Coral colonies have different morphologies including branching, columnar, and

*Email: kdelong@lsu.edu

boulder-shaped or massive corals, for which annual density bands are found in massive and columnar colonies. Massive coral colonies, which grow up to 8 m in height (Veron 1986; Isdale et al. 1998; Corrège 2006; Brown et al. 2009), can live for many centuries providing a continuous annual chronology preserved in its exoskeleton. Coral sclerochronology is used for establishing time for a variety of purposes including paleoceanographic and paleoclimatic reconstructions, investigations of environmental change, refining radiometric dating methods, assessing sea-level variations, and documenting earthquakes.

History

Research on coral reefs began in earnest with Charles Darwin's hypothesis of reef formation with the passage of time (Darwin 1842). Early work with the branching coral *Acropora palmata* in the Bahamas notes regular undulations on the surface of the broad fronds (Whitfield 1898) shown empirically as annual in nature (Vaughan 1915). A Chinese paleontologist, Ting-Ying H. Ma (1934), notes that Paleozoic and recent corals contain internal skeletal structures with varying densities. The report of Wells (1963) examines diurnal growth lines in the epitheca of Devonian corals, which he interprets as evidence for more days in a Devonian year compared to present.

Despite these early studies, the annual nature of density variations within coral skeletons is not confirmed until the study of Knutson et al. (1972) examines corals from the nuclear test site at Eniwetok Atoll. That study uses autoradiography to image radioactive layers in the coral colony by placing X-ray film in contact with a thin radial cross section for over one month. Next, they couple autoradiography with X-radiography, which reveals alternating high- and low-density bands in the cross section, and then count the number of density band couplets between the radioactive bands. They found the number of bands equals the number of years between nuclear weapons tests, thus confirming the annual nature of high-low-density bands in corals. Knutson et al. (1972) suggest combining the “coral internal calendar” with isotope thermometry in corals (Weber and Woodhead 1972) will allow for the “construction of coral-ring chronologies” of past oceanic variability, similar to dendrochronology. In June 1973, the papers presented at the Second International Symposium on Coral Reefs include publications related to sclerochronology (Buddemeier 1974; Macintyre and Smith 1974; Moore and Krishnaswami 1974). The use of term “sclerochronology” first appears in two 1974 publications (Buddemeier et al. 1974; Macintyre and Smith 1974), yet this term appears to originate from this conference. Subsequent studies confirm the annual nature of the density couplets for Atlantic and Indo-Pacific coral species by radiometric analysis, staining, and direct measurement (Buddemeier 1974; Buddemeier et al. 1974; Dodge and Thomson 1974; Macintyre and Smith 1974; Moore and Krishnaswami 1974) as well as revealing diurnal increments (Barnes 1970) and monthly or lunar cycles (Buddemeier 1974).

Sclerochronological Methods

Samples for sclerochronological studies include cores, 3–10 cm in diameter, extracted from large colonies using hydraulic or pneumatic drills or whole colonies if small enough to recover by divers or by a boat-mounted winch. The cores or colonies are sectioned along the primary growth axis to thin slabs of constant thickness of approximately 0.5 cm. The slabs are exposed to X-rays to produce X-radiographs (i.e., X-ray images) using either film or digital X-ray systems. X-radiographs are negative images exhibiting density variations from light high-density areas to

dark low-density areas in the coral slab for which alternating bands of high and low density represent a single year's growth. Years are assigned by counting annual density couplets from a known date or collection date from the top of the slab following the density bands and growth patterns. A floating chronology (e.g., year 1, year 2, etc.) is utilized for samples without a known collection date such as dead or fossil corals.

Two parameters of coral growth are measured from X-radiographs: linear extension per year (cm/year) and skeletal density (g/cm^3), both of which vary independently on a seasonal basis. Relative calcification rate ($\text{g}/\text{cm}^3/\text{year}$) is the product of linear extension and density. Annual linear extension (cm) is physically measured from the top of one high-density band to the top of the next high-density band using calipers. X-ray and gamma densitometers provide density measurements from coral slabs (Buddemeier 1974; Dodge and Thomson 1974; Chalker et al. 1985; Chalker and Barnes 1990). For digital X-radiographs, imaging software such as Coral XDS (www.nova.edu/ocean/coralxds) (Helmle et al. 2002), Image J (sb.info.nih.gov/ij), and Adobe Photoshop[®] (www.photoshop.com) are used to determine linear extension and relative density. Linear extension can be determined from the winter extremes in seasonal coral chemical variations (e.g., $\delta^{18}\text{O}$ or Sr/Ca) using the distance (i.e., cm from core top) between these samples. This method is particularly useful for comparing chemical variations and extension rates, but precision is limited to the chemical sampling resolution.

The study of Dodge and Thomson (1974) is the first to apply methodologies from dendrochronology to build a master chronology using density variations from multiple coral colonies in Bermuda. Further work with a larger network of colonies reveals long-term covariance with temperature and air pressure records (Dodge and Vaisnys 1975). The report of Hudson et al. (1976) demonstrates that stress bands in *Montastraea annularis* formed by cold events can be used as stratigraphic markers for cross-dating between live and dead colonies from the same reef. Some corals skeletons contain luminescent lines under ultra-violet light from soil-derived humic acids that are interpreted as proxies of coastal precipitation and runoff (Boto and Isdale 1985; Omata et al. 2006; Grove et al. 2010). Researchers utilize these lines to cross-date coral colonies to produce runoff histories for individual rivers and regional scale precipitation reconstructions that span multiple centuries (Isdale et al. 1998; Hendy et al. 2003; Nyberg et al. 2007; Lough 2011). Cross-dated luminescence corals are coupled with chemical records to extend these records back in time (Tudhope et al. 1996; Hendy et al. 2002). The study of Cobb et al. (2003) uses high-precision uranium-thorium dating (± 5 –10 years) and correlation between coral $\delta^{18}\text{O}$ variations to generate long overlapping coral records reconstructing El Niño-Southern Oscillation variability (Cobb et al. 2013). A relatively new application is cross-dating coral Sr/Ca variations, a temperature proxy, between cores from the same *Porites lutea* colony to produce a 350-year-long sea surface temperature (SST) reconstruction (DeLong et al. 2012). Those authors confirm their cross-dated Sr/Ca chronology with high-precision (± 1 year) ^{230}Th dating (Shen et al. 2008), which allows them to assess sources of chronology error (DeLong et al. 2013). Further application of this cross-dating method with live and dead *Siderastrea siderea* corals has produced a 274-year-long SST reconstruction for the Gulf of Mexico (DeLong et al. [In Review](#)).

Applications of Coral Sclerochronology

Growth in corals varies with environmental factors such as temperature, light, and nutrients; thus, environmental variations are recorded in the sclerochronology. Initial studies at Eniwetok suggest that density bands in the corals form in response to seasonal variations in cloud cover or

precipitation (Knutson et al. 1972; Buddemeier et al. 1974). Conversely, the report of Weber et al. (1975), with a wide array of corals in locality and genera, finds seasonal temperature variations drive coral growth rates. Further research with coral growth records continues to produce conflicting results (see reviews of Buddemeier and Kinzie 1976; Barnes and Lough 1996); consequently, these records were relegated to chronology development for coral chemical studies in the early 1990s, yet recent interest in ocean acidification has revived interest in coral growth histories (see reviews of Lough 2008; Lough and Cooper 2011).

Soon after the confirmation of annual increments in corals, researchers started sampling coral skeletons across the density bands to produce time series of chemical variability. These early studies coupled sclerochronology with coral chemistry including stable isotopes ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) (Goreau 1977; Emiliani et al. 1978; Nozaki et al. 1978; Fairbanks and Dodge 1979), trace elements (Fe, Mg, Na, and Sr) (Goreau 1977; Oomori et al. 1982; Schneider and Smith 1982), and radiocarbon (Druffel 1980). These coral chemical variations and others represent water chemistry histories (e.g., B, Ba/Ca, ^{14}C , Mn/Ca, P/Ca, and Pb/Ca) as well as serve as proxies for water temperature ($\delta^{18}\text{O}$, Mg/Ca, Sr/Ca, and U/Ca) and ocean circulation (e.g., ^{14}C , Ba, and Cd) (see reviews of Shen 1993; Druffel 1997). Advances in sampling methodologies (e.g., up to weekly) and analytical improvements (i.e., reducing the amount of sample needed and improved analytical precision) have resulted in rapidly expanding coral chemical research compared to growth-rate studies (Lough and Cooper 2011). Coral sclerochronology-chemistry studies include numerous high-resolution, multi-century long records (see www.ncdc.noaa.gov/paleo/corals) that provide valuable information to the fields of paleoclimatology, ocean circulation, and environmental change (see reviews of Swart 1983; Druffel 1997; Gagan et al. 2000; Cole 2003; Felis and Patzold 2004; Corrège 2006; Grottoli and Eakin 2007; Lough 2010).

The sclerochronology determined by counting the annual bands in corals allows for comparisons with radiometric dating methods (e.g., U-Th) to improve analytical methods (e.g., Shen et al. 2008, 2012; Clark et al. 2012). Radioisotopes are incorporated in the coral exoskeleton during calcification (e.g., ^{14}C , ^{228}Ra , and ^{210}Pb) or by decay after incorporation (e.g., ^{230}Th and ^{231}Pa). Uranium-thorium (U-Th) dating of carbonates provides ages with high precision (± 3 years) with relatively small sample sizes (Edwards et al. 1987). The study of Shen et al. (2008) refines U-Th dating for corals by measuring 141 coral samples each extracted from a single density band of known age, determined by counting annual bands. Those authors demonstrate that corals with an age less than 100 years can be ^{230}Th -dated with a precision of ± 1 year. Further analytical refinement resulted in reduced sample size for U-Th analysis (10–50 mg of coral carbonate) with a precision of less than ± 1 year (Shen et al. 2012). Such high-precision U-Th dates allow for the cross-dating of dead and fossil corals to extend the inclusive records further in time (e.g., DeLong et al. In Review).

Microatolls are massive corals in very shallow water with a dead flat or concave top resembling an atoll island. As these corals grow out of the water, the exposed surface dies while the submerge surface continues to live; thus, these corals serve as an indicator of sea level (Smithers and Woodroffe 2000). Counting the annual bands in the coral's X-radiograph reveals the date the coral surface emerged from the water. Using microatolls as tide gauges, the study of Taylor et al. (1987) documents the date of four earthquake events in Vanuatu, an island in the southwest Pacific, that uplifted the corals during earthquakes. These coral earthquake records provide dates of past earthquakes in remote areas that lack such records, as well as information on vertical uplifting rates and seismic movements (Buskirk et al. 1982; Taylor et al. 1982). Other researchers utilize microatolls to study twentieth-century sea-level variations (e.g., Smithers and Woodroffe 2001) and Holocene sea-level changes (e.g., Yu et al. 2009; Woodroffe et al. 2012). Investigations with

microatolls include corals from the tropical Pacific, Indian, and Atlantic oceans (see review of Buddemeier and Taylor 2000).

Summary

Coral sclerochronology started with the discovery of annual density bands within the coral skeleton. These bands are visible in X-radiographs and dates are assigned by counting bands from the collection date. The primary use of coral sclerochronology is assigning time to synchronous chemical records store in the skeletons of these long-lived organisms. These time series of coral chemical variations are used for paleoclimate reconstructions, investigations of environmental change, and refining radiometric dating methods. Additionally, annual density bands in corals are utilized to investigate changes in sea level and earthquakes. The field of coral sclerochronology is continually advancing with new applications being developed to decipher the hidden messages stored in the skeletons of corals.

Glacial Landscape (Cosmogenic Nuclide)

Joerg M. Schaefer*

Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA

Introduction

Cosmogenic nuclides have become powerful tools to explore glacial landscapes toward reconstructing cryospheric change (Balco 2011) on a wide spectrum of time scales and are currently revolutionizing the fields of glacial geology, terrestrial climate, cryosphere science, and earth surface process geomorphology. Whenever glaciers and ice sheets fluctuate, the mighty ice alters the earth surface, carves previously unexposed surfaces, and deposits glacial sediments, including moraine ridges. Exposure of such newly formed glacial surfaces to the cosmic radiation at the moment of ice retreat starts the cosmogenic nuclide clock (referred to as “► [Cosmogenic Nuclide Dating](#)”; See also “► [Cosmogenic Nuclide](#)” overview entry in the same issue and the following seminal review articles: Cerling and Craig (1994), Gosse and Phillips (2001), Granger et al. (2013), Lal (1991)). About 20 years ago, pioneering studies first applied cosmogenic nuclide techniques to date moraines, glacially formed ridges of rock and soil that mark former glacier positions (e.g., Brook et al. 1993; Gosse et al. 1995; Ivy-Ochs et al. 1999). Since then, originally paced by progress by John Stone (University of Washington, Seattle), the sensitivity of cosmogenic nuclide techniques has been transformationally refined (e.g., Stone et al. 2003). Also, new cosmogenic nuclide tools, further widening the application spectrum, have been introduced, most recently the “in situ ^{14}C ” technique, developed and implemented by Nat Lifton (Lifton et al. 2001). Time scales to cosmogenically clock land ice change now span from many million years (Bruno et al. 1997; Ivy-Ochs et al. 1997; Margerison et al. 2005; Schäfer et al. 1999) to 100 years ago and less (Kelly et al. 2008; Licciardi et al. 2009; Schaefer et al. 2009; Schimmelpfennig et al. 2014; Stroup et al. 2014). Novel cosmogenic nuclide applications include dating of the first maximum of the Laurentide Ice Sheet (Balco et al. 2005) using buried tills in the central USA and constraining past ice sheet fluctuations in Antarctica by cosmogenic nuclide dating of “nunatak dipsticks,” ice-free rock formations towering above the ice sheet (Balco et al. 2013; Johnson et al. 2014). Other recent studies pioneer the application of cosmogenic nuclide techniques to explore pro- and subglacial bedrock as environmental archive (Goehring et al. 2013, 2011). All these successes are the product of an integrated science approach, crosscutting the disciplines of Quaternary Geology (geomorphic mapping), Glaciology (glacier dynamics), Geochemistry (cosmogenic nuclide analysis), and Climate Science (synthesis). This short entry attempts to illustrate the breathtaking dynamic of progress in cosmogenic nuclide science by presenting application examples toward forefront questions in climate and glacier science. Here, we primarily focus on the cosmogenic nuclide ^{10}Be . Other cosmogenic nuclide techniques, in particular ^3He (Blard et al. 2013b; Goehring et al. 2010; Kurz 1986), ^{36}Cl (Schimmelpfennig 2009; Schimmelpfennig et al. 2011), and in situ ^{14}C (Goehring et al. 2014; Hippe et al. 2014, 2013; Lifton et al. 2001), are rapidly progressing, but covering all cosmogenic nuclides would be beyond scope and space of this entry.

Methods

Cosmogenic Nuclide Production Rates

Here, we review recent progress in our quantitative understanding of cosmogenic nuclide production rates. For a detailed methodological overview, see the accompanying entry “► [Cosmogenic Nuclide](#)” (REF) and references therein. Cosmogenic nuclide surface exposure dating is based on the measurement of minute amounts of cosmogenic nuclides, here ^{10}Be , produced in near-surface rocks as a function of time, after glacier retreat has exposed the “new” surface to cosmogenic radiation (time = zero of the cosmogenic clock). By careful sample selection in the field, we minimize secondary influences, compromising this approach, such as inheritance of cosmogenic nuclides in the sampled surface from prior periods of exposure, temporary shielding of the sampled surface by snow or sediment cover, or considerably erosion of the surface. These potentially compromising influences can also be evaluated by measuring many samples of the same glacial feature and thus the same expected cosmogenic nuclide inventory (see below).

To calculate a “surface exposure age” from the measured ^{10}Be concentration in the surface sample, we need to know the ^{10}Be production rate at the sample location integrated over the full period of exposure. The uncertainty of this production rate value linearly propagates into the overall age error. Because incoming cosmic radiation is shielded by the Earth’s atmosphere and the geomagnetic field, production rates of cosmogenic nuclides at the earth’s surface are a function of altitude, latitude, and time (see accompanying entry “► [Cosmogenic Nuclides](#)”). As an example, the altitudinal scaling factor from sea level to 2,000 is ~ 4.8 .

The uncertainty in the knowledge of the time-integrated production rate at the location of the study has remained the major source of error in cosmogenic nuclide studies. However, there is good news! Over the last few years, several studies have shown the potential to locally calibrate ^{10}Be production rates (and ^3He production rates) with a precision of better than 3 % (1σ) (e.g., Fenton et al. 2011; Kaplan et al. 2011; Putnam et al. 2010; Young et al. 2013). In Fig. 1, we plot a compilation of recent local ^{10}Be production rate calibrations that we believe to be robust, scaled

Fig. 1 Consistency of recent ^{10}Be production rate calibrations. Production rate calibration experiments from Norway (Oldedalen Landslide (Goehring et al. 2012a) and Grotlandsura Landslide (Fenton et al. 2011)), Greenland (Young et al. 2013), New England (Balco et al. 2009), tropical Peru (Kelly et al. in press), tropical Bolivia (Blard et al. 2013a), New Zealand (Putnam et al. 2010), and Patagonia (Kaplan et al. 2011) shown by *thin line*, the *bold curve* gives the integrative probability function. The *blue vertical line* is the arithmetic mean, and the *black vertical line* gives the 1σ uncertainties, *red line* the 2σ , and *green line* the 3σ range. Following the convention, all values are scaled to sea level and high latitudes using the time-dependent “Lm” scaling after (Balco et al. 2008) (see also text). This tight cluster of ^{10}Be production rate calibrations has been produced over the last 3 years and reflects the considerable progress relative to the earlier “global ^{10}Be production rate” value of 4.4 ± 0.4 atoms/(g year) (Balco et al. 2008)

for reference to sea level and high latitude using the same scaling scheme (Lal/Stone time-dependent “Lm” after Balco et al. (2008)). The overall picture is one of striking internal consistency, and these experiments afford for high-precision cosmogenic dating studies near the production rate calibration points. Simultaneously, new modeling approaches (Argento et al. 2012; Lifton et al. 2014) to scale between the locations of production rate calibrations improve and converge as well toward the original scaling factors published by Lal in 1991 (Lal 1991). With the current rate of progress of production rate calibrations and model interpolations in between, it appears realistic to project a robust, near-global network of production rate values allowing for precise and accurate cosmogenic dating studies anywhere on earth in the near future.

Novel Applications of Cosmogenic Nuclides to Glacial Landscapes

The First Glacial Maximum in North America

When did the first ice age peak? When did Earth’s climate commence to swing between full glacial and interglacial modes? These long-standing geological questions have been elegantly addressed recently by a series of studies (Balco and Rovey 2008; Balco and Rovey 2010; Balco et al. 2005), dating the lowest, and thus oldest, glacial tills in the central USA by means of cosmogenic $^{26}\text{Al}/^{10}\text{Be}$ burial dating (Balco and Shuster 2009; Granger and Muzikar 2001). The cosmogenic burial dating method makes use of the difference in half-life of two (or more) cosmogenic nuclides in sediments that had have been buried after a period of exposure and thus cosmogenic nuclide production. During the period of burial of sediments, the nuclide with the shorter half-life, here ^{26}Al ($t_{1/2} = 717,000$ years), decays faster than the longer-lived nuclide, here ^{10}Be ($t_{1/2} = 1,400,000$ years). Hence, the measured $^{26}\text{Al}/^{10}\text{Be}$ ratio in buried sediments quantifies the burial time and, in this case, dates the deposition of the oldest glacial tills and the first glacial maximum of the Laurentide Ice Sheet to about 2.42 ± 0.14 million years. This result represents the most robust date for the first maximum of the predominant northern continental ice sheet and postdates the onset of the Quaternary.

The Structure of the Last Glacial Maximum in New Zealand’s Southern Alps

A recent example of a comprehensive, high-sensitivity ^{10}Be chronology from boulders protruding from moraines at Lake Ohau, New Zealand’s Southern Alps, yielding new information about the structure of the Last Glacial Maximum (LGM) in southern mid-latitudes (Putnam et al. 2013b), is shown in Fig. 2. It is the internal consistency of ^{10}Be boulder ages within these multi-sample data sets that best highlights that glacier moraine records are uniquely suitable for the cosmogenic SED approach and that secondary, potentially compromising processes such as snow and sediment cover of the sampled surface, turning of the sample after deposition by the glacier on top of the moraine, and finally inheritance of cosmogenic nuclides in the sample from prior periods of exposure are not significant in well-selected settings.

This chronology shows an extended mountain glacier LGM in New Zealand, with culminations at about 32, 26, 22, and 18 ka ago, and illustrates the potential to reconstruct glacier fluctuations during the last ice age with millennial resolution. Beyond, the ^{10}Be ages on the green moraines in Fig. 2 indicate that in some cases, the SED method can provide age information about the glacier culmination at the end of the penultimate glacial cycle.

From the paleoclimatic perspective, the LGM moraine records from New Zealand add new and robust information about the onset, fine structure, and termination of the Last Glacial Maximum in southern mid-latitude. Because New Zealand’s glaciers respond most sensitively to summer temperatures (Anderson and Mackintosh 2006; Anderson and Mackintosh 2012; Golledge et al. 2012),

Fig. 2 ^{10}Be boulder chronology for Last Glacial Maximum glacier culminations in New Zealand's Southern Alps (Modified after Putnam et al. (2013b). Red = Last Glacial Maximum (LGM) moraines; green = pre-LGM moraines. Boxes give ^{10}Be ages of boulders on moraines, outliers plotted in italic. Note the high internal consistency of ^{10}Be ages from boulders from one moraine sequence, together with the detailed stratigraphic order of the moraine ages (inboard moraines are younger). The few old ages on the green moraine represent the glacier position at the end of the penultimate ice age, indicating that the SED method can be used over orbital time scales in some cases)

the glacier fluctuations can be transformed into a temperature record, which implies that LGM summers in New Zealand were about 6–7 °C cooler than today. Beyond, the long LGM in New Zealand was punctuated by multiple culminations that show striking similarity to Antarctic ice core temperature records (Fudge et al. 2013) and sea surface temperature records in the southern ocean. This multiple culmination structure of the LGM rules out southern summer insolation as driver of the LGM in New Zealand, because 44°S December insolation was rising steadily through the New Zealand LGM period, from its minimum 32,000 years ago until the insolation peak some 22,000 years ago. Finally, the abrupt termination of the LGM in the moraine record commencing at about 18,000 years ago is a near match to the atmospheric CO_2 curve. Together with the timing of the culmination during the long LGM period, a northern hemisphere driver connected to atmospheric greenhouse gas concentrations appears to be the most promising scenario to explain the southern mid-latitude LGM pattern (Putnam et al. 2013a).

Proglacial Bedrock as Climate Archive: Holocene Fluctuations of Rhone Glacier

Recent studies by Goehring et al. (2011, 2012b) introduce high-sensitivity cosmogenic nuclide techniques as tools to explore the bedrock exposed only a few years ago by Rhone Glacier, Swiss Alps, toward reconstructions of Holocene glacier dynamics. Here, two cosmogenic nuclides produce in quartz, in situ ^{14}C and ^{10}Be , were used in concert to evaluate the periods during which the

Rhone Glacier was smaller or bigger, respectively, than today over the Holocene period (the last 11,500 years). The cosmogenic nuclide concentrations through any glacier forefield decrease from margin to central trough, which is consistent with the erosion profile showing higher erosion rates where the glacier flows faster (center), compared to the slower-flowing margins. We can assume that this bedrock was free of cosmogenic nuclides at the end of the last ice age some 11,500 years ago, after tens of thousands of years of big glaciers and subglacial erosion. In turn, the ^{10}Be ages of the bedrock samples at the margin of the Rhone Glacier trough provide minimum estimates of exposure, so the integrated period of time during which Rhone Glacier was smaller than today over the last 11,500 years. The dual-nuclide approach in this case suggests that Rhone Glacier was smaller than today for about 55% of the Holocene and that the most likely scenario describes a small Rhone Glacier to the early and mid-Holocene, followed by a larger Rhone glacier over the last 4000 years. This cosmogenic nuclide-based scenario, updated toward higher precision in a second isochron-based study (Goehring et al. 2013), agrees well with climate proxy records from the Alps and elsewhere in the northern hemisphere, making the case for warmer-than-today climate during the early and mid-Holocene, followed by climate deterioration and regrowing glaciers around 4,000 years ago, peaking during the Little Ice Age (1300–1850 CE).

Rock Dipsticks to Measure Ice Sheet Fluctuations: Rapid Thinning of the Pine Island Glacier, a Major Outlet Glacier of the West Antarctic Ice Sheet

The West Antarctic Ice Sheet (WAIS) is potentially unstable in our warming world and could contribute up to 3.5 m of sudden sea level rise, which would be a disastrous environmental change. Applying for the first time ^{10}Be techniques to Holocene glacial deposits along an altitude transect (dipstick approach), Stone et al. (Stone et al. 2003) showed that the WAIS has been steadily thinning during the Holocene. On top of the long-term thinning trend, modern observation from the Pine Island Glacier (PIG), one of the major outlet glaciers of the WAIS, shows very rapid thinning at a rate of about 1 m per year over the recent years (Park et al. 2013). The questions whether the current rapid thinning is unique, how sustainable it might be, and what actually drives the PIG thinning are fundamental to WAIS stability and global sea level predictions.

A new study has applied cosmogenic nuclide techniques to a rock dipstick (Fig. 3) above an unnamed outlet glacier directly linked to the PIG. The rock formation towering over the ice sheet and the PIG tributary has been steadily exposed during the ice sheet thinning, and this signal is traceable by high-sensitivity ^{10}Be techniques. The data shown in Fig. 3 illustrates that a rapid thinning of the PIG occurred about 8,000 years ago and lowered the PIG surface over 100 m over about a century. Thus, the thinning rate of the PIG 8,000 year ago was similar to the modern thinning rate but was sustained over 100 years. The most likely explanation for the rapid and sustained PIG thinning 8,000 years ago is a breakup of the Pine Island Bay ice shelves (Fig. 3, upper panel). Such ice shelves buttress the outlet glaciers while intact, and vice versa, if the buttress disappears, the outlet glacier flow accelerates dramatically, thinning the outlet glacier and draining the ice sheet. This happened 8,000 years ago, during a climate period that was not even close to the current greenhouse gas-induced climate forcing. While the comparison between the PIG and WAIS dynamics 8,000 years ago and today is complex, this experiment illustrates the high sensitivity of the PIG and its ice shelves, and thus the WAIS, to climate forcing. This is a worrisome result, given that the warming of our planet accelerates and that transport of warm ocean waters to the Amundsen Sea Embayment (Fig. 3) is one of the observed consequences (Martinson 2012). By this argument, we must expect that current thinning of the PIG continues and might accelerate, which will translate into a rapidly increasing melt water signal coming from the WAIS.

Fig. 3 Rock outcrops as dipsticks of ice sheet thinning (Modified after Johnson et al. [in press](#)). *Upper left panel:* Map of the Amundsen Sea Embayment, showing location of the study area. The grounded ice sheet is shown in *dark gray* and ice shelves in *light gray*. The *inset* shows the location within Antarctica, and the *box* shows the study area. *Upper right panel:* Map of Pine Island Bay, showing flow velocities of Pine Island Glacier and the unnamed outlet glacier flowing through the Hudson Mountains. Contours are in meters. The *grounding line* is represented by the *solid black line*, and the crest of the sub-ice shelf ridge as a *dashed white line*. *Lower panel:* Dipstick rock outcrop towering above the unnamed outlet glacier connected to Pine Island Glacier, West Antarctic Ice Sheet, with sample locations along an altitude transect and ^{10}Be ages shown

Synopsis

Cosmogenic nuclide techniques have revolutionized our capabilities to exploit glacial landscapes toward reconstruction of past land ice change and climate variability. Yet, this might be just the tip of the iceberg. High-sensitivity cosmogenic nuclide techniques applied to the moraine record now afford for precise reconstruction of past glacier fluctuations with centennial resolution and on a time scale ranging from decades to beyond 100,000 years. It has been a long-standing dream of geologists

and climate scientists alike to precisely map land ice change during the last ice age through the deglaciation period and into the current interglacial, referred to as the Holocene. This dream appears now in reach. Of course, there is a tremendous amount of scientific work ahead to realize this dream, but there is no daunting scientific challenge ahead; we simply need to intensify the multidisciplinary efforts toward precise and accurate cosmogenic nuclide studies of glacial landscapes, which depends critically on more cutting-edge cosmogenic production rate calibrations at different latitudes and altitudes and also on funding resources! Beyond the moraine program, it is a central goal to further improve the sensitivity of other cosmogenic nuclide systems, in particular ^3He , ^{36}Cl , and in situ ^{14}C , and to develop the multi-nuclide approaches further. Finally, from the proglacial bedrock studies described above, it appears a natural next step to use subglacial bedrock as climate archive. Subglacial bedrock holds the isotopic answer to fundamental questions such as: When did the WAIS collapse the last time? When was Greenland ice-free? The answer to these questions form the foundation to evaluate whether the recent and ongoing polar ice sheet response to global warming might be the dawn of ice sheet collapse and potential abrupt sea level rise, which would represent a disaster of epic dimension for our society at a time when most of earth's population lives near coastal margins. From that perspective, cosmogenic nuclide techniques applied to glacial landscapes can contribute fundamental information toward sustainable development of our ever-growing society on a rapidly warming planet.

Ice Cores

Anders Svensson*

Niels Bohr Institute, Ice and Climate Research, University of Copenhagen, Copenhagen, Denmark

Introduction

Ice cores from Antarctica, from Greenland, and from a number of smaller glaciers around the world yield a wealth of information on past climates and environments. Ice cores offer unique records on past temperatures, atmospheric composition (including greenhouse gases), volcanism, solar activity, dustiness, and biomass burning, among others. In Antarctica, ice cores extend back more than 800,000 years before present (Jouzel et al. 2007), whereas Greenland ice cores cover the last 130,000 years (Dahl-Jensen et al. 2013). A few ice cores from high-elevation glaciers in the Himalayas (Thompson et al. 1997) and in the Andes (Thompson et al. 1998) extend back into the last glacial period, whereas most other ice cores from lower latitudes are constrained to the Holocene period (last 11,700 years). In order to make proper interpretation of ice core records, it is essential to establish accurate and precise ice core chronologies that assign an age to each depth segment of the core.

Under favorable conditions, the annual signal in ice cores can be traced thousands of years back in time. The temporal resolution of ice cores is generally high compared to that of other paleoarchives, such as marine and lacustrine sediments, stalagmites, and tree rings (Ruddiman 2008). The annual accumulation on glaciers ranges from a few centimeters of ice per year in high-elevation areas of Antarctica to several meters of ice at coastal sites and at lower latitudes. In the upper part of an ice sheet, snow compacts to incompressible ice in a transition zone known as the firn. Due to the continuous accumulation of snow, annual layers become buried in the ice sheet with time, and due to a general flow of ice toward ice margins, annual layers are thinned with depth (Fig. 1). Close to the base of an ice sheet and close to ice margins, the stratigraphy is often disturbed as the ice is pushed over bedrock undulations.

Ice Core Dating Methods

Ice core chronologies are based on a number of different techniques that include annual layer counting, use of well-dated reference horizons, glaciological modeling, and “orbital tuning” where ice core records are linked to well-known temporal variations of the Earth’s orbit. Often several techniques are combined to produce the optimal ice core chronology (Cuffey and Paterson 2010). In regions with significant surface melt, such as low-latitude glaciers or coastal regions, ice core dating may be particularly challenging as the stratigraphy will be disturbed to some degree.

Layer Counting

An annual signal in ice cores may be preserved in the isotopic composition of the ice itself or in ice impurities such as terrestrial dust or ionic species. The isotopic ratios $^{18}\text{O}/^{16}\text{O}$ and $^2\text{H}/^1\text{H}$ of the most

*Email: as@gfy.ku.dk

Fig. 1 Schematic cross section of a large glacier such as the Greenland ice sheet. *Thick arrows* indicate the main ice flow pattern, and *horizontal lines* represent descending annual layers that are stretched and thinned over time due to ice flow. The most well-preserved ice core profiles are obtained from the central part of the ice sheet where the ice flow is mostly vertical, and there is no melting

Fig. 2 A five meter section from a Central Greenland ice core showing annual layers in the stable water isotopes ($\delta^{18}\text{O}$). High $\delta^{18}\text{O}$ values are summer layers, and low values occur during winter. The ice core is dated by annual layer counting from the surface, and the shown depth interval covers the time period 1946–1955 AD. At high-accumulation sites, annual layers can be identified in ice cores water isotopes thousands of years back in time (Figure from www.iceandclimate.nbi.ku.dk)

abundant stable water isotopes in glacier ice are related primarily to the local temperature at the time of precipitation (Dansgaard et al. 1969). They therefore vary over the seasons and preserve a signal of the annual cycle (Fig. 2). The isotopic ratios are normalized with respect to a standard and reported as $\delta^{18}\text{O}$ for oxygen and $\delta^2\text{H}$ (or δD) for hydrogen. At high-accumulation sites, the annual signal of those isotopes may be traced several thousands of years back in time (Vinther et al. 2006). At lower accumulation sites, however, diffusion of water molecules in the firn reduces or completely erases the seasonal variation (Johnsen et al. 2000). Furthermore, layer thinning caused by ice flow eventually makes the water isotopic seasonal cycle disappear with depth.

Ice core impurities, such as terrestrial dust and sea salt, often express a seasonal cycle in ice cores. For example, at present, Greenland dust generally shows a maximum during springtime, whereas sea salt peaks during winter (Kuramoto et al. 2011). The dust annual cycle may even be observed directly in the visual stratigraphy of the ice core (Alley et al. 1997; Fig. 3). Because dust particles are fixed in the ice matrix, they are less vulnerable to diffusion than water isotopes and ionic species, and they, therefore, preserve annual layers much further back in time. Extensive high-resolution dust and

Fig. 3 The annual layering of the Greenland ice sheet is visible to the naked eye. This example shows 5×1.65 m sections of visual stratigraphy from 2050 m depth in the NGRIP ice core from Central Greenland. At this depth, the ice is some 38 thousand years (ka) old, and the shown sections cover some 275 years of precipitation. The image is obtained with indirect illumination of the ice core so that black areas correspond to clear ice, whereas white layers contain elevated amounts of dust (Data from Svensson et al. 2005)

chemical impurity datasets from several deep Greenland ice cores have allowed for multi-proxy layer counting and tracing of annual layers well into the last glacial period (Andersen et al. 2006).

The strength of the layer-counted time scales lies in the very well-constrained event durations that allow precise determination of the sequence of events and of the exact event duration of past climate change (Steffensen et al. 2008). On the other hand, the counting error of counted time scales increases with age making the absolute error fairly large compared to other dating methods. Recently, automated methods for annual layer counting in ice cores have become available (Winstrup et al. 2012), which may play a more important role in future ice core chronologies. Annual layer counting has been applied to ice cores worldwide, but Central Greenland and coastal (high-accumulation) sites in Antarctica are the only sites where annual layer counting is feasible in the early Holocene and in the last glacial period.

Stratigraphic Linking

Numerous well-dated volcanic eruptions have left traces in ice cores, sometimes in the form of ash particles or “tephra” (Abbott and Davies 2012; Narcisi et al. 2012) but more often in the form of elevated acidity levels (mostly sulfuric acid) (Fig. 4). For example, the well-known 1815 AD Tambora eruption (Indonesia) has been identified as an acidity spike in many ice cores. During the last glacial period, the North Atlantic Ash Zones I and II provide important tephra marker horizons for Greenland at 12 and 38 ka before present, respectively, whereas Mt. Berlin is a central reference tephra layer in Antarctica at 92 thousand years before present (ka BP). Besides providing information on the timing and magnitude of past eruptions, ice core acidity spikes are also widely used for synchronization of ice cores. All of the deep Greenland ice cores are thus synchronized throughout the last glacial cycle based on numerous volcanic markers (Rasmussen et al. 2008; Vinther et al. 2006), and within Antarctica ice cores are being linked in a similar way (Parrenin et al. 2012; Severi et al. 2007).

A number of different approaches have been taken to synchronize ice cores from Greenland with those of Antarctica whereby climate change can be studied on a global scale. The air bubbles in ice

Fig. 4 Example of a visible tephra layer from the Icelandic Katla volcanic in the Greenland NGRIP ice core. The layer is from 1895.24 m depth and has an age of about 29 ka. **(a)** The visible tephra horizon in the ice core. **(b)** The associated sulfate peak in the ice. **(c)** Basaltic glass shards from the eruption as found in the ice core (Figure modified from Abbott and Davies 2012)

cores from both hemispheres share a global signal of well-mixed atmospheric gases. For example, methane concentrations show great variability over the last glacial period and can be applied for bipolar ice core matching (Blunier and Brook 2001; EPICA Community Members 2006). Also the global signal of oxygen isotopes of air trapped in ice cores can be applied to match ice cores from the two hemispheres (Bender et al. 1994; Capron et al. 2010). Bipolar volcanic matching of ice cores is feasible when large low-latitude eruptions inject great quantities of acid into the stratosphere. Over the last two millennia, where ice cores are precisely dated, some 50 bipolar volcanic events have thus been identified (Sigl et al. 2013). Greenland and Antarctic ice cores are also synchronized at the time of the largest volcanic eruption of the last million years, the Toba eruption (Indonesia) occurring some 74 ka before present (Svensson et al. 2013). Furthermore, the global signal of cosmogenic ^{10}Be in ice cores has been applied to match Greenland and Antarctic ice cores at the Laschamp geomagnetic excursion that occurred about 41 ka ago (Raisbeck et al. 2007).

Orbital Tuning

On time scales of tens of thousands of years, the Earth's climate is modulated by orbital variations that influence the solar insolation distribution on Earth. Several parameters measured in ice cores are shown to vary with the orbital parameters that are known with high accuracy (Laskar et al. 2004). The older section of Antarctic ice cores is dated by tuning the ice core record variability to that of the orbital parameters applying so-called orbital tuning (Fig. 5). The ice core records expressing variability on orbital time scales include the oxygen isotope ratio of air bubbles (Landais et al. 2010; Sowers et al. 1989), the O_2/N_2 ratio of air bubbles (Bender et al. 1994; Kawamura et al. 2007), and the total air content of the ice (Raynaud et al. 2007). Unfortunately, the linking between orbital forcing and the ice core records is rather poorly

Fig. 5 Example of orbital tuning of the Antarctic TALDICE ice core for the past 250 ka. *Top*: stable water isotopes of the ice ($\delta^{18}\text{O}_{\text{ice}}$) with labeling of interglacial periods (MIS5e and MIS7e). *Middle*: stable water isotopes of the gas record ($\delta^{18}\text{O}_{\text{atm}}$) with colors referring to different datasets. *Bottom*: the Earth's orbital precession parameter that partly controls the $\delta^{18}\text{O}_{\text{atm}}$ and that is used for tuning the time scale (Figure from Bazin et al. 2013)

constrained. Therefore, the use of orbital tuning for ice core dating implies uncertainties of thousands of years (Bazin et al. 2013).

Glaciological Modeling

In the deeper part of the large ice sheets and at locations where annual layers are not available, ice core age scales are based on modeling. To model an ice core time scale, it is needed to reconstruct (1) past accumulation rates and (2) the thinning of annual layers with depth. In polar regions, accumulation rates are to first order linked to temperatures that may be estimated from temperature proxies, such as stable water isotopes ($\delta^{18}\text{O}$ and δD). However, many other parameters influence the accumulation as well, for example, past ice sheet elevation changes, “upstream effects” (i.e., due to ice flow, the ice in the deeper part of an ice core must be traced back to its origin at the surface), and changes in the precipitation source(s). The ice flow may be simulated by simple one- or two-dimensional approaches (Johnsen and Dansgaard 1992) or by sophisticated 3D models that take into account many of the physical properties of the ice sheet, such as ice temperatures, ice impurity content, ice crystal texture, and basal melting (Ritz et al. 2001). Generally, many of those properties are poorly known, and modeled ice core chronologies are often constrained by other dating methods, such as age markers or orbital tuning. The most recent ice core age models use inverse methods and combine records from several ice cores and their stratigraphic links to produce a consistent chronology common for all the cores (Bazin et al. 2013).

Radiometric and Other Dating Methods

Currently, radiometric methods have rather limited applications for ice core dating. Atmospheric testing of nuclear weapons has produced reference horizons in 1950–1960 that can be detected as elevated beta-activity of ice. Young ice can be dated by ^{210}Pb or ^{32}Si counting, but the precision

cannot compete with that of annual layer counting. Due to a significant in situ production, ice cores can generally not be dated by ^{14}C (Petrenko et al. 2013) unless the ice contains sufficient biogenic material (Jenk et al. 2009). As a consequence, ice core time scales and ^{14}C calibration curves may not be entirely compatible during the last glacial period (Muscheler et al. 2008). The cosmogenic isotopes of ^{10}Be and ^{36}Cl can be measured in ice, but due to long half-life times and poorly constrained production rates, they mostly have applications for age estimation of very old ice, such as basal ice. The Matuyama-Brunhes (M-B) geomagnetic reversal observed as a ^{10}Be minimum at 776 ka is applied as a reference marker to constrain ages of the oldest Antarctic ice cores (Raisbeck et al. 2006).

Recently, developments have been made toward dating Antarctic ice cores based on the accumulation of ^{234}U in the ice matrix from recoil during ^{238}U decay out of dust bound within the ice (Aciego et al. 2011). Also ^{81}Kr may have a potential for dating of old ice, but its abundance in glacier ice is very low (Jiang et al. 2012). The age of basal ice containing material from bedrock (silty ice) can be estimated by a number of alternative methods such as $^{10}\text{Be}/^{36}\text{Cl}$ isotope ratios, optically stimulated luminescence, amino acid racemization, and maximum likelihood estimates for the branch length of the invertebrate cytochrome oxidase subunit I sequences (Willerslev et al. 2007).

Gas Record Chronologies

An important issue for ice core time scales is that of dating the air bubbles enclosed in ice cores. The snow or firn in the upper part of an ice sheet is generally permeable to air, and air bubbles are only permanently enclosed in the ice at the so-called lock-in depth that occurs typically at 50–100 m depth when snow compacts to ice. Because of the mixing of air in the upper part of the ice sheet, the age of air in an ice core sample is always younger than that of the encapsulating ice (Schwander et al. 1993). This difference in age between the air bubbles and surrounding ice is site specific and depends mainly on past accumulation rates and temperatures (Goujon et al. 2003). The gas-ice age difference varies from a few decades at present-day high-accumulation sites to several millennia at low-accumulation sites during glacial periods (Loulergue et al. 2007). The age difference can be constrained by modeling and by isotopic measurements of air molecules that respond to temperature gradients in the snow during bubble formation (Severinghaus and Brook 1999). Because it is important to link the climate signal of the ice to that of the atmospheric composition contained in the air bubbles, there are generally two age scales associated with an ice core: one for the ice and one for the gas records.

Greenland and Antarctic Ice Core Chronologies

Numerous chronologies have been made available for Greenland ice cores over the last decades (Southon 2004). Today, all of the deep Greenland ice cores (DYE-3, GRIP, GISP2, NGRIP, NEEM, Camp Century, Renland; see references in Johnsen et al. (2001)) are on a common time scale named the Greenland Ice Core Chronology 2005 (GICC05). This time scale is based on layer counting in several ice cores and covers the last 60,000 years (Svensson et al. 2008). For the most recent 8000 years, GICC05 is based on counting of annual layers in the water isotopic signal (Vinther et al. 2006), whereas dating of the older part is based on layer counting in dust and other impurities in the ice (Andersen et al. 2006; Rasmussen et al. 2006). The GICC05 time scale is associated with a counting uncertainty that provides an error estimate. The absolute error is around 1 % in the Holocene and about

5 % in the last glacial period. GICC05 has been extended with an ice flow model to cover the 123,000 time span of the Greenland ice cores (Wolff et al. 2010). The Greenland ice cores are internally synchronized using common volcanic reference horizons (Rasmussen et al. 2008), and tephra is used to link the Greenland ice cores to other paleoarchives (Abbott and Davies 2012; Blockley et al. 2012).

For Antarctica, individual time scales have traditionally been developed for each of the deep ice cores (Byrd, Vostok, EDC, Dome Fuji, EDML, TALDICE, Law Dome, Taylor Dome, see references in Stenni et al. (2010)). The time scales are mostly based on ice flow models that are constrained by stratigraphic markers and orbital tuning (Kawamura et al. 2007; Parrenin et al. 2007). Recently, inverse methods have been applied to integrate several Antarctic ice core chronologies with those of Greenland (Lemieux-Dudon et al. 2010). The most recent ice core time scale for Antarctica is the Antarctic Ice Core Chronology 2012 (AICC2012) that applies to several deep Antarctic ice cores (Bazin et al. 2013; Veres et al. 2013). For the last 60,000 years, AICC2012 is synchronized to the Greenland ice cores through their global gas concentration records and through bipolar volcanic and geomagnetic events. For the older part, AICC2012 is constrained by independently dated tephra layers, by orbital tuning, and by the B-M geomagnetic boundary. For the last glacial cycle, the AICC2012 error estimate is similar to that of Greenland time scales, and beyond that the accuracy is within 5000 years back to the M-B boundary. It is expected that more Antarctic ice cores will be integrated with the AICC2012 time scale and that a new layer-counted time scale will become available from the recently recovered WAIS ice core reaching back to 68 ka (WAIS Divide Project Members 2013).

Synonyms

Radiocarbon

Definition

Lacustrine. Having to do with any part of a lake system.

Introduction

Lakes are extremely powerful archives of climate and environmental information, because they record changes in the landscape around them, and the records they preserve are thus directly relevant to the activities and environments of human societies (e.g., Adams et al. 2008). Lakes commonly have very high sedimentation rates (5–20 years/cm) and preserve biological, geochemical, and sedimentary proxies and therefore may contain highly detailed records of past change. However, lakes are also dynamic sedimentary systems, and steady, continuous sedimentation may be disrupted by floods, lake-level changes, slope failures, and seismic shaking (e.g., Smith et al. 2013). Along with sedimentary fabric, radiometric dating is the best way to identify missing or repeated sections (Grimm 2011) and to identify and quantify changes in sedimentation rate.

Radiocarbon dating is the technique most often used to build age models for proxy records of paleoenvironmental change over the last ~40,000 years. Identifiable terrestrial organic plant macrofossils are the gold-standard material for dating, because they are most closely tied to the coeval atmospheric ^{14}C content and least susceptible to postdepositional chemical alteration (Staff et al. 2011). The frequent paucity of terrestrial macrofossils, however, means that often other materials must be used. These materials should be carefully evaluated in comparison to independent age information.

The high throughput and small sample size of modern accelerator mass spectrometer (AMS) measurements of ^{14}C has been a boon to the development of lacustrine age models, permitting them to potentially match the centennial to decadal resolution of many proxy records. Unfortunately, radiocarbon analyses remain expensive relative to most proxy measurements, and the analytical precision is often degraded by calibration from ^{14}C years to calendar years, which is required to account for changes in atmospheric ^{14}C content through time. Tremendous sustained community effort has produced a robust, precise international calibration curve covering the entire range of ^{14}C dating from 0 to 50 ka (IntCal13, Reimer et al. 2013). The advent of user-friendly computer programs for application of Bayesian statistics to ^{14}C -based age-depth models (Blaauw and Christen

*Email: zimmerman17@llnl.gov

2011; Bronk Ramsey 1995; Bronk Ramsey and Lee 2013) in combination with the calibration curves enables the production of robust and relatively high-precision radiocarbon-based age models.

Sources of Carbon to Lakes

Carbon in lakes may be brought as dissolved or particulate carbon in surface water, groundwater, or springs, as organic molecules or particles recycled within the lake water, biota, and sediments, and through gas exchange with the atmosphere at the lake surface (Abbott and Stafford 1996; Jull et al. 2013; Alberic et al. 2013). In areas with ancient carbonate bedrock or old carbonate-rich surface material (e.g., lake sediments or glacial till), the dissolved carbon in surface waters is frequently depleted in or devoid of ^{14}C , and the flux of carbon to the lake water from other sources may overwhelm the rate of gas exchange with the atmosphere, producing the hard-water, or reservoir, effect (Deevey et al. 1954; Broecker and Walton 1959).

In addition, even where the bedrock does not contain carbonate minerals, groundwater that has been isolated from the atmosphere may have undergone significant radioactive decay of ^{14}C , the lacustrine equivalent of ^{14}C -depleted “old” deep water in the ocean. The oxidation of organic material deposited in a lake may also introduce old carbon to the lake water, as dissolved organic carbon (DOC). Finally, deeply circulating hot springs may introduce ^{14}C -dead geothermal fluids into a lake system (Oremland et al. 1987). Although this source is easy to rule out in many places, in tectonically active regions it may be a highly variable effect, as the flow rate from springs may change suddenly and drastically in response to tectonic forces. In lakes affected by any of these processes, the dissolved inorganic carbon (DIC) pool in the lake water, from which aquatic plants and animals and inorganic carbonates get their carbon, may be hundreds or thousands of years out of equilibrium with the coexisting atmosphere and variable through time (Deevey et al. 1954).

Sample Selection

The desire for radiocarbon-based age models to give the calendar year of events recorded in lake sediments sets several requirements for choosing appropriate materials for dating:

1. The ^{14}C content of the material should be that of the atmosphere in the year of its formation.
2. The material should be deposited in the lake sediment as soon as possible after isolation from the atmosphere (i.e., death of plant/animal).
3. The C-isotope composition of the material should not have changed after its deposition.

Thus, the best material is identifiable terrestrial plant material: needles, leaves, twigs, seeds, etc., and charcoal from these materials, along with insect parts that are identifiably terrestrial. In general, the best assurance of the nearly immediate deposition of the material is to select delicate macrofossils, such as leaves, which are unlikely to survive storage or reworking. However, it is quite common for lake sediments to be lacking in sufficient terrestrial material, especially in landscapes with sparse vegetation such as the Arctic (Saulnier-Talbot et al. 2009) and dry lands, Plazcek et al. (2006) as well as in cores from the depocenter of large lakes (Shanahan et al. 2013). The lack of sufficient high-quality datable material is a problem that increases with the need for large numbers of dates to build high-resolution age models. As a result, many investigators are left choosing between less desirable alternatives, each with its own drawbacks.

Fig. 1 Effect of small amounts of modern ^{14}C on increasingly old materials; with only 1 % modern carbon, all infinite-age materials will appear to be ~ 38 ka. (*Inset*) By 40 ka < 1 % of the original ^{14}C remains

Dating of pollen concentrated from sediments has been proposed by several authors, using a number of different methods to separate the pollen from other organic or inorganic sources of carbon (Brown et al. 1992; Mensing and Southon 1999). A recent development is the application of flow cytometry, developed to sort cells for biological applications, to the sorting of pollen (or microcharcoal) from a sediment sample (Tennant et al. 2013). Flow cytometry can separate millions of grains in a few hours, making the sorting of samples large enough for ^{14}C analysis straightforward, especially in settings with abundant sources of large pollen (e.g., *Pinus*). However, comparisons between pollen and other kinds of dates show mixed results (Newnham et al. 2007; Neulieb et al. 2013). With the easier application of pollen dating potentially enabled by flow cytometry, it may be that the main sources of difficulty (non-pollen matter, reworked pollen, etc.) can be identified and overcome in suitable cases.

Aquatic plant parts (Marty and Myrbo *in press*) and shells are secondary alternatives to terrestrial material, as they are produced from dissolved inorganic carbon (DIC) in the lake water, which may be older than the coeval atmosphere for reasons listed in the previous section. Plant material is preferred to shells because contaminating carbonate and organic acids are removed by chemical pretreatment (see “► 14C dating” entry), and it is as resistant to postdepositional alteration as terrestrial plant material. Carbonates require an additional caution, as calcium carbonate minerals (e.g., aragonite, calcite) are quite soluble and thus are easily altered after deposition. Mineralogical and microscopic examination of shells is important, especially in shells expected to be more than 20,000 years old, where even small amounts of younger carbon can have a large effect on the apparent age (Fig. 1).

In addition to the reservoir effect (making ages too old) and the possibility of alteration, carbonates exposed by lake-level drop may adsorb young carbon from the atmosphere or shallow groundwater. This “modern carbon” effect (Fig. 2) has the opposite influence as the reservoir effect, making dates too young; thus the true magnitude of each effect may be masked by the other (Zimmerman et al. 2012; Plazcek et al. 2006).

Fig. 2 Progressive dissolution experiment on late Pleistocene ostracodes (Zimmerman et al. 2012). ¹⁴C dating of CO₂ fractions evolved during reaction of ostracodes with acid shows large component of young ¹⁴C on outer surfaces. The true age of the ostracodes is the age of the last step *or older*; dotted line shows the integrated ¹⁴C age of ostracodes from the same sample (measured separately)

With these considerations in mind, carefully selected and prepared aquatic plants and shells (Pigati et al. 2010; Myrbo et al. 2011; Marty and Myrbo *in press*) can yield robust ¹⁴C analyses. However, it is still critical to remember that aquatic materials may hide a variable lake reservoir effect, when interpreting their ¹⁴C ages as dates. Pairing the dates on aquatic material to a few terrestrial ¹⁴C dates or other known ages at the same level in the sediment sequence may provide some measure of confidence and a basis for estimating a reservoir correction.

In lakes with little else to date, bulk sediment measurements should be used only with extremely close attention to the multiple processes affecting the cycling of carbon in the particular lake and only when measurements at several depths in the sediment column show a relatively consistent offset with independent age markers such as terrestrial macrofossils or well-dated tephra (Blaauw et al. 2011). All of the sources of solid and dissolved carbon discussed in the previous section may influence the carbon isotope chemistry of the sediment, and additional sources of old carbon may be region or lake specific and difficult to identify (e.g., Grimm et al. 2009; Colman et al. 1996). Most importantly, the kind and amount of organic matter, the degree and frequency of oxygenation, and rise and fall of lake level (natural or anthropogenic) all affect the carbon isotope composition of the bulk sediment, and all are likely to be changing through time.

A Word About Outliers

Radiocarbon ages that “look wrong” in the context of the whole dataset should be carefully examined, and there should be some basis for rejection of outliers that are <3-sigma different from the expected age. A few common causes of suspicious dates may include the following. Samples taken from too close to the core edge, top, or bottom, from a zone of disturbance, or from the core catcher may be too young or too old and can be rejected (and avoided in the future). Unidentified plant parts that are too old may be aquatic and indicate that the water had a reservoir age at the time the plant grew (regardless of the modern situation). Charcoal or wood that is too old may have been stored on the landscape before deposition or be from the interior of a long-lived tree.

Aside from coring disturbance, it is relatively difficult to make a radiocarbon sample too young. Small (<0.3 mg) or old samples (>20,000 years, depending on sample size and precision required) contain small amounts of original ^{14}C and therefore are more sensitive to contamination by small amounts of modern carbon. This may be from contamination by carbonate or microbiological growth (Wohlfarth et al. 1998) or simply from exposure to the atmosphere. Concurrent preparation of matrix-matched, similarly sized background materials is a critical tool for monitoring these effects.

Building an Age Model

A key consideration when building an age model for lacustrine sequences is the time resolution it provides for interpretation of the proxy records. The high sedimentation rates in many lakes provide an unparalleled view of paleoenvironmental change, but the number of dates in the accompanying age model is often an order of magnitude or even two lower than the proxy measurements. This mismatch results in a situation where decadal or centennial interpretations and correlations of proxies are made, when only millennial-scale time resolution is available.

Radiocarbon ages are reported, like most isotopic measurements, as values with some analytical uncertainty that is normally distributed about the measurement value; typical ^{14}C measurements made by AMS are reported with a 1-sigma analytical uncertainty of 20–40 years. The additional step of calibration to calendar years introduces a nonuniform probability to ^{14}C -based calendar ages, however, because of plateaus and reversals in the slope of the calibration curve (Reimer et al. 2013). That is, within the calibrated range of a ^{14}C measurement, some calendar years will be much more likely than others, and many ^{14}C ages have multiple ranges, separated by calendar years with zero probability (Fig. 3).

The information in the probability density function is not captured by simple linear or spline fits to a series of age-depth points nor by the practice of reporting a central or highest-probability age and the oldest and youngest ends of the ranges. In the usual lacustrine age model of 5 or 10 dates or more, it becomes impossible to express the precision with which the timing of a shift or event in the proxy records is known, unless it coincides in depth with a radiocarbon age measurement.

Programs such as OxCal (Bronk Ramsey 1995) and Bacon (Blaauw and Christen 2011) use Bayesian methods to take advantage of prior information (priors) about a sediment sequence, including stratigraphic order, the relative timing of events, and the location of hiatuses in the sequence, as well as the fact that the probability of any calendar year within the calibrated range varies (Bronk Ramsey 2009). Many thousands or millions of iterations of Monte Carlo analysis are used to define the probability of any depth in the sediment being equivalent to a particular calendar year (Fig. 4). This is especially powerful for defining the precision of an age model between dated horizons and for choosing locations in the sediment sequence where additional dates will provide the most valuable information.

Fig. 3 Probability density function produced by calibration of a ^{14}C age of 2565 ± 35 years before present (*left axis*); wiggles in the calibration curve (*diagonal line*) produce windows of ages with high and low probability (*bottom axis*), rather than an equal likelihood of any age within the calibrated range. Figure made with Calib 6.0 (Stuiver et al. 2005 ref)

Summary

Advances in AMS sample preparation and measurement and Bayesian modeling software enable construction of robust, relatively high-precision and high-accuracy radiocarbon age models to support the high-resolution, multi-proxy lake records that have proliferated recently. Fundamentally, radiocarbon chronologies require an investment in a sufficient number of ages to support the time resolution of the proxy-record interpretations. Furthermore, they must include acknowledgment of the geological uncertainties inherent to all sample types. While identifiable terrestrial macrofossils remain the preferred material for radiocarbon dating, reliable age models can be based on other materials, where careful consideration of pre- and post-depositional effects on the carbon is combined with application of as many chronological techniques as possible.

Fig. 4 Age model for a lake core built using the Bayesian-based program Bacon (Blaauw and Christen 2011). Purple shapes represent probability density functions for ¹⁴C dates; green ellipses are independently dated tephras. Dotted lines enclose envelope of 95 % confidence interval, with darker gray shading for depths with higher confidence intervals. Additional dates between 120 and 300 cm depth would greatly improve the precision of the age model

[Annually laminated sediments](#); [Laminated sediments](#); [Rhythmites](#)

Definition

The term varve is a Swedish word that means cyclic layer. It was first used in 1862 as *Hvarfig lera* by the Swedish Geological Survey to describe rhythmically deposited light and dark clay layers in a proglacial environment on one of the first geological maps of Sweden.

Introduction and History

The study of varved sediments extends back more than 150 years, when alternating pale and dark laminations in marine and lacustrine sediments in Europe and North America were first mapped and interpreted as a potential source of chronological information. The concept of annually laminated sediments was later developed by Swedish geologist De Geer, who applied the chronological information stored in varved clays deposited near the margin of the retreating Scandinavian ice sheet to determine the time elapsed since the termination of the last glacial period. De Geer established a network of sites along the Baltic coast of Sweden and linked them using recognizable variations in varve thickness (De Geer [1912](#)). In addition, he defined the term varve as being one complete annual cycle consisting of a coarse-grained pale summer layer and a fine-grained dark winter layer. Finally, De Geer coined the term geochronology and for the first time introduced a temporal unit (the year) to geology (De Geer [1912](#)). Following his work, varve research expanded to include a broad range of types with applications to different scientific disciplines.

Varve Formation and Preservation

Varved sediments are created primarily through the interplay of two processes: seasonal variations in the genesis, transport, and deposition of sediments and the preservation of that signal after burial. A strong seasonal cycle that influences sedimentation is the fundamental process controlling varve deposition. In most settings this is not a limiting factor because a dominant seasonal climate cycle with large impacts on the environment, particularly the hydrological cycle, can be found nearly everywhere. In temperate climates, for example, surface water runs freely in summer and freezes over in winter, greatly varying the amount of energy available for clastic sediment transport. Similarly, in the tropics, monsoons create dramatically different runoff during wet and dry seasons.

Of course, biology also follows seasonal cycles, and this influences sedimentation. Diatoms in freshwater lakes bloom during spring and summer and die out in winter, and production based on marine upwelling may fluctuate seasonally following movements of zonal winds. Such manifestations of seasonality result in different sedimentary regimes, delivering biological or mineralogical material to the sediment surface at different times of year as distinct layers.

Seasonal sediment layers are produced and deposited in many environments but are usually disturbed by bioturbation from benthic organisms, as well as sediment mixing and resuspension due to slumping and current action. In order for varves to be preserved, the fragile seasonal layers must remain intact after deposition. In lakes, morphometry of the basin is one of the most important features controlling laminae preservation and the potential for sediment disturbance. A relationship exists between lake area and depth in those sites with preservation of laminated sediments (O'Sullivan 1983). In general, very deep lakes or lakes that have great *relative* depth will avoid deep wind mixing and allow development of strong thermal stratification. Deep lakes, thus, experience reduced resuspension of surface sediments and, importantly, ventilation of bottom water. Oxidation of organic matter falling through the water column then depletes available oxygen and the deep waters become anoxic, preventing the growth of benthic organisms and the influence of bioturbation. Physical isolation of bottom waters can also occur in the ocean, in shallow-silled marine basins formed as deep fjords such as the Saanich Inlet, British Columbia (Blais-Stevens et al. 1997), or as tectonic basins such as the Santa Barbara Basin, California (Behl and Kennett 1996); Cariaco Basin, Venezuela (Peterson et al. 2000); and Guaymas Basin, Gulf of California (Calvert 1966). Water column stratification occurs due to chemical as well as thermal processes, such as can be found in coastal tidewater lakes where saltwater introduced at high tides is overlain

Fig. 2 Photomicrograph of biogenic varve couplets from Ogaq Lake, Baffin Island, core 91-2b, 73.5 cm. The sediment surface is toward the *top* of the photo. Scale bar is 100 μm (Photograph: K. Hughen)

by a freshwater cap from continual stream input (Hughen et al. 1996a). Dense, hypersaline bottom waters can also form from dissolution of exposed salt formations on the seafloor, as is found in the Orca Basin, Gulf of Mexico (Kennett et al. 1985). Although not absolutely required for varve formation, anoxic bottom waters are one of the best indicators of potentially laminated sediments and are often used to help guide coring expeditions. For example, anoxic bottom waters occur where the oxygen minimum zone intersects the seafloor on the continental slopes, and annually laminated sediments have been located and studied off the coast of Pakistan (Schultz et al. 1998) as well as California (Anderson et al. 1987) and Peru (De Vries and Schrader 1981).

Classification and Morphology

For convenience, varves can be classified into basic types according to the most prominent seasonal feature or layer components. The earliest recognized and most commonly studied varved sediments are *clastic varves*, composed primarily of allochthonous mineral grains that differ seasonally in grain size (De Geer 1912; O'Sullivan 1983; Saarnisto 1986). Clastic varves are common in glacial marine and lacustrine settings where mineral grain production and deposition rates are high, and biological productivity is low. A magnified image of clastic varves from an Arctic lake (Fig. 1) illustrates typical sedimentary structures and fabric in this type of varve. The sediments consist of couplets of a light-colored, coarser-grained layer covered by a thin dark layer. Grains as large as fine sand mark the bottom of the coarse layer and grade upward into silt-sized particles, whereas a dark layer of fine clays caps the top of each couplet (Moore et al. 2001). The silts grade gradually upward into the fine clays, but the boundary between the clays and the overlying coarse grains is typically sharp (Fig. 1).

The succession of fine sands to silts in a thick layer, topped by a thin clay cap, is the classic structure of glacial varves (De Geer 1912; O'Sullivan 1983; Saarnisto 1986; Leeman and Niessen 1994; Zolitschka 1996; Retelle and Child 1996; Moore et al. 2001). The upward gradation from relatively coarse to fine grains in the thick layer results from a decrease in the energy available for sediment transport over the course of the summer. During the spring meltwater freshet, runoff is at a maximum and sands and silts previously locked up in winter ice are first available to be transported. Glacial runoff continues throughout the summer, but with snow cover mostly melted, the flux of runoff and energy of transport are diminished, and the size of grains washed into the basin is reduced (Retelle and Child 1996). During winter in glacial environments, surface water freezes and transport of sediment is greatly reduced or ceases altogether. In the absence of continual mixing, fine, clay-sized particles suspended in the water column settle out and form an independent dark clay layer. This idealized sequence can be interrupted by abrupt events such as intense rainstorms during the late summer or fall (Retelle and Child 1996; Lamoureux 1999). An increased pulse of runoff from a rainstorm can result in a sub-lamina of larger grains, often recognizable as an anomalous sand lens. The most diagnostic part of the sediment fabric is the clay cap, usually used to distinguish consecutive years' accumulation.

Another widely studied type of varved sediments are termed *biogenic* (O'Sullivan 1983; Saarnisto 1986) or *biochemical varves* (Lotter 1991). Biogenic varves form due to distinct pulses of aquatic biological productivity, including seasonal plankton blooms. The biological layer may interrupt and temporarily dilute a more constant rate of background deposition, such as mineral grains from steady stream flow or eolian input, or else alternate with a different distinct pulse of sedimentation, for example, mineral grains from monsoonal river runoff. A magnified image of biogenic varves from a coastal Arctic tidewater lake illustrates an example of these seasonal layers (Fig. 2). The biogenic layers form during the ice-free summer months, and during the winter, suspended particles settle out of the frozen, low-energy environment and are deposited as dark-colored, clay-rich layers (Hughen et al. 1996a, 2000a). Biogenic laminae form in a variety of marine and lacustrine environments, and in many cases a succession of distinct sub-laminae can be deposited as different diatom species bloom throughout the growth season (Dean et al. 1999).

Varves may also form through seasonal changes in the physical and chemical properties of the water column and are usually restricted to lakes. *Calcareous varves* may form in lakes with high CO_3^{2-} content, when calcite layers precipitate out of solution during summer warming (O'Sullivan 1983; Lotter 1991). *Ferrogenic varves* may form due to changes in redox conditions affecting the solubility of Fe species and the formation of sulfides versus hydroxides throughout the year (O'Sullivan 1983). *Evaporite varves* may form as interbedded laminae of precipitates in shallow evaporite basins and can consist of couplets of calcite and anhydrite (e.g., Castile Formation; Anderson and Dean 1995) or aragonite with eolian grains (e.g., Lake Lisan; Katz and Kologny 1989), depending on water chemistry.

Analytical Techniques

Independent Dating and Age Control

Before laminated sediments can be counted and used to construct calendar-age chronologies, it must be demonstrated using independent dating techniques that the laminae couplets are indeed annually deposited varves. Simply identifying and counting laminae couplets can lead to misinterpretation of event deposits as seasonal layers, or the counting of layers representing seasonal processes, but ones that do not occur on a regular basis from year to year. Numerous studies have used independent dating techniques to demonstrate that supposed "varves" were not in fact annually deposited (e.g., Crusius and Anderson 1992). Whenever possible, a combination of

several dating methods, such as lead-210 and anthropogenic nuclides, should be used both to increase confidence and to provide temporal coverage over a broader range of time scales.

Chronology Construction

By their nature, varves are a result of changing sediment supply to a depositional basin and should be present and recognizable throughout that basin. Subtle disturbances may disrupt or distort the varve sequence recovered in single sediment cores, however, and numerous steps are necessary to create a reliable annual chronology from laminated sediments. In constructing a varve chronology, many of the principles used in dendrochronology must be applied. For example, multiple measurements of varves (tree rings) from a single core (tree) must be averaged, followed by cross-correlation and averaging between multiple cores to build a chronology representative of an entire sediment basin (stand of trees). Small fluctuations in varve thickness as seen in thin sections require that each lamination be measured several times and averaged to provide an objective, representative record from each sediment core (Zolitschka 1996). In addition, local disturbances such as turbidites and erosional scours, as well as core breaks or gaps arising from the sampling process, may limit the physical integrity of a record from any single sediment core. To minimize these sources of error, it is critical to correlate varve chronologies constructed from multiple different cores and produce a basin-wide average (Zolitschka 1996; Hughen et al. 2000a). Downcore patterns of variation in varve thickness are usually quite distinct and can be recognized in cores across a basin. Cross-correlation of these marker patterns allow the identification and bridging of missing or disturbed sections in single cores. A larger number of cores used for cross-correlation increases the likelihood of avoiding all core gaps and constructing an accurate and reliable varve chronology.

Varve Applications

Geochronology

The geochronological applications of varved sediments are too numerous to provide an exhaustive list. One significant application that should be emphasized is the calibration and development of other geochronological tools, specifically, calibration of the radiocarbon time scale. Varves from lakes and marine basins have been one of the primary tools used to provide calendar-age calibration of ^{14}C ages beyond the limit of tree rings, >12,000 years ago (Hughen et al. 2000b; Ramsey et al. 2012). Annual calendar-age varve chronologies also provide accurate dates for specific sedimentological events, as well as age models for continuous sediment time series. An example of a study investigating discrete events would be paleoseismology. Earthquakes cause turbidity flows and turbidite deposits that in the proper setting can be dated by counting overlying varves (Hughen et al. 1996b). Interbedded sequences of varved sediments and massive turbidites can be used to determine recurrence intervals of earthquakes in a specific region (Blais-Stevens et al. 1997).

Varve chronologies offer an excellent means for constructing age models for high-resolution paleoclimate records. Varves are well suited to studies comparing the relative timing and lead-lag relationships of rapid climate changes in different regions, based on high-resolution paleoclimate records with calendar-age chronologies from varved sediments, tree rings, and ice cores (Hughen et al. 2000b). In addition, varve chronologies provide excellent precision at the annual scale and are particularly well suited for studies involving spectral analysis at short (sub-decadal) periodicities (Rittenour et al. 2000).

Applications Other Than Dating

In addition to having geochronological applications, varved sediments may themselves contain valuable paleoenvironmental information. For example, hydrological and sedimentological process studies in glacier-fed lakes have shown that the fluxes of runoff and suspended sediment, as well as varve thickness, vary logarithmically as a function of average temperature during the snow or glacier melting season (Leeman and Neissen 1994; Retelle and Child 1996). Downcore records of clastic varve or clastic laminae thickness from both glacial and non-glacial lakes correlate well with average summer or snowmelt season temperatures (Leeman and Neissen 1994; Hardy et al. 1996; Wohlfarth et al. 1998; Hughen et al. 2000a; Moore et al. 2001). For use as a paleotemperature proxy, it is critical that the varve thickness signal in any new location is calibrated for the recent period using instrumental data from a nearby meteorological station.

Varves have also been used to reconstruct changes in other paleoenvironmental parameters. Biogenic laminae in marine upwelling regimes reflect primary productivity and therefore the intensity of upwelling and trade winds, in the tropical North Atlantic during the last deglaciation (Hughen et al. 1996c). Laminated sediments, and their absence, have been used to reconstruct the ventilation history of intermediate-depth waters off the coast of California (Behl and Kennett 1996), Pakistan (Schultz et al. 1998) and northern South America (Peterson et al. 2000). These studies and others have shown that abrupt climatic shifts first seen in the high latitude North Atlantic region were in fact global in scope. Finally, varves can be used to study changes in past glacial activity and evolution of sediment source regions, as well as evolution of sedimentary basins (Lamoureux 1999). The applications of varved sediments to geochronological and paleoenvironmental research are limitless and will continue to grow as increasingly sophisticated methods are developed for obtaining and analyzing them.

Conclusions

Annually laminated (varved) sediments are valuable tools for research in geochronology, as well as other disciplines including paleoclimatology, paleoseismology, and archeology. Varved sediments are formed when distinct layers of sediment are deposited during different seasons throughout the year and occur in a wide variety of environments all over the globe. They are found in diverse settings from alpine glaciers and coastal tidewater lakes to isolated marine basins and continental slopes and occur at all latitudes from the high Arctic to the tropics. Varves can be counted and measured, similar to tree rings, in order to provide accurate calendar-age chronologies. Varve chronologies can be used in geochronological research in order to study and develop sediment dating techniques, such as ^{210}Pb and ^{14}C , and to date single events such as earthquakes and turbidity currents. Varves can also be applied to the reconstruction of past environmental conditions. At a minimum, varves provide annual-resolution calendar-age models for records based on other climate proxies (stable isotopes, pollen, etc.). In the best cases, however, varves themselves can be shown to contain environmental information and thus combine high temporal precision and accuracy with paleoenvironmental reconstructions from the same archive.

Meteorites (^{36}Cl)

Kees Welten*

Space Sciences Laboratory, University of California, Berkeley, CA, USA

Definition

Cosmogenic nuclide: A stable or radioactive isotope that is produced by the interaction of terrestrial or extraterrestrial materials with galactic and/or solar cosmic rays.

Meteorites: An extraterrestrial rock or iron that survived passage through the atmosphere and landed on Earth. Most meteorites are pieces of collisional debris from asteroids or comets, although a small percentage are fragments of the moon and Mars.

Introduction

Cosmogenic nuclides provide information on a meteorite's history, specifically during their travel through space as meter-sized objects, in which they were exposed to cosmic rays. More than 50 different cosmogenic nuclides have been detected in meteorites, including the stable isotopes of the noble gases, He, Ne, Ar, Kr, and Xe, and radioactive nuclides with half-lives ranging from less than 1 day (^{24}Na) to 1.28 Ga (^{40}K). The measured concentrations of cosmogenic nuclides in meteorites provide information on the total exposure time of meteorites to cosmic rays, also known as the cosmic-ray exposure (CRE) age. Since cosmic rays penetrate about 1 m deep, the CRE age represents the time since a meteorite was ejected as a meter-sized object from its parent body, although a few meteorites show evidence of CRE on the surface of their parent body. The most commonly measured nuclides in meteorites are listed in Table 1, along with their production mechanism and the analytical method used to measure each nuclide. Although most cosmogenic nuclides are mainly produced by interactions with galactic cosmic rays (GCR), a few of the nuclides (including ^{22}Na , ^{22}Ne , ^{26}Al , ^{54}Mn , and ^{56}Co) are also produced by solar cosmic rays (SCR). However, since the SCR flux is dominated by particles with energies <100 MeV, SCR contributions are only expected in the outer few cm of a meteoroid, which is usually lost during atmospheric passage. Therefore, SCR effects are rarely observed in meteorites.

In addition, the cosmogenic radionuclides (such as ^{14}C , ^{41}Ca , ^{36}Cl , and ^{81}Kr) also provide information on the terrestrial age of a meteorite, the time elapsed since it fell on Earth and was shielded from the high cosmic ray flux it experienced in space. Terrestrial ages of meteorites are especially interesting for meteorites from hot deserts (e.g., Australia, Southwestern USA, Sahara, Atacama, and the Arabian Peninsula) and from Antarctica. In addition, the terrestrial age of a meteorite find is needed to calculate the ejection age, i.e., the time a meteorite was ejected from its parent body, which equals the sum of the CRE age and the terrestrial age. For most meteorites, the terrestrial age is small compared to the cosmic-ray exposure age, but for lunar meteorites and certain carbonaceous chondrites, both ages have to be taken into account.

Table 1 Cosmogenic nuclides produced in meteorites

Nuclide	$t_{1/2}$ (year)	Major target elements	Main production mechanism	Method of analysis
^{54}Mn	0.855	Fe, Ni	Spallation	γ -ray spectrometry
^{22}Na	2.61	Mg, Si	Spallation	γ -ray spectrometry
^{60}Co	5.27	Co	$^{59}\text{Co}(n, \gamma)$	γ -ray spectrometry
^{14}C	5.730	O, Mg, Si	Spallation	AMS
^{59}Ni	7.6×10^4	Fe, Ni	Spallation, $^{58}\text{Ni}(n, \gamma)$	AMS
^{41}Ca	1.04×10^5	Fe, Ca	Spallation, $^{40}\text{Ca}(n, \gamma)$	AMS
^{81}Kr	2.29×10^5	Rb, Sr, Y, Zr	Spallation	Noble gas MS
^{36}Cl	3.01×10^5	K, Ca, Ti, Fe, Cl	Spallation, $^{36}\text{Cl}(n, \gamma)$	AMS
^{26}Al	7.05×10^5	Si, Al, Mg, (Fe)	Spallation	AMS, γ -ray spectrometry
^{10}Be	1.36×10^6	O, Mg, Si, (Fe)	Spallation	AMS
^{53}Mn	3.7×10^6	Fe, Ni	Spallation	AMS, INAA
^{129}I	1.57×10^7	Te, Ba, La	Spallation, $^{128}\text{Te}(n, \gamma)$	AMS
^{40}K	1.28×10^9	Fe, Ni	Spallation	
^3He	Stable	O, Mg, Si, Fe	Spallation	Noble gas MS
^{20}Ne , ^{21}Ne , ^{22}Ne	Stable	Mg, Al, Si	GCR	Noble gas MS
^{36}Ar , ^{38}Ar	Stable	Ca, Fe	GCR	Noble gas MS
$^{78, 80, 82, 83, 84}\text{Kr}$	Stable	Rb, Sr, Y, Zr, Nb	Spallation, $^{79}\text{Br}(n, \gamma)$ ^{80}Kr , $^{81}\text{Br}(n, \gamma)$ ^{82}Kr	Noble gas MS
$^{126-136}\text{Xe}$	Stable	Ba, REE	Spallation	Noble gas MS

N_{th} : thermal neutron capture

Analytical Methods

Cosmogenic noble gases are measured using a noble gas mass spectrometer. Samples of 10–500 mg are usually wrapped in a metal (Al, Ni) foil and stored under vacuum in one of several storage arms that are connected to the mass spectrometer. After preheating the samples at 100–120 °C to remove absorbed atmospheric gases, the cosmogenic (as well as radiogenic and trapped) noble gases are extracted by heating the sample in a furnace for 15–30 min at 1,750–1,800 °C. The noble gases are then separated and purified, and their abundance and isotopic composition are measured in a mass spectrometer with a Nier-type ion source (Begemann et al. 1976; Signer et al. 1977). Using known ratios for the cosmogenic and trapped noble gases, the individual contributions of cosmogenic and trapped He, Ne, Ar, Kr, and Xe are calculated (e.g., Eugster 1988).

Short-lived cosmogenic radionuclides as well as ^{26}Al are measured by gamma-ray spectrometry (Evans et al. 1982). This method requires samples of 5–100 g and is nondestructive, but generally requires counting times of several days to several weeks. Long-lived cosmogenic radionuclides (including ^{14}C , ^{10}Be , ^{26}Al , ^{36}Cl , ^{41}Ca , ^{53}Mn , ^{59}Ni , ^{60}Fe , and ^{129}I) are measured by accelerator mass spectrometry (AMS). For this method, samples of ~100 mg are dissolved in the presence of known carrier amounts of the stable nuclide of each element of interest. After dissolution, a small aliquot of the sample is taken for chemical analysis, and each cosmogenic nuclide is separated by ion exchange and solvent extraction techniques. The isotopic ratio of the radioactive to the stable isotope is measured by AMS, and the concentration of the radionuclide (in atoms per gram meteorite) is calculated from the measured isotope ratio, the amount of carrier added, and the sample mass. Radionuclide concentrations in meteorites are generally reported in decay rates, i.e., disintegrations

per minute per kg (dpm/kg). Since most meteorites were exposed to cosmic rays in space long enough ($>10^7$ years) to reach saturation levels for radionuclides with half-lives up to a few Ma, the measured activities generally also represent the production rates (in atoms per minute per kg).

Cosmic-Ray Exposure Age Methods

Many different methods have been used to determine the CRE ages of meteorites (e.g., Herzog 2005). Some exposure age methods can only be applied for iron meteorites (and the metal phase of stony irons), while others only apply to stone meteorites. Production rates of cosmogenic nuclides in meteorites depend on their chemical composition, the size of meteoroid during irradiation in space, and depth of the samples within the meteoroid. The size and depth effects are generally lumped together under the term “shielding,” reflecting the attenuation of primary cosmic ray particles as well as the buildup of secondary particles (protons and neutrons). Since meteorites typically lose 50–99 % of their pre-atmospheric mass during atmospheric passage (breakup and ablation processes), the original size and pre-atmospheric depth of individual meteorites are not known and can only be estimated from the measured cosmogenic nuclide concentrations or cosmic-ray track densities. Many empirical relationships between different cosmogenic nuclides have been established that help in calculating absolute production rates in individual samples and thus to obtain shielding-corrected CRE ages.

In general, the most reliable CRE age methods are the ones that combine a stable nuclide (e.g., ^{36}Ar , ^{21}Ne , ^{83}Kr) and a radionuclide (e.g., ^{10}Be , ^{26}Al , ^{36}Cl , ^{81}Kr). In these methods, the radionuclide (if it has reached saturation level) serves as an internal shielding parameter, which can be used to calibrate the production rate of the stable nuclide. However, many exposure ages of stony meteorites, which generally come from objects of less than 1 m in diameter, are based on noble gas concentrations only, in combination with the $^{22}\text{Ne}/^{21}\text{Ne}$ ratio, which serves as a shielding parameter for objects <1 m in diameter.

Noble Gas Exposure Ages of Stony Meteorites

The majority of CRE ages of stony meteorites are based on the concentrations of cosmogenic ^3He , ^{21}Ne , and ^{38}Ar (Marti and Graf 1992; Graf and Marti 1994, 1995; Eugster and Michel 1995; Welten et al. 1997; Scherer et al. 1998; Scherer and Schultz 2000; Rai et al. 2003). The concentration of cosmogenic ^{21}Ne is generally considered the most reliable of the three nuclides, since ^3He is more susceptible to diffusion losses and ^{38}Ar is more sensitive to variations in chemical composition (mainly Ca, Fe). In some achondrites, including howardites and eucrites, the ^{38}Ar ages are more reliable than ^3He and ^{21}Ne , as the production of ^{38}Ar is higher due to the high Ca concentrations, while ^3He and ^{21}Ne suffer diffusive losses (mainly from plagioclase).

The production rates of ^3He , ^{21}Ne , and ^{38}Ar are generally derived from empirical relationships with the $^{22}\text{Ne}/^{21}\text{Ne}$ ratio, which serves as a shielding indicator and generally ranges from 1.05 at high shielding to 1.25 at low shielding. The relationship between ^{21}Ne and the $^{22}\text{Ne}/^{21}\text{Ne}$ ratio in chondrites was first established by Eberhardt et al. (1966) and was later refined by Herzog and Anders (1971a), Nishiizumi et al. (1980), and Eugster (1988). The most commonly used equation for the ^{21}Ne production rate, $P(^{21}\text{Ne})$, expressed in 10^{-8} cm³ STP/g/Ma, in chondrites is

$$P(^{21}\text{Ne}) = 1.61 * F21 / \left[21.77 * \left(^{22}\text{Ne}/^{21}\text{Ne} \right) - 19.32 \right], \quad (1)$$

in which F_{21} is the chemical correction factor for different types of chondrites and the term in the denominator serves as shielding correction.

Similar empirical relationships were proposed for the production rates of ^3He , ^{38}Ar , ^{83}Kr , and ^{126}Xe in chondrites (Eugster 1988) as well as for noble gas production rates in achondrites (Eugster and Michel 1995). Model calculations have shown that the simple relationships between production rates and the $^{22}\text{Ne}/^{21}\text{Ne}$ ratio are generally valid for chondritic objects <1 m in diameter, which dominate the meteoroid flux to Earth. However, these simple relationships fail for larger objects, for which they result in overestimation of the production rates (Graf et al. 1990b; Masarik et al. 2001; Welten et al. 2003; Leya and Masarik 2009). For larger objects, it is recommended to use exposure age methods which are based on the combination of a stable nuclide and a radionuclide with similar production mechanisms. We will discuss the most commonly used methods for stony and iron meteorites.

The ^{81}Kr –Kr Method

Cosmogenic Kr in stony meteorites is mainly produced from the trace elements Rb, Sr, Y, Zr, and Nb. Although the concentration of cosmogenic Kr is several orders of magnitude lower than for cosmogenic He, Ne, and Ar, cosmogenic Kr was first detected in lunar samples (Marti 1967) and later in many meteorites, including achondrites and chondrites (Eugster et al. 1967; Finkel et al. 1978; Freundel et al. 1986; Lavielle and Marti 1988; Eugster 1988). The ^{81}Kr –Kr method is based on the combination of stable Kr isotopes, mainly ^{78}Kr , ^{80}Kr , ^{82}Kr , and ^{83}Kr , and the radioactive isotope ^{81}Kr , which reaches saturation after ~ 1.5 Ma of exposure. To determine the CRE age of a meteorite, one has to know the $P(^{81}\text{Kr})/P(^{83}\text{Kr})$ ratio, which is shielding dependent. There are generally two ways to derive this ratio, i.e., by using the empirical relationship between $^{81}\text{Kr}/^{83}\text{Kr}$ and $^{78}\text{Kr}/^{83}\text{Kr}$ ratio derived from Apollo 12 samples (Eq. 2) (Marti and Lugmair 1971) or the theoretical relationship for Kr production by spallation (Eq. 3), in which the $^{81}\text{Kr}/^{83}\text{Kr}$ production ratio is determined from the measured $^{80}\text{Kr}/^{83}\text{Kr}$ and $^{82}\text{Kr}/^{83}\text{Kr}$ ratios assuming an isobaric fraction yield of 0.95 (Marti 1967):

$$P(^{81}\text{Kr})/P(^{83}\text{Kr}) = 1.262 * ^{78}\text{Kr}/^{83}\text{Kr} + 0.381 \quad (2)$$

$$P(^{81}\text{Kr})/P(^{83}\text{Kr}) = 0.95 * \left(^{80}\text{Kr}/^{83}\text{Kr} + ^{82}\text{Kr}/^{83}\text{Kr} \right) / 2 \quad (3)$$

The latter approach has the advantage that it is less dependent on variations in chemical composition of different meteorites, but its disadvantage is that in large meteorites, ^{80}Kr and ^{82}Kr are not only produced by spallation reactions but also by neutron-capture reactions on ^{79}Br and ^{81}Br , respectively, thus leading to an overestimation of the $P(^{81}\text{Kr})/P(^{83}\text{Kr})$ values. Therefore, Eq. 2, which uses the $^{78}\text{Kr}/^{83}\text{Kr}$ ratio as shielding indicator, is more widely applicable and thus has been used for many different types of meteorites (e.g., Eugster et al. 1967; Finkel et al. 1978; Freundel et al. 1986; Lavielle and Marti 1988; Eugster 1988; Shukolyukov and Begemann 1996; Leya et al. 2004). Since the relatively small cosmogenic Kr contributions have to be determined from a mixture of cosmogenic and trapped Kr components, the ^{81}Kr –Kr method is most reliable for meteorites with long exposure ages (>10 Ma), high concentrations of target elements (e.g., howardites, eucrites), and low concentrations of trapped Kr (either planetary or terrestrial). The latter condition is valid for equilibrated chondrites and achondrites and implies that observed falls are more suitable than weathered finds.

The ^{36}Cl – ^{36}Ar Method

The ^{36}Cl – ^{36}Ar technique is generally considered the most reliable dating method for iron meteorites (e.g., Lavielle et al. 1999) and the metal phase of stony irons (Begemann et al. 1976). The ^{36}Cl and ^{36}Ar are produced by spallation reactions on Fe and Ni (e.g., Begemann et al. 1976). Since the reaction mechanism of the two products is almost identical, the $^{36}\text{Cl}/^{36}\text{Ar}$ production rate ratio that is essentially independent from shielding conditions (Schaeffer and Heymann 1965; Lavielle et al. 1999). In addition, more than 98 % of the produced ^{36}Cl , which is in saturation after a few million years of cosmic-ray exposure, decays to ^{36}Ar . As a result, more than 80 % of the ^{36}Ar in the metal phase is from decay of the radionuclide ^{36}Cl (half-life = 3.01×10^5 year). Since ^{36}Cl and ^{36}Ar concentrations can be determined accurately and are relatively insensitive to silicate contamination, typical uncertainties in the ^{36}Cl – ^{36}Ar ages are 3–5 % (Lavielle et al. 1999; Graf et al. 2001). For calculating ^{36}Cl – ^{36}Ar exposure ages, T^{36} (in Ma), the following equation can be used (Lavielle et al. 1999; Leya and Masarik 2009):

$$T^{36} = 511 * P(^{36}\text{Cl})/P(^{36}\text{Ar}) * [^{36}\text{Ar}]/[^{36}\text{Cl}] + 0.36, \quad (4)$$

in which $[^{36}\text{Ar}]$ and $[^{36}\text{Cl}]$ are the measured concentrations of cosmogenic ^{36}Ar [in units of $10^{-8} \text{ cm}^3 \text{ STP g}^{-1}$] and ^{36}Cl (in dpm kg^{-1}) in metal and $P(^{36}\text{Cl})/P(^{36}\text{Ar}) = 0.835 \pm 0.040$ atom/atom (Lavielle et al. 1999). The additional constant (of 0.36 Ma) takes into account that – at the time of the meteorite fall – some of the cosmogenic ^{36}Cl has not yet decayed to ^{36}Ar (Leya and Masarik 2009). The ^{36}Cl – ^{36}Ar method is most reliable if the measured ^{36}Cl concentration represents the saturation value, i.e., for meteorites with CRE ages >2 Ma and short terrestrial ages, although corrections can be made for radioactive decay of ^{36}Cl during the terrestrial residence time if the terrestrial age is known (Lavielle et al. 1999). The ^{36}Cl – ^{36}Ar method has also been applied to the metal phases of stony irons (Begemann et al. 1976; Albrecht et al. 2000; Honda et al. 2002) and the metal phase of stone meteorites (Graf et al. 2001; Leya et al. 2001).

The ^{26}Al – ^{21}Ne Method

Iron meteorites. The energy dependence of ^{26}Al and ^{21}Ne production from spallation reactions on Fe (and Ni) is very similar, which makes the $^{26}\text{Al}/^{21}\text{Ne}$ ratio in metal insensitive to variations in shielding and thus suitable for determining CRE ages of iron meteorites. Lipschutz et al. (1965) calculated CRE ages of iron meteorites from the measured $^{26}\text{Al}/^{21}\text{Ne}$ ratio, in which ^{26}Al and ^{21}Ne concentrations are expressed in dpm/kg and $10^{-8} \text{ cm}^3 \text{ STP/g}$, respectively. Using Eq. 5, assuming a constant $^{26}\text{Al}/^{21}\text{Ne}$ production rate ratio of 0.37 (atom/atom), while later studies used slightly different ratios of 0.38 (Hampel and Schaeffer 1979; Lavielle et al. 1999) and 0.35 (Honda et al. 2002).

$$T(^{26}\text{Al} - ^{21}\text{Ne}) = 511 * P(^{26}\text{Al})/P(^{21}\text{Ne}) * [^{21}\text{Ne}]/[^{26}\text{Al}] \quad (5)$$

The ^{26}Al – ^{21}Ne ages of 17 iron meteorites of different pre-atmospheric size (Lavielle et al. 1999) and of 8 metal separates from a wide range of shielding depths in the large Brenham stony iron meteorite (Honda et al. 2002) generally yield good agreement (within ~ 10 %) with the corresponding ^{36}Cl – ^{36}Ar ages. Although the $^{26}\text{Al}/^{21}\text{Ne}$ method is reliable for most iron meteorites and the metal phase of stony irons, it has not been applied to the metal phase of chondritic meteorites due to large contributions of ^{26}Al and ^{21}Ne from silicates, which are difficult to remove from the chondritic metal phase. However, for chondrites and other stone meteorites, the $^{26}\text{Al}/^{21}\text{Ne}$ method can also be applied to bulk samples, albeit with a different production ratio.

Stony meteorites. The production mechanisms of ^{26}Al and ^{21}Ne in stony meteorites are dominated by low-energy reactions on Al + Si (for ^{26}Al) and Mg, Al, and Si (for ^{21}Ne). One therefore expects that the production rates of ^{26}Al and ^{21}Ne in stone meteorites show very similar dependence on shielding conditions (Herzog and Anders 1971b). The constancy of the $^{26}\text{Al}/^{21}\text{Ne}$ ratio in chondrites has been investigated by several empirical and semiempirical studies (e.g., Graf et al. 1990a, b; Nagai et al. 1993; Honda et al. 2002; Welten et al. 2003) as well as by model calculations (Leya et al. 2001; Leya and Masarik 2009). Although the shielding dependence of the $^{26}\text{Al}/^{21}\text{Ne}$ ratio varies slightly among different studies, a relatively constant $^{26}\text{Al}/^{21}\text{Ne}$ production ratio of 0.35–0.42 atom/atom seems consistent with most studies. This method has been used to calculate CRE ages for several large chondrites (e.g., Leya et al. 2001; Welten et al. 2001, 2003), for which the CRE age cannot be calculated from cosmogenic Ne data alone.

The ^{10}Be – ^{21}Ne Method

Iron meteorites. Cross-section data for the production of ^{10}Be and ^{21}Ne from high-energy proton reactions on Fe suggest that the production ratio of $^{10}\text{Be}/^{21}\text{Ne}$ in irons does not show a significant depth dependency, which is confirmed by relatively constant $^{10}\text{Be}/^{21}\text{Ne}$ ratios measured in samples from different shielding depths in two iron meteorites (Graf et al. 1987; Lavielle et al. 1999) and in metal phases of the Brenham stony iron (Honda et al. 2002). Therefore, Eq. 6 can be used to calculate the CRE ages from the measured $^{21}\text{Ne}/^{10}\text{Be}$ ratios in iron meteorites

$$T = 511 * P(^{10}\text{Be})/P(^{21}\text{Ne}) * [^{21}\text{Ne}]/[^{10}\text{Be}] \quad (6)$$

in which $[^{21}\text{Ne}]$ and $[^{10}\text{Be}]$ are the measured concentrations of ^{21}Ne [in $10^{-8} \text{ cm}^3 \text{ STP g}^{-1}$] and of ^{10}Be (in dpm kg^{-1}) in metal. For the $P(^{10}\text{Be})/P(^{21}\text{Ne})$ ratio, values of 0.55 (Lavielle et al. 1999) and 0.50 atom/atom (Honda et al. 2002) have been used. The latter study found that the $^{10}\text{Be}/^{21}\text{Ne}$ ages of metal phases in the Brenham pallasite agree with the ^{36}Cl – ^{36}Ar ages, while absolute production rates varied by three orders of magnitude. Despite empirical evidence that the $^{10}\text{Be}/^{21}\text{Ne}$ ratio in iron meteorites is remarkably constant, Ammon et al. (2009) caution against using the $^{10}\text{Be}/^{21}\text{Ne}$ ratio for CRE ages of iron meteorites, since their model calculations indicate that trace elements (such as P and S) can affect the $^{10}\text{Be}/^{21}\text{Ne}$ production ratio.

Stony meteorites. Depth profiles of ^{10}Be and ^{21}Ne in the large Knyahinya chondrite indicate that the $^{10}\text{Be}/^{21}\text{Ne}$ ratio in a meter-sized object is relatively constant even though concentrations of both nuclides increase by more than 20 % from the surface to the center of the meteorite (Graf et al. 1990a). The semiempirical model of Graf et al. (1990b) suggests that the $^{10}\text{Be}/^{21}\text{Ne}$ ratio is relatively constant at 0.14 atom/atom, although it may show small variations (5–10 %) as a function of shielding. Subsequent model calculations based on particle fluxes and proton and neutron cross sections (Leya et al. 2000; Leya and Masarik 2009) suggest that the $^{10}\text{Be}/^{21}\text{Ne}$ production ratio is more sensitive to shielding than in the semiempirical model of Graf and is probably lower for high shielding conditions. This conclusion is also confirmed by empirical studies, which suggest production ratios of 0.10–0.12 atom/atom for high shielding (Leya et al. 2001; Welten et al. 2004). Although the exact relationship between the $^{10}\text{Be}/^{21}\text{Ne}$ ratio and shielding is still a topic of ongoing research, and the $^{10}\text{Be}/^{21}\text{Ne}$ ratio thus has an uncertainty of $\sim 20\%$, the $^{10}\text{Be}/^{21}\text{Ne}$ method is already more reliable for very large meteorites, such as the Gold Basin meteorite (Welten et al. 2003), for which the simple relationship between ^{21}Ne production rate and $^{22}\text{Ne}/^{21}\text{Ne}$ ratio fails.

Terrestrial Age Methods

Cosmogenic radionuclide concentrations also provide information on the terrestrial ages of meteorite finds. The method that is most suitable for terrestrial age determination of a meteorite depends on the metal content of the meteorite (metal rich vs. metal poor), its find location, and its expected terrestrial age. We will discuss the most commonly used methods below.

^{14}C and $^{14}\text{C}/^{10}\text{Be}$ Terrestrial Ages

The terrestrial ages of stony meteorites that fell less than 30–40 ka ago can best be determined by measuring the cosmogenic ^{14}C concentration of finds relative to falls. Since 99 % of cosmogenic ^{14}C in stony meteorites is produced from oxygen, the ^{14}C production rate is simply a function of bulk O content, which is generally well known and does not vary more than 20–30 % among different types of stone meteorites. Measurements of ^{14}C in observed falls suggest saturation values of 30–60 dpm/kg for chondrites with radii of <50 cm (Jull et al. 1989; Wieler et al. 1996), which is valid for more than 90 % of all stony meteorites. For average-size meteorites (<1 m in diameter), a constant production rate, $P(^{14}\text{C})$, is generally assumed, leading to the following equation for the terrestrial age, $T(^{14}\text{C})$, in which T is expressed in ka and $P(^{14}\text{C})$ and $A(^{14}\text{C})$ in dpm/kg:

$$T(^{14}\text{C}) = 8.27 * \ln[P(^{14}\text{C})/A(^{14}\text{C})] \quad (7)$$

This method was first applied to meteorite finds from the Southwestern USA (Boeckl 1972), revealing terrestrial ages up to ~13 ka. With the introduction of ^{14}C AMS measurements, the required sample size was reduced to <1 g. The method was applied to meteorites from other hot deserts (Jull et al. 1990; Bland et al. 1998) as well as Antarctica (Jull et al. 1989).

However, the assumption of an average production rate of 45–50 dpm/kg is not valid for very large meteorites, as was shown for the Gold Basin chondrite shower (Kring et al. 2001). In very large meteorites, the terrestrial age is best determined by measuring the ratio of $^{14}\text{C}/^{10}\text{Be}$, which is relatively insensitive to shielding effects and is assumed to be constant at ~2.5 in chondrite falls. This method is valid on the condition that the meteorite had a minimum CRE of 5–7 Ma, i.e., long enough to saturate both ^{14}C and ^{10}Be , or that the CRE age is well known, so that corrections for undersaturation of ^{10}Be can be made. Kring et al. (2001) showed that the measured $^{14}\text{C}/^{10}\text{Be}$ ratio in fragments of the large Gold Basin meteorite is relatively constant, even though absolute ^{14}C and ^{10}Be concentrations varied by more than a factor of 10 due to differences in shielding depth. Comparison of ^{14}C ages with shielding-corrected ^{14}C – ^{10}Be ages for a set of meteorites from the Nullarbor desert in Australia shows that the two ages generally agree within 1–2 ka, which is the typical uncertainty in the ^{14}C method (Jull et al. 2010). For meteorites older than 30–40 ka, the ^{14}C method only provides a lower limit, and measurements of longer-lived radionuclides, such as ^{41}Ca , ^{36}Cl , ^{26}Al , or ^{81}Kr , are needed to further constrain the terrestrial age (Nishiizumi et al. 1989; Welten et al. 2004, 2006, 2008).

^{36}Cl and $^{36}\text{Cl}/^{10}\text{Be}$ Terrestrial Ages

For Antarctic meteorites, which have typical terrestrial ages of 10 ka to ~1 Ma, the radionuclide ^{36}Cl is most suitable for terrestrial age determinations due to its half-life of 0.3 Ma and the relatively constant ^{36}Cl production rate of 20–25 dpm/kg in small irons and the metal phase of most chondrites (Nishiizumi et al. 1989). The terrestrial age (in ka) can then be calculated from the following equation:

$$T(^{36}\text{Cl}) = 434 * \ln[P(^{36}\text{Cl})/A(^{36}\text{Cl})] \quad (8)$$

in which $P(^{36}\text{Cl})$ is generally assumed to be 22.1 ± 2.8 dpm kg^{-1} (Nishiizumi 1995), leading to typical 2σ uncertainties of ~ 55 ka in the terrestrial age.

As with most other cosmogenic nuclide methods for meteorites, this simple approach is not valid for large iron meteorites (Chang and Wänke 1969; Nishiizumi et al. 1987; Lavielle et al. 1999) or large chondrite showers, such as Queen Alexandra Range 90201 (Welten et al. 2011). A more reliable terrestrial age method for iron meteorites, which often show large variations in shielding and large chondrites, is based on the $^{36}\text{Cl}/^{10}\text{Be}$ ratio. Although this ratio was initially assumed to be constant at ~ 4.3 (Chang and Wänke 1969), additional measurements have shown that the ratio increases systematically from ~ 3.5 in small irons to ~ 6 in large irons (Lavielle et al. 1999). The $^{36}\text{Cl}/^{10}\text{Be}$ saturation ratio shows a strong correlation with the ^{10}Be concentration in the metal phase, yielding the following equation:

$$[^{36}\text{Cl}/^{10}\text{Be}] = 5.97 - 0.184 * [^{10}\text{Be}] - 0.024 * [^{10}\text{Be}]^2 \quad (9)$$

This equation was later updated with the three constants as 6.01, 0.28, and 0.009, respectively (Welten et al. 2006), in which the ^{10}Be saturation value ranges from 0 to ~ 7 dpm/kg. The 2σ uncertainty in the $^{36}\text{Cl}/^{10}\text{Be}$ ratio is estimated to be $\sim 6\%$, corresponding to an uncertainty of ~ 35 ka in the shielding-corrected terrestrial age. The terrestrial age (in ka) is calculated from the measured $^{36}\text{Cl}/^{10}\text{Be}$ ratio and ^{10}Be concentrations in a few iterative steps, in which the $^{36}\text{Cl}/^{10}\text{Be}$ saturation value is recalculated in each step from the decay-corrected ^{10}Be concentration:

$$T(^{36}\text{Cl}/^{10}\text{Be}) = 557 * \ln \left[\left(^{36}\text{Cl}/^{10}\text{Be} \right)_{\text{sat}} / \left(^{36}\text{Cl}/^{10}\text{Be} \right)_m \right] \quad (10)$$

This method is straightforward for iron meteorites for which both ^{36}Cl and ^{10}Be are generally saturated at the time of fall, since they have CRE ages > 50 Ma. For the metal phase of chondrites, sometimes a small correction has to be made for undersaturation of the ^{10}Be concentration if the CRE age is < 10 Ma (Welten et al. 2006, 2011).

^{41}Ca and $^{41}\text{Ca}/^{36}\text{Cl}$ Terrestrial Ages

The production mechanism of ^{41}Ca is similar to that of ^{36}Cl , i.e., it is mainly produced by spallation from Fe. The average saturation value of ^{41}Ca in small iron meteorites is 24 ± 1 dpm/kg (Fink et al. 1991), i.e., slightly higher than the average ^{36}Cl value of 22.1 ± 1.4 dpm/kg. Although it was initially assumed that the $^{41}\text{Ca}/^{36}\text{Cl}$ ratio is relatively constant at 1.0–1.1 (Fink et al. 1991; Klein et al. 1991), additional measurements in larger iron meteorites and the metal phases of stony irons and chondrites have shown that the ratio exhibits a small shielding dependence (Nishiizumi and Caffee 1998). This shielding dependence is also confirmed by model calculations (Leya and Masarik 2009). The shielding dependence of the $^{41}\text{Ca}/^{36}\text{Cl}$ ratio is best described by the following empirical relationship with the ^{36}Cl concentration (Welten et al. 2006, 2011):

$$[^{41}\text{Ca}/^{36}\text{Cl}] = 1.25 + 0.003 * [^{36}\text{Cl}] - 0.0006 * [^{36}\text{Cl}]^2 \quad (11)$$

in which the ^{41}Ca and ^{36}Cl concentrations in the metal fraction are expressed in dpm kg^{-1} .

The terrestrial age (in ka), $T(^{41}\text{Ca}/^{36}\text{Cl})$, is then calculated from the measured $^{41}\text{Ca}/^{36}\text{Cl}$ ratio and ^{36}Cl concentration, using equation 12. The $^{41}\text{Ca}/^{36}\text{Cl}$ saturation value is calculated in a few iterative steps using Eq. 11 and the decay-corrected ^{36}Cl concentration until the terrestrial age changes less than 0.1 ka:

$$T(^{41}\text{Ca}/^{36}\text{Cl}) = 229 * \ln \left[\left(^{41}\text{Ca}/^{36}\text{Cl} \right)_{\text{sat}} / \left(^{41}\text{Ca}/^{36}\text{Cl} \right)_{\text{m}} \right] \quad (12)$$

^{81}Kr – Kr Terrestrial Ages

Terrestrial ages >40 ka are more difficult to determine for achondrites, which usually have very little (if any) metal, therefore hampering the determination of ^{36}Cl or ^{41}Ca ages from the metal phase. For meteorites with high plagioclase contents, such as eucrites, the combination of radioactive ^{81}Kr with stable ^{83}Kr provides a good alternative for terrestrial age determinations. In this method, the measured $^{81}\text{Kr}/^{83}\text{Kr}$ ratio is both a function of the CRE age (as described above) and of radioactive decay of ^{81}Kr during the terrestrial residence time (Freundel et al. 1986). If the CRE age of the meteorite is well known from independent measurements (such as cosmogenic ^{38}Ar), then the $^{81}\text{Kr}/^{83}\text{Kr}$ ratio provides a measure of the terrestrial age. This method is most suitable for ages of 100–600 ka and has been applied to Antarctic eucrites (Freundel et al. 1986) as well as for a few achondrites from hot deserts (Nishiizumi et al. 2002).

Bivalve Sclerochronology

Donna M. Surge^{a*} and Bernd R. Schöne^b

^aDepartment of Geological Sciences, University of North Carolina, Chapel Hill, NC, USA

^bInstitute of Geosciences, University of Mainz, Mainz, Germany

Synonyms

Bivalve shell chronometer; Related to dendrochronology

Definition

Sclerochronology: The study of incremental growth patterns in hard part remains of organisms that grow by accretion (i.e., adding on discrete growth layers throughout the life of the organism). The term “sclerochronology” was introduced for the study of growth patterns in calcareous exoskeletons or shells and applied to study the rate and patterns of coral growth (Buddemeier et al. 1974). It is analogous to the earlier established approach of dendrochronology. The application of the term “sclerochronology” has since broadened to the hard parts of many other aquatic taxa (e.g., bivalves, limpets, fish, and coralline sponges).

Bivalve: Bivalves are in the class Bivalvia of the phylum Mollusca and include freshwater, marine, and estuarine clams, mussels, quahogs, scallops, and oysters. They have a wide biogeographic distribution, extending from the equator to the poles, and occur from shallow to deep water. Furthermore, bivalves have a long geologic history and are archaeologically important. Fossil bivalves document more than 500 million years of evolutionary history. Bivalves from archaeological deposits (e.g., shell middens) provide information on food-gathering activities of historic and prehistoric people and insights into human-climate interactions. Many taxa are relatively short-lived (e.g., *Mercenaria* spp., *Spisula* spp., *Chione*, spp., *Crassostrea virginica*); however, many other bivalve species are extremely long-lived (e.g., *Arctica islandica*, *Neopycnodonte zibrowii*, and *Margaritifera margaritifera*). Their shells are composed of calcium carbonate (CaCO₃), most commonly in the form of aragonite and/or calcite. The ultrahigh-resolution (daily, seasonal, annual) records of growth increments enable bivalve shells to serve as unique skeletal diaries.

Introduction

Many hard part remains of aquatic organisms form by accretionary growth, implying that the accretion of new material is periodically retarded or interrupted which results in the formation of growth lines. Growth lines delimit growth increments, i.e., periods of fast growth. Growth increments represent time slices on annual, fortnightly (tidal), circadian (24-h cycle), circalunidian (lunar day; on average, 24 h and 50 min), and ultradian (period shorter than a day, minutes to hours) scales. Together, growth lines and increments can be used to estimate ontogenetic age and season

*Email: donna64@unc.edu

of growth and add a calendar date to discrete shell portions. Biological clocks entrained by environmental pacemakers (e.g., light/dark cycles, tidal cycles, food availability) apparently control the regular formation of growth lines and increments. This entry focuses on the use of sclerochronology in bivalve shells.

Bivalve sclerochronology can provide environmental and ecological data from many different spatial, temporal, and cultural settings. Combining sclerochronology with geochemical analyses (e.g., oxygen and carbon isotope ratios; $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values, respectively) can provide additional environmental and ecological information, such as water temperature, precipitation, glacial melt-water pulses, primary productivity, etc. The key criterion for chronological research, however, is precise time control. The following section provides an overview on the formation of periodic growth patterns in bivalves and focuses on daily, fortnightly, and annual increments. We refer the reader to Schöne and Surge (2012) for a more detailed discussion of bivalve sclerochronology and geochemistry.

Shell Growth Patterns

Shell growth patterns result from changes in the rate of deposition associated with variations in chemical composition and crystallographic properties. Growth lines separate the growth pattern into time slices referred to as growth increments. Together, growth lines and increments form a shell calendar, providing an ideal method to measure time. They are typically studied in the outer or middle shell layers of cross-sectioned valves cut along the maximum axis of growth. Several methods, such as staining and acetate peels, have been developed to visualize growth patterns (Clark 1980; Kennish et al. 1980; Tevez and Carter 1980; Richardson 1987; Schöne et al. 2005a).

The outer shell layer and portions of the middle shell layer provide a complete and undisturbed shell record, assuming no diagenesis or taphonomic alteration. New shell material is deposited along the shell margins including inner surfaces when the shell is open (gaping). Shell dissolution may occur along the inner shell layer and portions of the middle shell layer when the valves are closed for extended periods of time (e.g., during seasonal anoxia, beyond temperature or salinity tolerances) (Crenshaw 1980). Therefore, these portions of the shell should be avoided for calendar-dated studies. The outer shell layer and outer portion of the middle layer are not affected by dissolution during shell closure.

Many bivalve shells contain daily microgrowth increments, which are ideally studied in fast-growing, young portions of the shells. Under optimal growth conditions, some pectinids and giant clams (*Tridacna* spp.) form increments corresponding to the number of solar days that elapsed during that growth interval (Clark 1974, 1975; Parsons et al. 1993; Watanabe and Oba 1999; Chauvaud et al. 2005). This finding suggests that such microgrowth increments form with circadian periodicity (Clark 1975).

Some bivalves from intertidal habitats produce distinct, tidally controlled growth patterns in their shells. Growth cessation occurs when they are aerially exposed during low tide and resumes during high tide when they are submerged (House and Farrow 1968; Evans 1972; Ohno 1989; Goodwin et al. 2001; Miyaji et al. 2007). It should be noted, however, that most bivalves form circalunidian increments regardless of whether or not they are aerially exposed at low tide. Under semidiurnal tidal conditions, two growth lines and increments (two circatidal growth patterns) can form per lunar day. Growth lines produced during spring tides are more prominent than those formed during neap tides. The distance from the shoreline influences the duration of aerial exposure and, hence, the number of growth lines and increments. For example, bivalves living in

the high intertidal zone can be exposed for several days during extreme spring tides without forming growth lines and increments. In comparison, individuals farther away from the shoreline are submerged for longer intervals and can have significantly more growth lines and increments relative to specimens from the high intertidal zone (Ohno 1989). Moreover, shells from the low intertidal zones typically have broader growth increments than shells from mid-intertidal settings. This pattern is influenced by the duration of submergence. Similarly, shorter submergence times during spring tides produce narrow growth increments relative to wider increments formed during neap tides. Tidally influenced lines and increments form distinct bundles of ~13–15. Schöne and Surge (2012) provide a more detailed explanation about the mechanisms controlling daily and semidiurnal shell growth.

Most bivalve species produce annual growth lines or increments in their shells (Hall et al. 1974; Jones 1980; Brey and Mackensen 1997). Prominent dark growth lines or increments are often visible with the naked eye on the outer shell surface or in cross section along the maximum axis of growth. Under high magnification, annual growth increments appear as bundles of closely spaced daily growth lines (Barker 1964; Hall et al. 1974). Daily growth lines gradually decrease in width (i.e., growth slows) toward annual growth lines and increase gradually afterward as growth rates increase. This important feature distinguishes annual growth lines from disturbance lines. Disturbance lines are characterized by abruptly changing microgrowth increment widths and can occur when the animal is exposed to a sudden environmental stress, such as a major storm. Some species (e.g., *Mercenaria mercenaria*, *M. campechiensis*, *Spisula solidissima*) form couplets of dark and light increments visible under reflected light (translucent and opaque under transmitted light), which together represents 1 year of growth (Lutz and Rhoads 1980; Jones 1983; Peterson et al. 1983; Jones et al. 1990; Arnold et al. 1998). Dark/translucent increments occur during periods of slow growth, whereas light/opaque increments form during fast growth intervals (Jones 1983; Jones et al. 1990). It should be noted that not all bivalve species produce obvious periodic growth lines or increments. Surge et al. (2001) reported that annual cycles in shells of the American oyster, *Crassostrea virginica*, are only apparent through stable isotope analysis (see, however, Kirby et al. 1998).

Possible mechanisms that produce annual growth line formation include reproductive processes (i.e., gonad development and spawning), food supply, and minimum or maximum temperature thresholds (Pannella and MacClintock 1968; Lutz and Rhoads 1977; Jones 1980, 1983; Jones et al. 1990; Cerrato et al. 1991; Jones and Quitmyer 1996; Brockington and Clarke 2001; Surge et al. 2001; Schöne et al. 2005b; García-March et al. 2011). Thermal tolerance is an important control for annual growth line/increment formation in many shallow-water mollusks (e.g., Kraeuter and Castagna 2001 and references therein; Beukema et al. 1985; Brown 1988; Tanabe and Oba 1988; Schöne et al. 2003b; Surge et al. 2013). In their seminal paper on isotope sclerochronology, Jones and Quitmyer (1996) reported that the timing of slow growth (dark/translucent increments) in *Mercenaria mercenaria* and *M. campechiensis* shells from the east coast of North America and Gulf of Mexico occurs during cold winter temperature in mid latitudes (cold-temperate zone), whereas specimens from low latitudes (warm-temperate zone) slow their shell growth during summer (see, however, Elliot et al. 2002; Henry and Cerrato 2007). They noted that at the transition between the warm- and cold-temperate zones, both winter and summer growth increments are present. Despite the importance of thermal tolerance on shell growth rates, the formation of annual growth lines/increments is probably a function of a combination of environmental factors, physiology, and endogenous rhythms (Brockington and Clarke 2001). In many cases the underlying reason for annual growth formation remains obscure. For example, at different latitudes of the North Atlantic, the ocean quahog, *A. islandica*, spawns at different times of the year or even year-

round (Thórarinsdóttir 2000), and the reproductive cycles of different populations are not synchronized (Fritz 1991). Yet, according to $\delta^{18}\text{O}$ data, annual growth lines always form about a month after the seasonal temperature maximum (Weidman et al. 1994; Witbaard et al. 1994; Schöne et al. 2005b, c). It appears likely that circadian/circalunidian biological clocks are used to measure time that elapsed after the summer temperature peak in order to determine the timing of seasonal growth retardation.

Applications of Shell Growth Pattern Analysis

Sclerochronology offers a wide range of potential applications in a variety of disciplines, such as biology, ecology, archaeology, and climate research. Here we provide examples of selected applications.

Two approaches have been used to estimate the timing, duration, and rate of seasonal shell growth. The translucent-opaque staging technique identifies the stage of terminal growth as being within either the translucent (dark) increment or the opaque (light) increment on a cross-sectioned valve cut along the maximum axis of growth (Jones et al. 1990; Arnold et al. 1998). Next, the growth phase is determined within each stage of terminal growth based on the relative thickness of the terminal growth band (Quitmyer and Jones 1992, 2012; Quitmyer et al. 1997; Arnold et al. 1998; Quitmyer 2013). Another approach counts the number of daily growth lines between annual increments to estimate the duration of the growing season and assign precise dates to each shell portion (assuming the date of the last-formed growth line is known). This method is potentially accurate to the nearest 2–4 weeks (Hallmann et al. 2009). If maximum and minimum temperature thresholds of a species are known, such data can be used to determine changes in seasonal temperature variability and climate through time and space (Ansell 1968; Tanabe and Oba 1988; Jones and Quitmyer 1996; Schöne et al. 2004; Lohmann and Schöne 2013).

When combined with oxygen and carbon isotope ratios (discussed more fully in the next section), isotope sclerochronology can be used to address ecological questions in modern and fossil shells to interpret life history and to assess the timing of the initial introduction of invasive species (Jones and Quitmyer 1996; Schöne et al. 2002; Henry and Cerrato 2007; Goodwin et al. 2010; Haveles and Ivany 2010). For example, it was recently discovered that bivalves are among the longest-lived solitary animals with some species living for many centuries (Thompson et al. 1980; Shaul and Goodwin 1982; Mutvei and Westermarck 2001; Schöne et al. 2005b; Wanamaker et al. 2008; Wisshak et al. 2009; Butler et al. 2013). Such long-lived species have been used to generate master chronologies for long-term climate reconstruction (Noakes and Campbell 1992; Marchitto et al. 2000; Schöne et al. 2003a; Strom et al. 2004, 2005; Wanamaker et al. 2008; Butler et al. 2010, 2013). Paleoclimate, paleoceanographic, and paleoenvironmental reconstruction based on isotope sclerochronology provides critical information on seasonality in seawater temperature, North Atlantic Oscillation (NAO) variability, paleoproductivity/upwelling, drought conditions, changes in river discharge, and aquatic pollution (Schöne et al. 2003b, 2005b; Dettman et al. 2004; Dunca et al. 2005; Carroll et al. 2009; Schöne and Fiebig 2009; Harding et al. 2010; Wanamaker et al. 2011; Wang et al. 2011; Sadler et al. 2012). Sclerochronologic analysis of shells from archaeological midden deposits (trash heaps) allows interpretation of human activity, such as site occupation, season of harvest, and intensification of resource exploitation (Bailey et al. 1983; Milner 2001; Milner et al. 2007; Carré et al. 2009; Andrus 2011; Gutiérrez-Zugasti 2011; Andrus and Thompson 2012; Reitz et al. 2012 and references therein; Burchell et al., 2013a, b).

Isotope Sclerochronology

Stable carbon isotope ratios of bivalve shells are reported in delta notation:

$$\delta^{13}\text{C}_{\text{shell}} = \left(\frac{\frac{^{13}\text{C}}{^{12}\text{C}}_{\text{shell}} - \frac{^{13}\text{C}}{^{12}\text{C}}_{\text{VPDB}}}{\frac{^{13}\text{C}}{^{12}\text{C}}_{\text{VPDB}}} \right) \cdot 1,000$$

where VPDB is the Vienna Pee Dee Belemnite standard and values are in per mil units (‰). In principle, $\delta^{13}\text{C}_{\text{shell}}$ values can provide information on the carbon isotope ratio of dissolved inorganic carbon (DIC) and, hence, serve as a proxy for primary productivity and remineralization (e.g., respiration, oxidation of organic matter) (Mook and Vogel 1968). Plants preferentially incorporate ^{12}C in their organic tissue, thereby enriching the remaining carbon pool in ^{13}C . Thus, increases in photosynthesis results in higher $\delta^{13}\text{C}_{\text{DIC}}$ values, whereas increased respiration lowers $\delta^{13}\text{C}_{\text{DIC}}$ values. Bivalves sample the carbon isotope ratio of the ambient water and in theory record changes in the $\delta^{13}\text{C}$ value of DIC. For example, higher $\delta^{13}\text{C}_{\text{shell}}$ values would reflect increased primary productivity, whereas lower $\delta^{13}\text{C}_{\text{shell}}$ values suggest increased respiration. However, bivalves also incorporate up to ca. 10 % metabolically derived CO_2 into their shells (McConnaughey and Gillikin 2008). Many species seem to incorporate increased amounts of respiratory CO_2 through their lifetime, resulting in more negative $\delta^{13}\text{C}_{\text{shell}}$ values as the animal ages (Gillikin et al. 2007; McConnaughey and Gillikin 2008). Therefore, $\delta^{13}\text{C}_{\text{shell}}$ values should be treated with caution. More recent studies have reported that long-lived bivalves that grow slowly during their youth are not hampered by such ontogenetic effects on the carbon isotope ratio of shell carbonate. In these cases, studying past carbon cycle dynamics in the ocean or tracking the anthropogenic increase in atmospheric and oceanic CO_2 (i.e., the Suess effect) is possible (Butler et al. 2011; Schöne et al. 2011).

Unlike stable carbon isotope ratios, metabolic effects (also known as vital effects) do not seem to impact oxygen isotope ratios recorded in bivalve shells. Oxygen isotope ratios are reported in similar delta notation as stable carbon isotope ratios:

$$\delta^{18}\text{O}_{\text{shell}} = \left(\frac{\frac{^{18}\text{O}}{^{16}\text{O}}_{\text{shell}} - \frac{^{18}\text{O}}{^{16}\text{O}}_{\text{VPDB}}}{\frac{^{18}\text{O}}{^{16}\text{O}}_{\text{VPDB}}} \right) \cdot 1,000$$

They are the most widely used geochemical proxy of bivalve shells and are a function of variations in the ambient water temperature and $\delta^{18}\text{O}_{\text{water}}$ value (Urey 1947; Epstein et al. 1953). Many studies have demonstrated that almost all bivalves precipitate their shells in oxygen isotopic equilibrium with the ambient water (Mook and Vogel 1968; Surge et al. 2001; Elliot et al. 2003; Hallmann et al. 2009; see, however, Owen et al. 2002, 2008; Hallmann et al. 2008; Yan et al. 2012). Values of $\delta^{18}\text{O}_{\text{shell}}$ have been used to estimate salinity (assuming temperature can be held constant and the mixing relation between marine and freshwater is known; Ingram et al. 1996) or water temperature (assuming the $\delta^{18}\text{O}_{\text{water}}$ value can be held constant; Jones et al. 1989; Wefer and Berger 1991; Weidman et al. 1994; Dettman et al. 1999; Surge et al. 2001; Carré et al. 2005; Schöne et al. 2005b, c; Wanamaker et al. 2006; Ivany et al. 2008). Several experimental studies have demonstrated a 1 ‰ change in $\delta^{18}\text{O}_{\text{shell}}$ value that represents a temperature change of ~4.3 °C (Epstein et al. 1953; Grossman and Ku 1986; Dettman et al. 1999). Higher $\delta^{18}\text{O}_{\text{shell}}$ values

correspond to cold temperatures, whereas relatively lower values indicate warmer temperatures. Advances in microsampling techniques enable high-resolution isotopic records that can produce temperature reconstructions on seasonal to subdaily time scales, depending on shell growth rates, to the nearest 0.35 °C (Dettman and Lohmann 1995). Sclerochronologic analysis ensures that the reconstructed temperature record from $\delta^{18}\text{O}_{\text{shell}}$ values is placed within a precise temporal context.

Other geochemical proxies in bivalve shells used to reconstruct environmental conditions with varying degrees of success include clumped isotopes, nitrogen isotopes, and minor and trace elemental ratios. We refer the reader to Schöne and Surge (2012) and Schöne and Gillikin (2013) (and papers therein) for more details and examples regarding these topics.

Summary

Bivalve sclerochronology developed from the observations of visible growth lines and increments on the outer shell layer and along cross-sectioned shells cut along the maximum axis of growth. Such growth patterns are often visible with the naked eye, but in some species these features are more clearly revealed with staining or acetate peels. Sclerochronologic records from long-lived bivalves provide master chronologies used to reconstruct climate change on decadal to centennial time scales. Records from short-lived bivalves can be resolved on seasonal time scales. In combination with geochemical proxies, sclerochronologic records can produce time series of environmental variability that can be quantified (e.g., estimating water temperature, salinity). Their abundance in fossil and archaeological deposits and their wide biogeographic distribution make bivalve shells unique and valuable archives for a wide range of interdisciplinary study.

Peat (^{14}C)

Philippa Ascough*

AMS Laboratory, Scottish Universities Environmental Research Centre, East Kilbride, Scotland, UK

Definition

Peat. A highly organic soil that results when waterlogged anaerobic conditions suppress the degradation of vegetation.

Radiocarbon dating of peat. Measurement of the radiocarbon content in samples of either bulk peat or carbon-bearing fractions isolated from bulk peat by physical and/or chemical treatments. The objective is usually either to provide an absolute chronology for environmental or archaeological records contained within a peat deposit or to understand the biogeochemical cycling of carbon within the peat system.

Introduction

Peat is a highly organic deposit (e.g., 50–95 % organic matter on a dry mass basis), comprising a thin, more rapidly cycling “acrotelm” layer, overlying a thick, saturated “catotelm” layer, in which vegetation decay is very slow (Ingram 1978; Clymo 1984). Peat develops as a result of waterlogged anaerobic and acidic conditions that inhibit vegetation decomposition (c.f. Yavitt and Lang 1990; Johnson and Damman 1991; Valentine et al. 1994; Maltby and Proctor 1996; Bridgham et al. 1998). When the rate of net primary production at the peat surface exceeds losses from decomposition, the peat deposit grows in depth and/or extent. Peatlands (also termed “bogs,” “mires,” “fens,” or “swamps”) are hence commonly located on low-gradient slopes where glacial deposits or bedrock impede drainage (Rabassa et al. 1996; Coronato et al. 2006). Peat growth is an important form of carbon storage; although peatlands cover around 3 % of the Earth’s land area, they contain 20–30 % of the global soil carbon (C) pool, storing an estimated 270–450 Pg (1 Pg = 10^{15} g) of C, equivalent to c. 50 % of C in atmospheric CO_2 (Gorham 1991; Turunen et al. 2002; Zoltai and Martikainen 1996; Moore et al. 1998; Limpens et al. 2008). Carbon inputs in peat include C fixed via photosynthesis from atmospheric CO_2 or dissolved carbon and C delivered to the peat from atmospheric deposition, surface runoff, or groundwater flow. Peat is also a source of carbon, as anaerobic decomposition releases methane (CH_4) to the atmosphere (Wang et al. 2004), and water transport from peatlands carries dissolved organic carbon to the oceans (Hope et al. 1994).

Bulk peat can be described as a “heterogeneous mix of organic matter of different origins and different ages in varying stages of biological degradation and humification” (Brock et al. 2011, p. 550), meaning that radiocarbon dating of this material presents a range of practical and theoretical problems and should be approached with care in order to obtain accurate and precise results. Radiocarbon dating of peat and its subfractions is desirable however, as this material forms a valuable long-term archive of environmental and archaeological data extending over timescales of up to 10^5 and even 10^6 years. Material held within the peat deposit, as well as the peat itself, can serve as a proxy for environmental conditions (e.g., temperature, precipitation, volcanic activity, fire

*Email: philippa.ascough@gla.ac.uk

histories) at the time of deposition. Examples of proxies studied from peat include macrofossils (e.g., Barber et al. 2003), geochemical parameters (e.g., Shotyk 1996), atmospheric cations/particulates (e.g., Clymo et al. 1990), pollen (e.g., Edwards 1979) and charcoal (e.g., Ohlson et al. 2006). In addition, peat deposits frequently contain archaeological material, including structural (e.g., Coles and Coles 1986) and human remains (e.g., Stead et al. 1986). Ongoing decomposition and compaction within peat deposits, coupled with varying accumulation rates through time, mean that depth is generally not linearly related to age within a peat deposit (Clymo 1984; Clymo et al. 1990) and absolute dating methods are required to construct a reliable timescale upon which to place proxy records obtained from peat and compare between records (c.f. Blaauw and Christen 2005). The variations in net peat accumulation rates through time that are identified through radiocarbon dating also provide a useful climatic proxy in themselves, as accumulation rates vary as a response to past climate change (e.g., Mauquoy et al. 2008).

In addition to being an environmental/archaeological archive, peatlands form a key component of the global carbon cycle, and ^{14}C is also used as a tracer to investigate the biogeochemical cycling of carbon within the peat system. Understanding peatland carbon dynamics is particularly important in the light of potential future climatic change, which is likely to be pronounced at higher latitudes, where peat deposits are concentrated. This is achieved through analysis of specific chemical fractions in peat to quantify their turnover/transport rates and residence times within peatlands. Examples include ^{14}C measurement of gases and dissolved organic carbon released from peatland sample sites (Billett et al. 2007; Tipping et al. 2010; Garnett et al. 2011).

Sampling and Pretreatment of Peat for ^{14}C Dating

Prior to radiocarbon measurement, peat samples must undergo laboratory pretreatment. The aim of the pretreatment process is to isolate material of interest for dating from contaminating carbon that has a different ^{14}C age. The first step in radiocarbon dating of peat involves the selection of a suitable section of peat, obtained from a deposit in the field. The aim of sampling peat for ^{14}C dating is to select the sample that is most representative of the age of the peat layer itself. Larger samples may be subdivided in the laboratory, depending upon the chronological resolution required. To date the peat itself, initial processing (c.f. Harkness et al. 1989) involves air-drying, followed by sieving (typically <3 mm) to remove large root fragments (which may represent intrusive material of a different age to the peat itself), and finally the sample is homogenized by grinding. At this stage, it is possible to obtain a ^{14}C measurement on the sample. Several studies have, however, raised doubts over the reliability of dates obtained on bulk peat (Kilian et al. 1995; Shore et al. 1995; Nilsson et al. 2001), and in practice it is more common to extract specific chemical fractions from peat for dating. Radiocarbon dating laboratories consequently usually separate peat into three operationally defined fractions for dating on the basis of pH-dependent solubility. These are humin (acid and alkali insoluble), humic acids (alkali soluble, acid insoluble), and fulvic acids (acid and alkali soluble) (Cook et al. 1998). Humic and fulvic acids are a product of the humification processes that occur as decomposing vegetation is transformed into peat, while humin is the fraction most representative of the original plant material that was converted to peat. Isolation of fulvic acids is performed in order to remove this fraction from the humic acids and humin and discard it. This is because the acid solubility of fulvic acids renders them mobile in the peat profile, meaning they are unreliable for dating (Shore et al. 1995). Conversely, humic acids and humin are thought to provide ^{14}C ages that more accurately reflect the time at which the peat sample formed. Pretreatment to isolate humic acids involves an acid wash, followed by an alkali wash, to extract both humic and fulvic acids. The

extract is filtered to isolate solids (i.e., the humin fraction) and then acidified to precipitate the humic acids (e.g., Brock et al. 2010). Fulvic acids remain in solution and can be discarded. Precise procedures used vary between laboratories, with differences between factors such as acid/alkali concentrations, extraction duration, and number of extractions (Cook et al. 1998). Along with peat itself, intact organic remains contained within the peat may be obtained for dating, most commonly plant macrofossils or charcoal fragments. The usual process for dating such material is firstly isolation from the bulk peat matrix by handpicking or wet-sieving. Isolated plant material or charcoal is then subjected to an acid–base–acid pretreatment (e.g., Hatté et al. 2001) to remove contaminating carbon, where removal of fulvic and humic acids by alkali extraction is followed by a final acid wash to remove any contamination added through the absorption of atmospheric CO₂ during alkali treatment.

Considerations to Maximize Accuracy and Precision of ¹⁴C Dates on Peat

Peat presents difficulties when applying the ¹⁴C method, particularly when the aim of the work is to date the time since a specific layer in the peat was formed. For the date to be accurate, the carbon that is dated must solely represent this formation event. Bulk peat is hence thought unreliable for ¹⁴C dating because it contains a variable mix of material of different ages (including aboveground biomass, roots, fungi, insect remains, diatoms, spores, pollen, charred vegetation, etc.) (Blaauw et al. 2004a; Brock et al. 2011), and any radiocarbon age will therefore simply be an integration of the ages of these substances, weighted by mass in the sample, rather than reflecting an actual date of deposition/final formation for a peat horizon. However, multiple studies show that the humic acid and humin fractions in peat can differ substantially in age and radiocarbon content (Stout et al. 1981; Hammond et al. 1991; Shore et al. 1995), raising questions over which fraction is most suitable for dating. Whichever fraction is selected, the accuracy of radiocarbon dates on peat is improved by minimizing the possibility that the sample contains contaminating carbon. Contamination can be introduced either while the peat deposit is in situ or following sampling. Contamination introduced in situ includes modern roots and rhizomes penetrating into the peat from above (Saarinen 1996) and the movement of dissolved organic carbon (including humic acids) through the peat profile (Nilsson et al. 2001; Turetsky et al. 2004). Care should be taken to identify the possibility that physical movement through frost-heaving has not disturbed the peat profile and buried surface peat with older deposits.

Another factor to consider is the possibility of whether peat samples are affected by radiocarbon reservoir effects. A ¹⁴C reservoir effect is a ¹⁴C age offset between a particular carbon reservoir versus the atmosphere at any particular point in time. This means that samples grown or formed in the affected reservoir will have a ¹⁴C age that is offset from their “true” atmospheric ¹⁴C age. Radiocarbon reservoir effects typically result from the introduction of “pre-aged” carbon into a reservoir, such as carbon derived from dissolution of geological carbonates, also known as the “hard-water” effect (Shotton 1972). Aquatic mosses in peat have been found to have a reservoir effect due to uptake of ¹⁴C-depleted carbon during growth (MacDonald et al. 1987), meaning that macrofossils or vegetation selected from peat for radiocarbon dating should be restricted to species that solely obtain carbon from atmospheric CO₂ (Turetsky et al. 2004). Other potential sources of old carbon include in-washing of ancient soil carbon to peat deposits via groundwater or overland flow (Edwards and Rowntree 1980) and organic matter released via thawing permafrost (Damon et al. 1996). Following sampling, as with any sedimentary or soil material, peat can be contaminated by the growth of vegetation or bacterial action during storage (e.g., Geyh et al. 1974). Appropriate

preventative measures include shortening storage time before analysis and storing samples cold, frozen, or dried prior to analysis.

Constructing Absolute Peat Chronologies: Calibration and Age–Depth Modeling Considerations

The radiocarbon method requires that the ^{14}C content of the sample at the time of measurement (A_s) is compared with the ^{14}C content of the sample when it was living (A_0). A primary standard material (currently Oxalic Acid II) is used to give a universal value for (A_0). This, however, assumes that the ^{14}C content of the atmosphere has been constant through time. In fact, fluctuations in atmospheric ^{14}C content due to reasons including variations in the Earth's magnetic field, fluctuating intensity of the solar wind, and human influence mean that radiocarbon ages must be calibrated to convert to the calendar timescale. For samples formed in equilibrium with the ^{14}C content of atmospheric CO_2 , the current curve is IntCal09 (Reimer et al. 2013). Calibration of ^{14}C ages in a peat deposit can be performed in conjunction with age–depth modeling to estimate the calendar age ranges of depths within the peat profile that lie between ^{14}C -dated layers (e.g., Blaauw et al. 2007; Bronk Ramsey 2008). Particular considerations are required when constructing ^{14}C -based chronologies in peat for periods after around AD 1650, due to large fluctuations in atmospheric ^{14}C content, due to both solar activity minima (the Maunder and Dalton events) and anthropogenically induced changes. The latter involve the reduction of atmospheric ^{14}C content due to release of ^{14}C -dead CO_2 from fossil fuel burning (also known as the Suess effect) and an elevation in atmospheric ^{14}C content due to detonation of nuclear weapons in the years up to AD 1963. With respect to the period after c. AD 1950, the bomb ^{14}C fluctuations can be used advantageously to achieve highly precise dates of peat deposits with uncertainties on the order of 1–2 years (e.g., Goodsite et al. 2001). For other periods where calibration is problematic due to atmospheric ^{14}C fluctuations, the technique of “wiggle-matching” can be used to obtain accurate chronologies (e.g., Blaauw et al. 2004b). Wiggle-matching relies on the premise that a time-ordered sequence of ^{14}C dates from a peat deposit should match the sequence represented in the ^{14}C calibration curve and can produce highly precise and accurate calibrated chronologies, particularly when combined with Bayesian statistics (e.g., Blaauw et al. 2007). Radiocarbon dating can also be usefully combined with other dating methods in order to reduce uncertainties and improve the robustness of age models. Such methods include ^{210}Pb dating (e.g., Clymo et al. 1990; Oldfield et al. 1997; Malmer and Wallén 1999; Loisel and Garneau 2010; Le Roux and Marshall 2011), chrono-stratigraphic markers from nuclear weapons testing, or the Chernobyl accident and tephrochronology (e.g., Dugmore et al. 2000).

Summary and Conclusions

Radiocarbon dating of peat presents particular problems, not least due to the chemically and physically heterogeneous nature of this material, potentially comprising a mix of carbon-containing compounds with ages spanning several thousand years. Despite this, ^{14}C dates on peat provide crucial chronological information for a key source of climatic, archaeological, and paleoenvironmental data. To obtain the best results, in which both precision and accuracy of ages are maximized, careful sample selection and chemical pretreatment are required, which should be combined with consideration of potential calibration issues. The application of statistical approaches, such as wiggle-matching combined with Bayesian analysis, is likely to improve

chronological resolution in instances where sufficient ^{14}C dates are performed on a profile, as is the combination of ^{14}C measurements with other dating methods.

Synonyms

[Bombardment history](#); [Cratering statistics](#); [Projectile flux](#)

Definitions

Planetary surface: Interface between the solid (or liquid) material of a planet and either its atmosphere or the outer space. Actual planetary surfaces are found only on solid planetary bodies, such as the terrestrial planets, moons, or planetesimals.

Cratering rate: The rate at which craters of a given size form per time interval and surface unit.

Introduction

Planetary surfaces carry the imprint of geological evolution of the specific planetary body and, when dated, allow estimates of the timing and rates of geological processes. Establishment of the geological evolutionary history (chronostratigraphy) of solid-surface planetary bodies is based on the most common surface-modifying geological process, impact cratering. The crater density indicates a relative sequence of events, and when calibrated by radiometric dating of returned samples (e.g., Apollo samples from the Moon), crater density-based relative ages can be converted to absolute temporal information. This can allow dating of, for example, volcanic or structural events and frame the thermal evolution of a planetary body.

Cratering on Planetary Surfaces

Impact cratering occurs at all scales. Projectiles can range from micrometer-sized dust particles to planetesimals of 10s or even 100s of kilometers in size. Planets without atmosphere can record millimeter-sized craters to impact basins of 2,500 km width. One of the largest impact events during solar system evolution is probably the collision of a large planetesimal with proto-Earth that resulted in the Moon's formation (e.g., Canup 2004). Remnants of planetesimals of the planet-forming period are found in the asteroid main belt between Mars and Jupiter and beyond the orbit of Neptune. From these belts, objects can be moved into planet-crossing orbits due to gravitational resonant interaction and collisions or due to solar radiation pressure. These objects are the projectiles that have hit the terrestrial planets and the Moon.

Fig. 1 Spatial impact crater distribution of all known craters on Earth (according to the Earth Impact Database, June 2013, <http://www.passc.net/EarthImpactDatabase/>). The craters are plotted with symbols representing gradually increasing crater sizes

Fig. 2 Spatial impact crater distribution for the Moon (after Head et al. 2010). Craters larger than 20 km (*black*) and lunar basins larger than about 250 km (*gray*) in diameter are plotted to scale

On Earth, craters are almost exclusively found on continents, with slightly denser crater populations on the old cratonic units. Only few craters are detected on continental shelf units. No crater is so far confirmed for oceanic units. Craters are found on the seafloor with lower probability, because of the relative young age of oceanic crust, which is, on average, about 67 Ma old (calculated here according to Müller et al. 1997), and because of the strong shielding effect of the, on average, 5-km-deep water column. Figure 1 shows the total known crater record on Earth with crater diameters assigned by gradually changing symbol sizes for visibility. A very different picture of cratering history is preserved on the Moon (Fig. 2). The lack of a significant atmosphere, very old surface ages, as well as relatively limited endogenic geological activity suggest that the lunar cratering record was accumulated during nearly the entire evolution of the solar system.

Fig. 3 Examples of four different but commonly used cumulative crater size–frequency distributions in log–log space, determined for the Moon

The oldest solid material found on the Moon has been dated at 4.47 Ga. Therefore, the lunar surface is commonly considered a good basis for calibration of cratering rates throughout solar system history. Additionally, the Moon is the only other planetary body (besides Earth) for which datable samples are available and that yielded ages determined in the laboratories on Earth using radiogenic isotopes.

Dating of cratered planetary surfaces requires combining the information from geological mapping and crater count statistics. Mapping delineates materials by geomorphological, multi-spectral, or reflectance features based on natural breaks in the rock sequence, while crater count statistics provide a quantitative tool for defining relative ages and absolute model ages (calibrated by isotope ages). The determination of absolute model ages on the Moon (and other solid-surface objects) is based on the application of a crater–production function (Fig. 3) and a cratering chronology model, which describes the integrated cratering rate through time (Fig. 4). The crater–production function describes the expected crater size–frequency distribution observed for a geological unit at a specific time and is, when scaled, similar for all planetary bodies (e.g., Ivanov et al. 2002).

For statistical evaluation and age determination, craters are recorded by their size and plotted into histograms, such as the crater size–frequency distribution curves. Graphs used to display crater statistics plot *cumulative* crater frequencies (number of craters greater than a given size per square kilometer, N_{cum}) against the crater diameter D on log–log plots. Distribution characteristics are defined by polynomial functions or multiple-segment power laws, where the cumulative frequency N_{cum} is proportional to D^{-b} and b varies between 4 and 1.5 (e.g., Hartmann 1999; Neukum et al. 2001, Fig. 3). There are other representations, such as *incremental* or *relative* (R) plots. The latter

Fig. 4 Cratering chronology model according to Neukum et al. (1975). Calibration points beyond 4.1 Ga (the currently best estimate for the age of the Nectaris Basin, Fernandes et al. 2013) are speculative, and, therefore, earlier cratering rates are debated

Fig. 5 Cratering. A planetary clock: sequence A, B, and C and sequence A, F, and G depict the effect of resurfacing activity on the crater distribution when (B) the entire unit is partially resurfaced, and only smaller craters were erased, and (F) half of the unit is completely resurfaced. The resulting crater size–frequency distributions are shown in (E) in comparison to artificial isochrons; event (B) as circles, event (F) as squares. Martian surface examples of resurfacing are shown in (D) as caused by erosion and in (H) due to emplacement of volcanic flows

describe the curve relative to a D^{-2} distribution and are used to compare distribution shape variations. The theoretical concept and mathematical background for dating techniques based on crater counts were developed in the 1960s and 1970s, as summarized by the *Crater Analysis Techniques Working Group* (Arvidson et al. 1979).

The sketches in Fig. 5 describe the crater size–frequency distribution modifications as a result of partial and complete resurfacing due to erosion or volcanic emplacement. Both these geological processes can modify the cratering record, and only thorough geological mapping permits a meaningful interpretation of the cratering record. The comparison of measured crater size–frequency distributions and the crater–production function (see below, Fig. 3) can aid the interpretation only if photogeological mapping and crater statistics were performed well beyond the image resolution limit. The relative differences of the calculated areal crater densities are interpreted as relative ages, and geological events at a global scale can be compared even if no superposition relations are detected.

Cratering Statistics and Cratering Rates

The approach of dating planetary surfaces by crater densities (i.e., the number of craters per square kilometer) was first proposed by Öpik (1960), whereas linking crater densities with isotopic ages was pioneered by Shoemaker et al. (1962). The Apollo and Luna sampling missions provided lunar rock samples that were isotopically dated; these isotopic ages were later correlated to crater densities on the lunar surface (e.g., Hartmann 1970). This permitted dating of surface features so that the planetary evolution could be studied through absolute geological time, and thus, the crater counting method is the only tool to date planetary surface evolution when in situ samples are not available.

To determine absolute surface ages of planetary surfaces other than those for the Earth or Moon, some basic assumptions are made: (1) the rate of impact crater formation is known, and the rate is size dependent as assigned by the crater–production function and is stable with time (Fig. 3); (2) the cratering process is spatially and temporally random, i.e., no preferential bombardment seasons exist; (3) target–property variations across the target body are negligible; and (4) surface units are mapped according to geological criteria. The conversion from crater frequencies (relative ages) to absolute ages requires a cratering chronology model. Such models link crater frequency and absolute ages derived from isotope geochemistry and were developed in the early 1970s (the most commonly adopted one is by Neukum et al. 1975, Fig. 4). The crater densities measured on different planetary surfaces that have been exposed for the same duration are assumed to be similar for all planetary bodies.

For planetary bodies beyond the Earth and Moon, the lunar chronology model is transferred to the impact conditions on the other bodies. The scaling of crater sizes between planetary bodies requires knowledge of (1) the flux ratio of impactors at different sizes considering celestial mechanical aspects and (2) how the conditions of crater formation differ from one planet to another. These conditions are mainly defined by mass of the projectiles, impact velocities, impact angles, gravity acceleration, and target properties of the impacted bodies, and are not always fully understood (Werner and Ivanov 2014).

Planetary System Evolution and Cratering Chronology Models

The bombardment history of the Moon is closely related to our understanding of planetary formation and evolution of the solar system. The discovery of extrasolar planets has revolutionized research on the dynamical evolution of our own planetary system. The opportunity to observe planetary systems in evolutionary stages, both younger and older than ours, has inspired ideas of

orbital migration of the gaseous planets during their primordial accretion phases. New dynamical orbital evolution models comprising the orbital inward and outward migration of the gaseous giant planets have emerged, with important implications for orbital changes of the surviving planetesimals (e.g., Tsiganis et al. 2005; Gomes et al. 2005). These models suggest that the average impact velocities have changed through time, making it difficult to relate cratering statistics on old surfaces with crater counts on young surfaces, as increased impact velocities would result in larger crater sizes (Werner and Ivanov 2014). Traditional cratering statistics for planetary surface-age determination assumes monotonic decay of the cratering rate at constant average impact velocities.

Summary

Understanding the evolution of planets in the solar system critically depends on accurate estimates of time and rates at which processes, e.g., volcanism, occur. Absolute time scales for planetary surface evolution in the inner solar system (except the Earth and the Moon) can only be derived by linking the lunar crater frequencies with isotopically dated lunar samples. The crater counting method, the only tool to date in absolute terms planetary surface evolution when samples are not available, is challenged by many observational uncertainties and the great diversity of approaches. Diverse crater–production functions are used to calibrate crater density measurements, which has resulted in a variety of different lunar chronology models. This diversity propagates to other planets such as Mars and adds ambiguity to the related temporal interpretations (e.g., Werner and Tanaka 2011). Commonly used cratering statistics for planetary surface-age determination assume monotonic cratering rate decay, but other interpretations have been put forward due to the discovery of extrasolar planetary systems. Cratering rates prior to formation of the Nectaris Basin on the Moon are not constrained and therefore debated in the light of solar system evolution concepts (Werner and Ivanov 2014). Nevertheless, currently cratering statistics are the only method to determine globally and across the solar system relative and absolute ages and rates of planetary surface evolution, until such time as datable samples will become available from other planetary bodies.

Definition

We discuss ^{14}C dating of plant macrofossils from different contexts and consider the various complicating effects of the history of the samples on the ^{14}C measurement.

Introduction

Late Quaternary chronologies are commonly constructed using AMS ^{14}C dating of plant macrofossils, because they are generally argued to provide the most reliable chronology. Although plant macrofossils are often relatively abundant and well preserved in a variety of site type, they are still potentially subject to a range of complications. Be they terrestrial or aquatic, plant macrofossils are prone to absorb CO_2 of mixed origin during photosynthesis, to be reworked, contaminated by dissolved organic carbon and by modern carbon due to inappropriate storage and analysis. They can also be potentially impacted by measurement effects relating to small sample sizes.

We will overview different macrofossils here, in dry and then humid environments, will give few notes on insects and invertebrates commonly retrieved besides plant macrofossils and finally, we will highlight good practices in the laboratory.

Dry Environments

Numerous archeological and paleoclimatological studies are performed in dry environments and chronological frameworks are then established from (carbonized or non-carbonized) vegetal remains. This section deals with tree products, phytoliths, and pollen.

Tree Products

Every year, tree growth adds wood to the outside part of the trunk. The date measured on heartwood may be already many centuries old by the time a tree was cut down. This is particularly true for long-lived tree specimens, such as oak and juniper. An ideal material to date, if available, would be a twig or branchlet of small trees that can integrate 5 years in the worst case. Seeds and other food remains are also reliable material to be dated. Specific cultural or environmental conditions must equally be seen as potentially impacting radiocarbon dates. This is the case for arid, coastal, volcanic, and “industrial” environments.

*Email: christine.hatte@lsce.ipsl.fr

“Old Wood Effect”

The problem of the “old wood” effect in radiocarbon dating has long been recognized for charcoal and wood samples (e.g., timber), the age of which may be hundreds of years older than expected. Besides this, the archeological field faces another difficulty linked to possible time lags between felling and final deposition. The timber may have an extensive history of use and reuse, especially in arid environments where hard trees are rare. We should be aware that the date we are measuring is the death of the tree and not its last use (e.g., Saliège et al. 2012).

Atmospheric CO₂ of Different Origin and ¹⁴C Signature

Costal environnement Significant effect from ocean upwelling can be recorded in some coastal regions. There, ¹⁴C-depleted CO₂ degassing from deep ocean water in an upwelling system can mix with free atmospheric CO₂ and be incorporated by coastal vegetation, which results in older apparent ages, or “ageing.” There are indications that there may be small but significant offsets in Japan (Nakamura et al. 2007). This offset is difficult to assess as it is directly linked to the highly fluctuating ocean circulation and equilibrium.

Volcanic environnement It is also documented that equivalent effects can be local variations close to volcanic vents, where terrestrial macrofossil may be affected by magmatic CO₂ devoid of ¹⁴C (e.g., Cook et al. 2001a; Pasquier-Cardin et al. 1999). Usually, such effects seem to be localized and not be recognized around lakes under windy influence (e.g., Hajdas et al. 1998).

Industrial modern environnement Industrial-scale release of fossil fuel-derived CO₂ can have a similar large local effect, and this could be relevant for the use of radiocarbon dating for historical (postindustrial revolution) times.

Phytoliths

Phytoliths are increasingly used for isotopic studies performed on organic matter embedded into the skeleton-building silicate (e.g., Hodson et al. (2008) and references therein). Phytoliths trap trace amounts of organic carbon (typically 0.1%wt) that is encased in silica (Mulholland and Prior 1993). This very small amount of carbon available for a ¹⁴C measurement requires the highest control of the blank quality (Santos et al. 2010). In a recent study performed in highly controlled conditions, Santos et al. (2010, 2012) showed that phytolith carbon may be released from old soil organic matter and might not be directly linked to the age of the plant, but this is still under debate (Sullivan and Parr 2013).

Pollen

Because many continental paleoclimatic studies are based on pollen assemblages, it appears judicious to directly base the chronology on pollen itself. However, very few ¹⁴C dating attempts were performed on pollen grains themselves (Long et al. 1992; Mensing and Southon 1999), most are performed on pollen concentrate from sediment (e.g., Brown et al. 1989; Kilian et al. 2002; Neulieb et al. 2013; Piotrowska et al. 2004) and the results are highly variable, from a clear rejuvenation, that is, the age is too young, to some hundreds of years older, or an age in agreement with larger identified macrofossil. Hence, pollen dating is still in development.

Humid Environments: Lake, River, and Peat

The main other types of carbon reservoirs, relevant to radiocarbon dating, are lakes, rivers, and peats. Humid environment sediments reflect a variety of different deposits ranging on a scale from purely allochthonous to purely autochthonous, minerogenic, and/or organic material. They may contain, for example, precipitated and/or in-washed mineral matter, terrestrial and aquatic plant and animal remains, including algae, bacteria, and fungi, as well as reworked older organic material. Such freshwater systems not only act as ^{14}C reservoirs in their own right and exchange CO_2 with atmosphere but also incorporate carbonate and organic carbon from surrounding catchments. This means that the radiocarbon concentration can lie anywhere between the levels of the atmosphere and those of the bedrock (zero for geological carbonate).

Generalities on “Freshwater Reservoir Effect” and “Hard Water Effect”

Aquatic cells photosynthesize subaquatically and hence build carbon from dissolved inorganic carbon (DIC) into their cellular material, so they reflect the ^{14}C : ^{12}C ratios of the water from which they grow. The DIC is influenced by (1) exchange with the atmospheric CO_2 reservoir, (2) decomposition of organic matter, (3) residence time of lake or peat bog water and in areas with calcareous bedrock and/or soils, and (4) dissolved carbonate from surrounding limestone catchments. This means that the ^{14}C activity of DIC does not reflect the ^{14}C activity of atmosphere, but it is ^{14}C depleted. This results in an artificial ageing, the so-called freshwater reservoir effect in soft water environments and the “hard water effect” in calcareous areas, inherited by algae cells and which can show wide variation (Fontana 2005; Macdonald et al. 1991).

As example, in arctic oligotrophic lakes, it has been suggested that ^{14}C -depleted particulate and dissolved organic carbon (POC and DOC) transported from soils and peat in the watershed of the lakes may have a large influence on the age of the surface sediments (e.g., Abbott and Stafford 1996) with reservoir ages of up to 1,000 years. In such extreme environments, with lakes of low aquatic production, the allochthonous organic fraction may make up a large part of the total organic matter and may thus influence the composition of the sediments. If the allochthonous fraction consists of old organic matter, washed out from peats and soils, it will obviously increase the age of the sediment. Such considerations may be very important for paleolimnologic studies of lakes with low productivity surrounded by a landscape rich in peat lands and thick soils. Perennial lake ice cover, which seals off the lake water from the atmosphere (e.g., Doran et al. 1999) and/or inflow of glacial melt water (enrichment by old CO_2), may also act in favor of artificial ageing. However, there are some examples of peat bogs that do not seem to be subjected to freshwater effect, such as the case of lacustrine or palustrine environments developed on glacial till (e.g., Blaauw et al. 2004; Hajdas et al. 1998; Walker et al. 2001).

Furthermore, in fluvial systems, the actual radiocarbon concentrations can vary seasonally and depend on details of the recent weather conditions (e.g., Neff et al. 2006). In larger lakes, the variation will generally be slower and reflect long-term climatic trends.

Algae and Aquatic Moss Macrofossils

As “freshwater reservoir effect” and “hard water effect” vary according to environment specificities, their magnitudes affect the relevance of plant macrofossils for dating that are recovered from sediments. Algal macrofossils should thus be avoided if possible. If there is no other choice, an evaluation of the reservoir age should be associated with the measurements. This could be done by the collection, in a “reference” level, of algae macrofossils and subaerial plants. But once again, attention must be brought to the choice of the reference level. Indeed, the level chosen to determine

the reservoir age should correspond to an equivalent climatic context to the one to which the correction will be done.

Relevance/Match of Some Identified Terrestrial Plant Macrofossils

Based on the assumption that superior (terrestrial) plants that photosynthesize from free gaseous CO₂ instead of DIC are less susceptible to contamination by inert carbon than their aquatic counterparts, since they obtain their carbon by subaerial photosynthesis, many scientists have advocated the exclusive use of superior plant macrofossils for radiocarbon-dating lacustrine and palustrine sediment sequences. However, they also are not free of problems.

***Potamogeton* Seeds and Other Floating Superior Plant Macrofossils**

Floating superior plants photosynthesize from the CO₂ available at the water surface that mostly results from a mixture of free atmospheric CO₂ and degassing DIC. Indeed, a high content of mineral carbon in water can result from strong limestone catchment erosion or from high organic matter mineralization, such as is commonly observed following a production bloom that may result in DIC degassing. Consequently, floating superior plants inherit part of the DIC ¹²C:¹⁴C composition, and even if diluted, the “freshwater effect” affects the ¹⁴C activity of *Potamogeton* seeds. The conversion of this activity into a date would induce significant ageing (i.e., the sample appears too old) (e.g., Hatté et al. 2013) or even rejuvenation (too young) in the specific case of modern environments that absorbed high “bomb peak” ¹⁴C. Indeed, the DIC may thus be imprinted by peak bomb organic carbon and then the floating plants appear ¹⁴C enriched (e.g., Olsson and Kaup 2001).

There are some examples of peat bogs where DIC degassing is not significant, and dating obtained on *Potamogeton* seeds gives a reliable chronological framework (e.g., Walker et al. 2001). Nevertheless, since this is linked to water organic production and thus to seasonal cycle, the degassing can fluctuate greatly, and therefore, a quantitative evaluation is difficult. It remains hazardous to work on this kind of macrofossil. Therefore, it is better to avoid the use of floating plant macrofossils for dating as much as possible.

Sphagnum, Terrestrial Mosses, and Smaller-Sized Superior Plant Macrofossils

As ombotrophic peat deposits are very common and sphagnum-formed, sphagnum macrofossils are often used for ¹⁴C dating (Kilian et al. 1995). These superior plants do not grow in the water context and are not subjected to a “hard water effect” or DIC degassing influence; however, they are not free of old carbon effects. Indeed, palustrine areas may be highly organic, especially in ombotrophic bogs, and then very efficient environments for organic matter mineralization. As this mineralization can be from recent as well as old organic matter, the resulting mineralized CO₂ emitted by the “soil” shows an old apparent ¹⁴C age. Thus, at the ground surface, CO₂ results in a mixture between free atmospheric CO₂ and mineralized organic matter CO₂. At a lower scale, this effect can be linked to the well-known canopy effect in a tropical forest. Close to the surface, the smaller-sized superior plants like sphagnum and mosses may thus show ¹⁴C ageing (Jungner et al. 1995). Some mosses are calciphilous and thus may incorporate limestone as a carbon source; this effect may result in an ageing (Zazula et al. 2006). These mosses may not constitute the most reliable support to establish a chronology. Considering the uncertainty ranges associated with ¹⁴C dating, this ageing can sometimes not be significant, and chronologies based on ¹⁴C on sphagnum can be reliable. But with the increasing precision of ¹⁴C dating, the ageing risk linked to organic matter mineralization has to be taken into account.

Tall Superior Plant Macrofossils

Finally, larger superior plant macrofossils seem to be the most suitable macrofossils for ^{14}C dating. A plethora of such macrofossils can be found in peat and lake sediment. We can list needles of *Pinus*, *Larix*, and *Picea*; seeds of *Betula*, *Carex*, and *Eleocharis*; and leaves of *Salix*, *Dryas*, *Erica*, and *Calluna* as the most common.

On account of their high resistance to diagenesis, *Carex* seeds were intensively used in support of chronological frameworks. However, this effective resistance does not permit verification of the state of preservation, and so some possibly reworked or redeposited seeds might not be recognized from indices on macrofossil shape and entirety. This was the origin of some inconsistent chronologies based on macrofossils of several centimeter tall superior plants (Turney et al. 2000). We would recommend the collection of “fragile” macrofossils from which it is easy to check that they are unlikely to have been physically transferred within the sediment matrix and/or otherwise reworked from the surrounding catchment and/or reworked by fauna and/or the rhizosphere. For example, intact *Betula* seeds surrounded by a fragile voile or survival of the fragile *Salix* leaves can be ideal candidates for ^{14}C dating to establish a chronological framework.

Insects, Amphibians, and Invertebrates

Beside plant macrofossils, insects are common and often abundant in a range of sediment types. Examination of their utility as dating materials has focused on bark beetles and chironomids. Beetles sclerites (Elias et al. 1991; Porch and Kershaw 2010) and chironomid head capsules (Fallu et al. 2004; Jones et al. 1993) extracted from lake sediments have shown to provide reliable radiocarbon dates. However, it should be remembered that some animals such as detritus feeding beetles will ingest carbon that might have been photosynthesized some years to hundreds of years before and are part of soil organic matter. They are thus ^{14}C depleted relatively to atmosphere and will result in older than expected ^{14}C ages. In lakes affected by erosion of surrounding catchment, these burying beetle remains can become part of lake sediment and thus also yield for ^{14}C inversion. Finally, aquatic beetle species that feed with algae mimic the addition of old carbon to their food.

Land snails might also exhibit a similar (even more extreme) radiocarbon signature. They can use calcium from limestone as major component of their shells and incorporate at the same time the limestone carbon that, mixed with ingested plant carbon, might result to very high ageing (up to 2,400 years) especially in arid and semiarid regions (Goodfriend et al. 1999). Furthermore, snail shells are quite soluble and chemically interact with the environment. Dissolution and recrystallization are highly probable and would induce apparently rejuvenated radiocarbon age. Humid phases that followed a dry fossilization inevitably imply carbonate dissolution and recrystallization. Dating land snail carbonate should be avoided.

Some animals spend time in different parts of the biosphere. That is the case of amphibians that live in atmosphere and water and of some fishes as salmons and eels that spend part of their life in ocean and then freshwater. They thus get their food from a whole variety of sources. This means that the carbon they incorporate will ultimately come from different primary reservoirs and that animals integrate a large variety of ^{14}C signatures (e.g., Cook et al. 2001b). Disentangling the resulting ^{14}C signal is impossible and this kind of support should be avoided.

Sample Fossilization

Once an organism dies, its constituent parts are constantly being broken and reformed, and usually little remains after a few years. However, in some conditions, most notably waterlogged deposits and very dry conditions, there is better preservation. It is important to remember that this preservation is exceptional and therefore that in most cases, the excavated sample composition is not representative of its original composition.

An important factor to consider is mechanical disturbance and downward movement through bioturbation by roots, burrowing animals and insects, and geological instabilities. The reworking risk can be evaluated by animal and insect identification and by a detailed sedimentological study. A reliable chronological analysis cannot be carried out alone and has to be jointly conducted in a collaborative mind.

The organic materials that survive intact for longest with their original complement of carbon atoms are normally the polymers. The carbon from organisms that degrade is not always lost, but can often present in form of soluble molecules such as dissolved organic carbon or the well-known but poorly characterized humic and fulvic acids. Such components can be recovered from sediment but are highly mobile and cannot however be related to a single organism or to a well-defined photosynthesis event. Even when carbon remains in some stable form (non mobile form), there will usually be many other more mobile carbon-containing compounds and other contaminants that become incorporated into the material remains of an organism. These contaminants will have different origins and so will not share the same radiocarbon signal. Removing these contaminants will be a key step in the lab processing.

In the Lab

Sample Preservation

The core storage and the preparation and identification of small macrofossil samples are usually carried out in a nonsterile environment; however Wohlfarth et al. (1998) have shown that the long-term storage of wet macrofossil samples appears to have a significant effect on radiocarbon age, even when samples are kept cool. Fungal spores and microorganisms can easily be incorporated into the sample. As they might use ambient water carbon as source of carbon besides from fossil leaf materials, they therefore contaminate the sample. Similar findings were previously evidenced for marine cores preserved at 4 °C that were contaminated by recent carbon from modern, terrestrial bacteria (Colman et al. 1996; Geyh et al. 1974). Wet storage of the selected macrofossils should be avoided in order to prevent bacterial/fungal activity and the sample should be either dried at 100–110 °C as quick as possible (Björk and Wohlfarth 2001) or dried under vacuum at lower temperature (60 °C) (Gauthier and Hatté 2008). The choice between these procedures should be done according to the sample sturdiness. Dry samples can then be stored in a clean (850 °C pre-combusted) glass bottle or on clean (400 °C pre-combusted) aluminum foil.

Sample Size

Very small samples are likely to be prone to contaminations, especially lab contamination and allochthonous input. To avoid this high risk, large amount of macrofossils should be sampled if possible. For example, Bronk Ramsey (2008) weighed up a rejuvenation of 840 years consecutively to adjunction of 1%wt of modern contamination in a 20 000-year sample. Such a high

rejuvenation that results in only 1 µg contaminating C in a 100 µg C sample has to be put in regard to the weight of a 1 cm long hair (# 50 µg) and of a pullover fiber (# 15 µg).

Furthermore, a larger than expected scatter in measured values for subsamples lower than 0.3 mg C was reported (Oswald et al. 2005; Stuiver and Pearson 1993). Two factors contribute likely to these findings: the uncertain completeness of the graphitization reaction and the increasing impact on contaminant carbon background (Brown and Southon 1997). An incomplete graphitization reaction yields for ^{14}C fractionation up to -60‰ that could be interpreted in case of decoupled $\delta^{13}\text{C}/^{14}\text{C}$ measurements ($\delta^{13}\text{C}$ measured on gas sample, prior graphitization) as an apparent older age up to 500 years.

The best compromise between the lab risk and the error inherent to macrofossil nature (e.g., linked to freshwater or burrowing effect) should be found. What is the best between an isolated *Betula* seed of few µg and beetles sclerites not perfectly identified in high quantity? That will always remain the question.

Conclusion

It is impossible to suggest a universal strategy for obtaining reliable radiocarbon dates, because each approach has to be adapted to the type of soil, lake, peat bog, and sediment material under investigation, as well as to the objective of the study. However, before deciding on the sampling and dating strategy, the following considerations should be made:

1. What are the scientific objectives of the project in terms of dating?
2. Which type of organic material is available and in which quantity?
3. How will the present and the past environment and climate influence the radiocarbon measurement?

These questions are an important precondition to highlight radiocarbon issues such as freshwater effect and its variability within the study period, recrystallization risk, and multiple ^{14}C reservoirs, etc., and finally to adapt the sampling to the chronological framework one needs to obtain.

Skeletal Remains (^{14}C)

Gregory W. L. Hodgins*

University of Arizona Accelerator Mass Spectrometry Laboratory, Department of Physics, School of Anthropology,
University of Arizona, Tucson, AZ, USA

Bone and teeth are complex tissues and thus radiocarbon dating them is also complex. They contain carbon in both organic and inorganic mineral phases. The organic phase is primarily collagen. It is a fibrous extracellular structural protein. The mineral phase is bioapatite. Bioapatite is a biologically synthesized hydroxylapatite that is predominantly calcium phosphate within which carbonate ions are substituted.

Biomineralized tissues tend to survive better than soft tissues after death. Nevertheless, they undergo a variety of structural and chemical changes caused by physical, chemical, and biological agents. Post mortem processes that alter tissue structure and chemistry are termed diagenesis. Diagenetic reactions lead to both the loss of endogenous carbon and the uptake of exogenous carbon. One of the main challenges in radiocarbon dating skeletal materials is reliably removing the exogenous carbon that has accumulated within the sample over time. Many different sample preparation protocols have been developed to cope with different sources and levels of contamination. Each protocol has its strengths and weaknesses and no single protocol is suitable for all sub-fossil skeletal remains.

The origin of bone dating goes right to the earliest publications on the ^{14}C method (Arnold and Libby 1951). The earliest dates were derived from total bone carbon. The reliability of these early measurements was almost immediately questioned because bone dates frequently contradicted dates obtained from stratigraphically associated wood and charcoal. This focused attention on determining whether fractions of bone could be identified that would provide reliable dates, and this objective has propelled bone dating research up until the present day.

Chemical preparation methods have tended to focus either on the organic fraction, principally collagen, or the inorganic mineral fraction, the bioapatite. The following discussion deals first with collagen dating. It begins with a description of the structure of the protein itself, followed by a presentation of the five common methods used for collagen extraction from bones and teeth. The parameters that define collagen purity are presented, and this is followed by a brief consideration of burnt bone dating. Protocols for dating bioapatite, the mineral phase of bone, are then discussed. This entry concludes with a review of a special case of bone mineral phased dating, radiocarbon measurement from cremated or “calcined” bone.

Collagen in Bone and Teeth

Most radiocarbon dates on bone, teeth, tusk, and antler are derived from the radiocarbon content of collagen in the organic phase. This is because, in contrast with bone mineral, collagen does not readily exchange carbon with its surrounding environment.

Collagens are in fact a family of proteins (Nelson and Cox 2009). The major type, Type I collagen, is the primary structural protein in bone. It comprises approximately 20 % of dry bone mass. The

*Email: ghodgins@physics.arizona.edu

collagen content of tooth enamel is lower than bone, typically about 3 % by mass. The collagen content of tooth dentin is similar to that of bone.

The genes that encode collagen are highly conserved both between collagen types and across species. Organisms on widely separated branches of the evolutionary tree have collagen genes with similar structure. Consequently, collagen purification protocols can be applied without modification to a wide range of animal species.

A single collagen molecule is composed of three polypeptides hydrogen bonded in a rigid triple-helical rod. A small number of covalent bonds within the triple helix stabilize the structure. Each polypeptide is approximately 350 amino acids in length, with a molecular weight of 100,000 Da. The amino acid composition is unusual in that every third amino acid is glycine, frequently followed by proline and hydroxyproline. Hydroxyproline is rarely encountered in other proteins and so can function as a marker molecule for collagen.

Individual collagen tripeptides are bundled in a staggered array, and these arrays are ordered into higher structures and filaments. Cross-links between molecules accumulate within the filaments over time. Hydroxylapatite crystals form within the arrays and the fibrous nature of these biomineralized structures give bones, teeth, and antlers rigidity and compressive and tensile strength. Collagens are also present in non-mineralized tissues, arranged into both ordered and unordered fibers and sheets. The accumulation of cross-links within and between collagen molecules slowly alters the mechanical properties of collagen-based tissues during life.

Archaeological Collagen

Collagen can survive in archaeological bone for extremely long periods, and survival beyond the 50,000 year radiocarbon time frame is not uncommon. The mechanisms of decay are diverse (Collins et al. 2002). Typically, collagen is progressively lost from archaeological bone during diagenesis. Bones retaining less than 1 % collagen by mass are usually too decayed to be reliably dated. Depending upon the burial environment, hydrolytic reactions can fragment the polypeptides decreasing collagen molecular weight and lowering collagen melting temperature. Condensation reactions that cross-link collagen molecules to other biomolecules can also occur, thereby covalently linking contaminants into the collagen matrix. These changes alter the behavior of the collagen fraction during purification and can reduce collagen yield.

Methods for Extracting Collagen from Bones and Teeth for Radiocarbon Dating

A variety of methods exist for extracting collagen from bones and teeth. Considerations that affect the decision about what method to use include the quantity of bone available, its estimated age, its condition, whether or not other isotopic parameters are to be determined, equipment availability, cost, and other factors. Five methods will be discussed: (1) total collagen purification by the Longin and the Modified Longin method, (2) collagen ultrafiltration, (3) total amino acid purification by ion-exchange chromatography, (4) single amino acid purification including hydroxyproline extraction, and (5) the ninhydrin method.

It is important to keep in mind that although the more elaborate preparation protocols seem to promise more reliable dates, this is not necessarily the case. Theoretically, they more precisely exclude contaminants that infiltrated the skeletal remains during burial, yet the paradox is that more elaborate protocols require more extensive laboratory handling and thus are prone to higher levels of

laboratory-induced contamination. It is very important to carry out the experimental controls so contamination levels are clearly defined.

The Longin Method

Berger et al. (1964) first proposed a collagen isolation method based upon the suspension of bone powder in dilute strong acids such as 0.1 N HCl. Acidification causes the bone mineral to decompose. The mineral carbon is released as carbon dioxide gas; the mineral salts dissolve into the acidic solution, as do soluble organic molecules, and an insoluble collagen-rich organic fraction remains. Contaminants can be washed out of the insoluble fraction without substantially reducing collagen yield. The isolated “collagen” fraction is quite crude, often contaminated with humic or fulvic acids, but radiocarbon measurements of it were a clear improvement over whole bone measurements.

Longin (1971) proposed a simple but powerful modification to this early collagen purification protocol. It utilized the acid extraction of collagen in 0.5 N HCl, but followed this with a gelatinization step that rendered the collagen into soluble gelatin. Heating an aqueous suspension of collagen to temperature of greater than 65 °C causes the triple helices in the individual collagen molecules to unwind, producing randomly coiled, soluble polypeptide monomers. Intramolecular and intermolecular cross-links prevent the polypeptides from completely dissociating. Upon cooling, the solution forms a gel. Triple-helical collagen molecules do not reform, but a high degree of hydrogen bonding links monomers together in a random manner. Depending upon the concentration, the randomly coiled collagen peptides either stay in solution or at higher concentrations form a gel. Gelatin is the common name for this solubilized collagen and denotes both the material and its form.

The rationale of the Longin method is that it is unlikely that contaminants absorbed into the bone during burial would undergo the same change in solubility that occurs with collagen as a result of heating in aqueous solution. The initial acid demineralization step allows the removal of acid-soluble contaminants from the insoluble collagen matrix by simple washing steps, and then gelatinization changes the game so that any remaining insoluble contaminants can be removed from the collagen solution by either centrifugation or filtration.

The Modified Longin method adds a NaOH extraction step after the initial acid demineralization step. If the bone is contaminated with soil-derived organic matter that is insoluble in acidic solution, washes in high pH solutions can extract these from the collagen matrix. As atmospheric carbon dioxide dissolves readily in high pH solutions, the base wash must be followed by another acid wash to ensure that any absorbed atmospheric carbon dioxide is removed before the gelatinization steps.

The Modified Longin method is commonly referred to as an “ABA plus gelatinization” method where ABA = acid/base/acid. It has the advantage that it requires a minimum of equipment and minimal sample handling, but achieves a high degree of purification. The acid–base–acid washing steps can be automated using readily available chromatography equipment, and when carried out in continuous-flow systems, there is an added advantage that extracted contaminants are completely removed from the system during extraction. Finally, the gelatinized collagen can be isolated from near-neutral pH solutions by freeze-drying. This dried collagen solid is easy to handle, store, and archive.

Ultrafiltration

This method is a modification of the Longin method. First suggested by Brown et al. (1988), it exploits the large size of collagen protein (>100 kDa for intact protein monomers) and hypothesizes that contaminants are likely to be much smaller molecules. The method involves isolating collagen by the Longin or Modified Longin method, followed by ultrafiltration using 30 kDa molecular weight cutoff membranes. The retained fraction, containing high molecular weight collagen molecules, is retained and dated, while the pass-through fraction containing low molecular weight contaminants is discarded.

Extensive washing of the ultrafiltration membranes have been found necessary. Higham et al. (2006) suggest using the method in contexts in which bones are several half-lives old, and small amounts of contamination have a large effect on the resulting radiocarbon date.

Collagen Total Amino Acid Dating

Ho, Marcus, and Berger (1969) first proposed a method to date bone by isolating and dating collagen-derived amino acids. Collagen was first isolated from bone by 1.0 N HCl hydrolysis of bone mineral. The proteinaceous residue was then hydrolyzed in 6 N HCl at 100 °C for 24 h. The amino-acid-containing residue was then purified by ion-exchange chromatography. After contaminants were washed through the column, total amino acids were eluted and subsequently combusted for radiocarbon measurement. This approach was also developed by Gillespie et al. (1984). Stafford et al. (1987) published a variant using a mixed-bed ion-exchange resin called XAD-2. The use of ion-exchange chromatography exposed a risk that the ion-exchange columns themselves bleed off carbon that contaminated the sample; care was required to minimize it and control it at the measurement phase.

Hydroxyproline Dating

In parallel with the development of total collagen, amino acid dating was the targeting of specific amino acids. Hydroxyproline, though uncommon in most proteins, is approximately 8–12 % of collagen. Its rarity made it a good marker for collagen and several investigators focused on developing methods for its isolation. Stafford et al. (1982), Gillespie et al. (1984), and others have published hydroxyproline isolation protocols. Until recently, these methods have had relatively little impact on bone dating, probably due to their complexity, concerns about column bleed, and the fact that 90 % of collagen carbon is discarded during hydroxyproline purification.

Recently, new hydroxyproline purification methods have been developed (McCullagh et al. 2010; Marom et al. 2012). The development of preparative scale HPLC systems, new ion-exchange resins with low bleed columns, and improved techniques for the measurement of small radiocarbon samples has made this possible.

The Ninhydrin Method

Ninhydrin is a reagent that reacts with primary and secondary amines. In the presence of a solution of amino acids, ninhydrin condenses with the amino group nitrogen and ultimately releases the carboxyl carbon of the amino acid as carbon dioxide gas. A blue-colored ninhydrin chromophore is also a product of the reaction. Nelson (1991) formulated an elegant two-step protocol for extracting collagen carbon using the ninhydrin reaction, and it has been utilized extensively by Tisnérat-Laborde et al. (2003). In the first step, crude collagen extracts are treated with ninhydrin in a slightly acidic buffered solution. A small amount of carbon dioxide is produced from the terminal amino acid of each collagen polypeptide and any free amino acids or other contaminants in the preparation that contain primary or secondary amines. The first pulse of carbon dioxide gas is discarded. The ninhydrin-treated collagen polypeptides are recovered and then hydrolyzed to their constituent amino acids in hot 6 N HCl. When this preparation is treated a second time with ninhydrin, the resulting carbon dioxide gas is recovered for radiocarbon dating.

Part of the power of the method lies in the selectivity of ninhydrin for collagen amino acids. Burial contaminants comprised of lipids, carbohydrates, humic acids, and other organic compounds are unreactive. Another advantage comes from the phase change that occurs in the carbon of interest during the reaction. The ninhydrin reaction takes place in a solution, but the carbon of interest bubbles out as a gas so unwanted contaminants remain behind.

The main disadvantage of the method is inefficiency. At best, only one tenth of the collagen carbon is available for radiocarbon measurement. There are further complexities if stable isotope data are required, and these were investigated by Keeling et al. (1999).

The inefficiency of the ninhydrin, hydroxyproline purification, and other elaborate protocols that by their nature only recover a small percentage of collagen carbon presents a paradox: Only bones in a good state of preservation contain sufficient collagen so that elaborate purifications are possible, yet if bone preservation is good, then elaborate protocols are probably not needed.

Collagen Quality Indicators

Collagen structure has been elucidated both biochemically and genetically in a broad range of species. A archaeological collagen more difficult to characterize. Nevertheless, several basic parameters are used to define it. Solubility characteristics, carbon content, nitrogen content, carbon to nitrogen ratio, carbon $\delta^{13}\text{C}$ and nitrogen $\delta^{15}\text{N}$ values, glycine content, the presence of hydroxyproline, and other parameters have been used to identify collagen in extracts of archaeological bone. Moreover, these parameters can, to some extent, be used to assess the purity of the preparation (van Klinken 1999). This is in contrast to the short list of parameters that defines the other two most commonly dated organic materials, charcoal and wood cellulose. The identification of contaminants within these materials is much more difficult because the only parameters available are carbon content, which is not particularly enlightening because the principle component of potential contaminants is also likely to be carbon, and $\delta^{13}\text{C}$.

Burnt Bone

Burnt bone and teeth present several challenges for radiocarbon dating. The degree of charring affects the survival of organic material and also changes its chemistry. Consequently, protocols for collagen purification are not reliable and the collagen quality indicators such as carbon and nitrogen content cannot be applied. For these reasons, burnt bone is best avoided.

Carbonate Dating

The crystals of bioapatite, though predominantly calcium phosphate, contain carbonate substitutions to the extent that the mineral phase of bone contains about 5 % of total bone carbon. The carbonate content of bioapatite is about 0.5–1.0 % by weight. The crystal morphology varies within and between bones and teeth and also changes during life, after death, and during burial.

The earliest bone radiocarbon measurements were carried out on total bone carbon and thus included mineral carbon. The variability of such bone dates compared to associated charcoal made it clear that groundwater infiltration during burial could deposit secondary calcite, contaminate the mineral fraction, and thus alter the radiocarbon date. Haynes (1968) demonstrated that acetic acid was capable of removing secondary calcite, and this treatment was adopted within protocols designed to extract stable isotope information from bone and tooth mineral (Koch et al. 1997). In spite of this advance and subsequent attempts to refine it (Haas and Banewicz 1980), radiocarbon dates on mineral carbon persistently generate dates offset from associated charcoal or other organic material. These findings have limited the use of bone mineral in dating studies. Nevertheless Zazzo

and Saliège (2011) have recently called for renewed research on apatite dating because in some environments, typically hot and arid regions, apatite carbon is all that survives.

Calcined Bone Dating

When bone is burnt above approximately 650 °C, as can be encountered during cremation, its mineral structure is altered. The bone fragment, the organic fraction, is completely lost, and the color of the interior becomes pure white. The majority of the carbonate is lost, and apatite crystal size and degree of order (crystallinity) increase (Stiner et al. 1995). The bone becomes “calcined.” Calcined bone is initially very friable after burning but undergoes recrystallization, after which the bones become structurally stable and resistant to environmental carbonate exchange reactions.

Lanting et al. (2001) first demonstrated that the radiocarbon content of calcined bone generally matched the radiocarbon content of associated organic material and concluded that traces of carbonate carbon survived the high-temperature decomposition. Subsequently, calcined bones were shown to give identical radiocarbon dates to stratigraphically related organic material in a variety of burial circumstances (DeMulder et al. 2007; Starkovich et al. 2013). The question of why this is the case motivated considerable research (e.g., Van Strydonck et al. 2005). Subsequently, Van Strydonck et al. (2010) and Hüls et al. (2010) demonstrated that at least some of the carbon within calcined bone originates from the fuel used during cremation. This opened up the possibility that radiocarbon dates on calcined bones might be altered if old wood was utilized during cremation. Evidence of this effect can be seen in Olsen et al. (2008) in which cremated remains were older than associated dendrochronologically dated wood.

Summary and Conclusions

Skeletal remains contain two carbon pools, an organic phase that is primarily collagen protein and an inorganic mineral phase containing calcium carbonate. The organic phase, primarily collagen, is the preferred target for radiocarbon dating because it does not readily incorporate carbon from the burial environment, whereas secondary carbonates from the burial environment readily precipitate within the mineral phase. Diagenesis, the physical and chemical reactions that alter skeletal remains during burial and decay, differs according to the particular chemistry of the burial environment. Thus, the preservation state of a particular bone is difficult to predict. A variety of purification protocols have been developed to isolate collagen protein or subcomponents of it.

Although historically skeletal remains were considered a riskier material for radiocarbon dating than cellulosic materials, their inherent complexity translates into increased information content. Advances in understanding how dateable components in archaeological bone and teeth survive, and how they can be extracted, have made them important materials for radiocarbon dating.

Big Bang

Gary R. Huss*

Hawai'i Institute of Geophysics and Planetology, University of Hawai'i at Mānoa, Honolulu, HI, USA

The most widely accepted model for how the universe came to be is the Big Bang model. According to this model, the universe expanded from an extremely hot, dense state of essentially zero size (a singularity). From this state, the universe expanded rapidly and cooled. As the temperature dropped, energy was converted to subatomic particles, which then formed protons, neutrons, and electrons. Simple atomic nuclei formed at ~3 min after the Big Bang, but it took ~379,000 years for neutral atoms to form. Over the next billion years, slightly denser regions of the nearly uniformly distributed matter gravitationally attracted nearby matter and began to form clouds, stars, galaxies, and other structures we observe today.

The Big Bang theory is based on three lines of evidence. The first is Edwin Hubble's observation that the farther away a galaxy is, the more redshifted its light is. The spectrum of a light source moving away from us at high speed is shifted to longer wavelengths (toward the red), while that of an object moving toward us will be shifted to shorter wavelengths (toward the blue). Distance can be reliably determined from Type 1a supernovae, which occur in binary star systems where a white dwarf accretes matter from its companion until it reaches the Chandrasekhar limit of 1.4 solar masses. The star is completely disrupted in a thermonuclear runaway that makes a supernova as bright as an entire galaxy. Because the precursor stars of Type 1a supernovae have similar mass, the brightness is always about the same, providing a "standard candle" against which the observed brightness can be calibrated to give distance. The general observation is that galaxies are receding from us in all directions, with those farther away receding more rapidly, much as the points on the surface of a balloon all become farther apart as the balloon is inflated.

The second line of evidence for the Big Bang is the cosmic microwave background that permeates the universe. The microwave background was discovered by accident in 1964 by Arno Penzias and Robert Wilson, who were conducting diagnostic observations at Bell Laboratories using a new microwave receiver. During the initial stages of the Big Bang, all of the particles and photons in the universe were in thermal equilibrium. Atoms and electrons were unbound and photons were continuously scattered by the electrons. Under these conditions, electromagnetic radiation had a black-body spectrum. When the temperature of the universe fell sufficiently, electrons and protons began to combine to form atoms. The scattering of photons ceased and photons could travel unimpeded. As the universe expanded, the spectrum of photons was redshifted. Today, this primordial radiation falls into the microwave region of the electromagnetic spectrum and corresponds to a temperature of ~3 K.

The third line of evidence for the Big Bang is the relative abundances of H and He. The Big Bang model makes specific predictions about how much H and He (and Li, Be, and B) should have been produced as the temperature dropped during expansion. The observed abundances of H and He in the universe match the predictions very well.

*Email: ghuss@higp.hawaii.edu

The age of the universe can be estimated from the expansion rate of the universe estimated from the rate at which galaxies are receding from one another and from the temperature of the microwave background. Models of the evolution of the universe from the Big Bang until today have become very sophisticated, giving an age of the universe of about 13.8 billion years.

Lichenometry

William B. Bull*

Department of Geosciences, University of Arizona, Tucson, AZ, USA

Definition

Lichenometry dates when a young rock surface was created by measuring the sizes of lichens whose growth rate is known.

Introduction

Lichens are an ancient type of symbiotic growth where algae create food for fungi, that provide shelter for the algae. Their great variety includes delicate foliose lichens growing on trees and rocks. Lichenometry uses only the crustose types (Figs. 1 and 2) that can adhere tightly to rock substrates for a 1,000 years. Figure 2 shows the type of block for dating a block. It has a range of thallus sizes, but only the largest lichen is measured, the assumption being that it most closely approximates the rockfall arrival time.

Recent geomorphic events are dated using the sizes of crustose lichens growing on blocks. Times of landslides, advance and retreat of glaciers, earthquakes, floods, climate change, fires, slush avalanches, and human construction disturbance can all be dated with lichens.

This chapter summarizes the considerable promise of using lichens for accurate, precise dating. First is how to select a field study site and calibrate rates of lichen growth. Then the emphasis is on precision, and diversity, of dating when many measurements allow definition of peaks in a lichen-size distribution.

Lichenometry started in the 1950s (Beschel 1950, 1957, 1959) to study glaciation – at the same time that radiocarbon dating began. But now lichenometry has been virtually abandoned in favor of geochemical methods such as radiocarbon dating of organic matter, optically stimulated luminescence of quartz and feldspar, and cosmogenic radionuclide dating of quartz crystals. The traditional lichenometry method (Innes 1985; Locke et al. 1979) uses only the five largest lichens on moraines left by a retreating glacier. The histogram lichen-size peaks used here are measures of central tendency, not statistical outliers. My New Zealand-California-Sweden database contains ~80,000 lichen-size measurements.

Detailed annual measurements of the entire circumference of lichens by botanists describe highly erratic growth of crustose lichens on rock surfaces (Bradwell 2010; Matthews and Trenbirth 2011). No outward growth may occur for several years, or only one side of a thallus grows. Some presume that dating with lichens is truly hopeless (Loso and Doak 2006). But the circular shape of large crustose lichens is indicative of uniform outward growth over the long term. I avoid erratic growth tendencies by using digital calipers to measure maximum lichen growth. This is the longest axis of the largest lichen on many rock surfaces of interest, such as each 0.5–2 m rockfall block on

hillside talus or a sequence of adjacent 4 m² areas of beveled rock surface exposed by recent retreat of a glacier.

Calibration of Lichen Growth Rate

Initial calibration of lichen growth rate in California was done in AD 1994 in Yosemite National Park. The long axis of the largest lichen was measured on blocks exposed by construction of a trail to Nevada Falls in AD 1940 and on a AD 1908 landslide that fell off a granitic dome named Liberty Cap. Blocks for an AD 1872 coseismic landslide were identified by cross-dating annual growth rings of adjacent damaged trees. These three calibration points in Fig. 3 span only 68 years, not sufficient for dating old events.

Fig. 2 This 1.8 m long block has many nice *Acarospora chlorophana*. South Fork Kings River, Sierra Nevada, California. The lichen on the right side seems to be the largest; its thallus has acceptable quality for measurement. The handle on the small day pack is 11 cm wide

Fig. 3 Calibration of *Rhizocarpon* subgenus *Rhizocarpon* growth rate in Yosemite National Park, California

A prehistoric rock avalanche called “The Slide” (Huber et al. 2002) stopped abruptly in a forest of alpine hemlock trees. Tree-ring analysis dated landslide damage to the forest as occurring between the end of the growing season in September AD 1739 and before the start of renewed growth in June AD 1740. This fourth point in the calibration Figure 3 falls on the same line as the other three points, nicely defining a long-term linear style of lichen growth. Regression of mean lichen size in millimeters, D , and calendric years, t , describes uniform *Rhizocarpon* subgenus *Rhizocarpon* growth as

$$D = 189.43 - 0.095t \quad (1)$$

Uniform-phase growth is a constant 9.5 mm per century. Lichens growing on substrates exposed in the year AD 1 would have a mean size of 189 mm in AD 1994. Calibration of three other lichen species allowed dating of geomorphic processes in diverse climatic settings. Subsequent addition of five new calibration points has not changed Eq. (1).

Site Selection

Site selection determines what lichenometry will date. Markedly different geomorphic processes occur in different parts of the Fig. 4 hillslope. The flume-like features on the left side of the view are debris-flow channels. They have created debris cones with the passage of time. Lichens on debris-flow levee boulders could be used to date individual events and assess frequency of storms capable of creating such events.

Such processes do not occur on the small patches of talus in the lower-right part of the Fig. 4 view. Most of these blocks are detached from their source outcrops by earthquakes. Not much happens between times of seismic shaking, other than freeze-thaw cycles. There are no trees to be uprooted by windstorms, and water flowing off the outcrops just infiltrates into highly porous talus.

The site-evaluation routine for either site is as follows. Hike up the hill to see which calibrated lichens are present: *Acarospora chlorophana*, *Lecanora sierrae*, *Lecidea atrobrunnea*, and *Rhizocarpon* subgenus *Rhizocarpon*. After finding the largest lichen on a block, assess if its thallus quality meets our standards. How smooth and complete are the thallus edges at where we will measure each optimal lichen size to 0.01 mm with digital calipers? Quality ratings of 1 through 4 are assigned to every measurement. Evaluate both transported blocks and the source outcrop joint surfaces from which blocks were derived.

Fig. 4 Diverse granitic mountainside along Lone Pine Creek, Sierra Nevada, California. Debris flows at *left*; rockfall block talus at *right*. Two-lane dirt road in lower left for scale (Image courtesy of Goggle Earth)

We seek a dataset of several hundred measurements; less than 200 is fine if the size range is only 10–50 mm. The Fig. 2 view of *Acarospora chlorophana* is the type of block we prefer. It has a range of thallus sizes; much better than having only one lichen to measure. Very nice, but in this case reconnaissance up the talus slope revealed few blocks with no usable lichens.

Much time is spent finding sites that have many lichens of suitable quality. Surprisingly, some California talus slopes may be completely barren – lichens! Only first-generation crustose lichens growing on fairly smooth rock surfaces should be measured. Rough surfaces, such as coarsely crystalline rocks, provide sizes that are smaller than the same age lichens on ideal substrates such as smooth quartzite joint planes. The finite lifespan of a lichen may be less than the age of the ancient substrate it is growing on. Second- or third-generation lichen growth never dates the exposure time of when blocks were deposited and colonization by lichens was first initiated. These older surfaces typically have a confusing array of small to large lichens that have grown together.

Precise, Accurate Lichenometry Dating

Historical earthquake rockfalls can be used to test the lichenometry method as proposed by Bull and Brandon (1998). The Strawberry Peak site yields typical results (Fig. 5). A first impression may suggest noise instead of actual rockfall events. It looks like too many closely spaced, narrow peaks in the 15–30 mm size range. We need to compare the dates implied by these lichen-size peaks with dates of historical earthquakes (Table 1).

Each peak nicely records the time of a historical earthquakes; so Fig. 5 data noise is minimal. These were large earthquakes – Mw magnitude >6.8. The AD 1857 Fort Tejon event was Mw 7.9 and is recorded by the dominant 29 mm lichen-size peak. It is southern California's largest earthquake. Its epicenter was fairly distant, but ~9 m of right-lateral slip occurred along much of the 350 km long surface rupture that passed only 30 km to the north of Strawberry Peak (http://www.sjvgeology.org/geology/tejon_earthquake.html).

Fig. 5 Distribution of lichen sizes measured in 2013 on rockfall blocks northwest of Strawberry Peak cliffs, central San Gabriel Mountains, Southern California. 0.5 mm class interval. Latitude is 34.28687°N. Longitude is -118.12007°W. Altitude is 1,560 m

The lack of noise in the Fig. 5 distribution of lichen sizes and low earthquake dating error in Table 1 underscore how few nonseismic rockfalls are included in this lichen-size dataset. Careful site selection was essential in order to avoid dating several geomorphic processes.

The broader 37 mm peak records the two big earthquakes of December 1812. The Wrightwood event was on the plate-bounding San Andreas fault to the east, and the Santa Barbara earthquake to the west occurred offshore. Both had strong foreshocks and aftershocks.

The AD 1882 date for the 24.75 mm lichen-size peak does not match the time of a known earthquake. This peak occurs at many sites; being regional implies a seismic-shaking origin. Historic earthquake records can be incomplete in both New Zealand and California (Bull 2007).

Table 1 Accuracy of dating historical California earthquakes using the lichen-size peaks of Fig. 5

Earthquake name (s)	Date, AD	Distance to epicenter	Lichen-size peak, mm	Peak Date AD	Dating error, years
Wrightwood, Santa Barbara	1812.9	40 160	37.75	1813.3	0.4
Fort Tejon	1857.0	170	29.25	1858.2	1.2
Hayward, San Francisco	1866.8	540	27.75	1866.1	0.7
Lone Pine	1872.9	250	26.75	1871.9	1.0
			24.75	1882.0	
Laguna Salada	1891.3	370	23.00	1892.1	0.8
San Jacinto	1900.0	170	21.00	1901.9	1.9
San Francisco	1906.3	550	19.75	1908.5	2.2
Imperial Valley	1915.5	270	18.25	1916.4	0.9
Long Beach	1933.2	60	15.75	1929.7	3.5

Dating Method	~1715 AD event	~1615 AD event	~1580 AD event
Lichenometry	1716 AD ± 2.80 n=10	1613 AD ± 1.78 n=9	1579 AD ± 2.08 n=8
Tree-ring analyses	1716 AD ± 2.78 n=12	1615 AD ± 2.58 n=9	1578 AD ± 3.12 n=9

Fig. 6 Comparison of dendrochronology and lichenometry dating of prehistoric earthquakes on the Alpine fault, New Zealand. From Bull 2007, p. 234. n is the number dates for an event

Even a Mw magnitude 7.5 San Andreas fault event was missed until recognized recently by Toppozada and Borchardt (1998).

Four event epicenters (Table 1) were at least 250 km away. Recording the strong San Francisco earthquake of 1906 is not surprising. That event was felt even farther away, 150 km to the east according to Ellsworth (1990).

A mean lichenometry dating error of about 2 years is the same accuracy as for other studies in New Zealand, California, and Sweden (Bull et al. 1995; Bull 1996a, b, 2003). Bull-Brandon lichenometry dating has a conservative ± 5 -year estimate of dating precision. Such consistent quality can only be cross-checked by still better dating methods – dendrochronology and historical records. Calibration site ages should be known to the year.

New Zealand tree-ring analyses and lichenometry precisely dated three prehistorical earthquakes. Trees were killed, and marked suppressions of annual growth rings occur in New Zealand cedar (*Libocedrus bidwillii*) at the seismically sensitive sites. One is a boggy swamp and the other is a cliffy ridgecrest directly above the 45° dipping plate-bounding Alpine fault. The times of these forest disturbance events were synchronous (± 2 years at the 95 % confidence level) with times of regional rockfall events dated by lichenometry using *Rhizocarpon* subgenus *Rhizocarpon* (Fig. 6).

Lichen-Kill Events

Univariate scattergrams detect lichen-kill events caused by climate change or fire. A scattergram shows the sequence of lichen-size measurements made while slowly traversing across a bouldery deposit. Uniformly dispersed talus accumulating during frequent events has a scattergram with constant density of measurements and range of lichen sizes across the entire traverse. There is a systematic decrease in density abundance for the largest lichen sizes. This decrease is attributed to the removal of old lichens by death or burial by incoming younger blocks. In contrast, a snowkill or firekill event is revealed by a scattergram that has an abrupt decrease in density with increasing lichen size. A transition to markedly lower density marks the approximate time of the lichen-kill event.

Dating a Fire Event

A New Zealand talus site called Cattle Gully highlights a firekill event. The scattergram (Fig. 7) shows two density domains; the transition at 47 mm dates to about AD 1700. Dating precision is lower for scattergrams than for the Fig. 5 histogram. Pieces of charred, rot-resistant *totara* wood on

Fig. 7 Univariate scattergram of *Rhizocarpon* subgenus *Rhizocarpon* size measurements at the Cattle Gully site, South Island of New Zealand, reveals two lichen-size measurement domains. Measurement densities are different above and below the 47 mm line; the time of a firekill event that killed most lichens; $n = 1,388$. Bull and Brandon 1998, Fig 12C

the Cattle Gully hillslopes suggest that fire may have killed many lichens, perhaps as newly arrived Maoris used fires for clearing travel routes and flushing game (McGlone 1979).

Dating Climate Change

Times of colder climate in the high Sierra Nevada of California occurred during a recent cooler global climate known as the Little Ice Age. Valley glaciers became larger and many snowfields became permanent, killing lichens after ~3 years of burial. Lichens would recolonize these surfaces as snowbanks melted.

A lichenometry transect across the Chickenfoot glacial moraine of latest Pleistocene age records two of the Sierra Nevada snowkill events of the past 1,000 years (Fig. 8). These data show largest lichen maximum diameters on consecutive blocks. A 200 mm *Lecidea atrobrunnea* would date back to about AD 1070, well before the onset of the Little Ice Age.

The density distribution of the first 200 lichen-size measurements is similar to a height of 150 mm. Few lichens were found above this size. Establishment of a perennial snowbank would kill all lichens except those on blocks that rose above the snow. It appears that the Little Ice Age began here shortly before 150 mm time. A pulse of persistent snow cover ended and recolonization began at about AD 1290. The even distribution of lichen sizes below the 150 mm horizontal line indicates that this part of the measurement transect was not subject to further snowkills.

An article by Miller et al. 2012 about causes of the Little Ice Age postulates that cooling was caused by episodes of SO₂-rich volcanic eruptions that also affected oceanic circulation. When did it begin? End? “summer cold and ice growth began abruptly between AD 1275 and AD 1300.” The Miller et al. data suggest that the Little Ice Age ended by AD 1850.

The next 220 lichen-size measurements along the Fig. 8 transect are much smaller; none are larger than 76 mm and most are smaller than 20 mm. A second snowkill event ended at 20 mm time

Fig. 8 Univariate scattergram of *Lecidea atrobrunnea* at the Chickenfoot moraine lichenometry site, altitude of 3,540 m, in the Sierra Nevada of California. Two domains of anomalous decrease in density of lichen sizes that suggest times when snowkill events ended. $n = 481$. Bull and Brandon 1998, Fig 12B

(AD 1853 $\pm$ 10 years). The many lichen sizes between 5 and 20 mm suggest that renewed additional colonization did not occur on all blocks at the same time. The thickest, more persistent snow took longer to melt. Other Sierra Nevada sites with different topographic settings might reveal times of multiyear snowfields between AD 1290 and AD 1850.

Discussion

The crustose lichens used in these studies seem to have a preferred geographic distribution and abundance. Most are found in cooler latitudes, or above 1,000 m altitude in mid-latitude and low latitude mountains. This may restrict areas where lichenometry can be used. Fortunately, rocky mountain ranges are common. Detailed information about how landscapes evolve is a major virtue of lichenometry, but only for the past 1,000 years for most studies. Precise surface-exposure dating of fluvial, glacial, and mass-movement landforms can be used to address landscape change rates and the frequency of geomorphic hazards to humans. Landslides, floods, and seismic shaking can be deadly.

Reconnaissance and measurement field time are the main costs. Fieldwork is a mix of working at sites of known age to calibrate and further test rates of lichen growth for several species of a genus, and collecting longest-axis lichen size data at other sites to better understand the history and extent of a geomorphic process. After calibration of a lichen growth rate is complete, the cost per lichenometry age determination is quite low, and one does not have to wait months or years for expensive laboratory work to be completed. The more expensive aspect of lichenometry is the field time spent in finding good sites and collecting representative samples of lichen sizes.

Botanists wonder why geologists assume that crustose lichens grow in a predictable manner that can be defined with an equation, when their year-to-year measurements suggest nonsensical confusion. Geologists would like botanists to tell them why each crustose lichen does not vary in

growth rate throughout the varied climate of a lofty 600 km long mountain range such as the Southern Alps or the Sierra Nevada.

The lichenometry method of dating summarized here is precise and accurate. Lichenometry is a surface-exposure type of age determination, so it dates the actual time of an event. The vastly more popular radiocarbon dating method estimates the time of formation of organic matter created before or after the event of interest, such as rupture of layered sedimentary deposits.

Suggested Innovative Studies

Human-induced global warming has reached the point where record high temperatures greatly outnumber record lows and storms seem ever more powerful and prolonged. Lichenometry can be used to assess recent retreat of glacial ice that leaves behind moraines of lichen-covered rocks. How much deglaciation is the result of natural climate variation? Does acceleration of montane glacier retreat in places such as the Andes, Himalayas, and Europe match the trend of an ever-increasing carbon dioxide in the Earth's atmosphere? What is the pace of retreat of the Greenland ice cap? Have any recent lichen snowkill events occurred, indicative of climate variability? Arctic lakes have diminished and some are now gone (Smol and Douglas 2007). We should date ages and rates of retreat of now-exposed rocky shorelines, comparing small ponds with large lakes. The timespan for these studies should start before the industrial revolution at ~ AD 1750–1800.

Southern California earthquake studies have focused on radiocarbon dating of surface ruptures by the plate-bounding San Andreas fault (Biasi and Weldon 2009). We know little about other prehistoric earthquakes that occurred between the San Andreas fault events of AD 1812 and AD 1680. How frequently did strong regional seismic shaking occur in Southern California during recent prehistoric times? Seismic shaking decreases with distance away from an earthquake epicenter. So, mapping the decrease in coseismic rockfall abundance should be a useful proxy for seismic shaking. Lichenometry suggests that 13 strong regional seismic-shaking events occurred between AD 1680 and AD 1812. Four are recorded by the 41, 44, 48, and 50 mm lichen-size peaks of Fig. 5 of this article. How did the intensity of seismic shaking for these recent prehistoric events compare with the San Andreas fault events of 1680, 1812, and 1857? Lichen-size data from sites in three mountain ranges could be used to make maps depicting regional seismic shaking to compare with maps for seismic shaking caused by the 1812 and 1857 earthquakes.

Meteoritic ^{10}Be

Jane Willenbring*

Department of Earth and Environmental Sciences, University of Pennsylvania, Philadelphia, PA, USA

Synonyms

Atmospheric ^{10}Be ; Fallout ^{10}Be ; Garden-variety ^{10}Be

Definition

Most terrestrial beryllium-10 (^{10}Be) is produced by spallation of nitrogen and oxygen nuclei in the atmosphere by cosmic rays. The relatively high atmospheric production rate of ^{10}Be (global mean of $\sim 10^6$ atoms $\text{cm}^{-2} \text{year}^{-1}$) varies regionally by latitude by a factor of ~ 2 (Lal and Peters 1967). Meteoric ^{10}Be is scavenged quickly from the atmosphere by aerosols and is transported to the Earth's surface, mostly by precipitation. When ^{10}Be falls onto land, it binds tightly to soil particles. Stable soil with prolonged exposure to rain becomes highly enriched in ^{10}Be , whereas soil in areas of high erosion accumulates little ^{10}Be . When ^{10}Be falls on water, it eventually accumulates on sediments or in precipitates. Movement and cycling of ^{10}Be in the Earth's reservoirs has been reviewed in detail by Morris et al. (2002) and Willenbring and von Blanckenburg (2010).

In recent years, ^{10}Be has been measured most widely in continental ice cores to determine snow accumulation rates and for comparison with cosmogenically produced radiocarbon to determine variations in solar activity through time. Meteoric ^{10}Be is used for a growing number of geomorphic studies including discriminating river sediment sources, understanding soil transport, and quantifying long-term sediment fluxes from watersheds. Beryllium-10 is radioactive with a half-life of 1.39 million years and is often used in conjunction with the native, stable nuclide beryllium-9 (^9Be) to account for variable absorption behavior. The $^{10}\text{Be}/^9\text{Be}$ ratio is used in deep-sea sediments for estimating ages via ^{10}Be decay, for calculating the growth rates of manganese encrustations, and for understanding the past variability in the Earth's magnetic field and chemical weathering fluxes.

Most natural concentrations of ^{10}Be range from $\sim 10^3$ atoms g^{-1} in rain and ice to $\sim 10^6$ – 10^8 atoms g^{-1} in marine and terrestrial sediments. These levels are now easily measured by accelerator mass spectrometry after a chemical process to purify the Be from other elements and boron – an isobar and the daughter product of ^{10}Be decay (Granger et al. 2013). Well-known geochronologic techniques using cosmogenic ^{10}Be called surface exposure dating typically uses the abundance of ^{10}Be produced in situ within crystal lattices of minerals rather than the abundance of meteoric ^{10}Be . The larger flux of meteoric ^{10}Be (on a per-surface-area basis) that is about two to four orders of magnitude greater than the rate of in situ production complicates the chemical purification of the in situ produced component by contamination of grain surfaces. Etching is specifically carried out to remove every trace of atmospheric ^{10}Be adhered to surfaces of grains.

Definition

Any of a number of methods used to determine the spectrum of isotopic abundances in a given material based on the measurement of relative masses of atoms or molecules present in that material. As applied to scientific dating, mass spectrometry is most commonly used to determine abundances of parent and progeny isotopes in naturally radioactive decay systems that have half-lives of geological relevance (years to billions of years).

Introduction

Scientific methods for dating materials of geological interest commonly utilize natural radioactive isotopes that spontaneously transform to progeny isotopes at constant and well-known rates of decay. In order to use this property to estimate absolute ages, it is essential to accurately determine the abundances of both parent and progeny isotopes in a mineral or rock sample that has remained closed to isotopic exchange with its surroundings since its formation. Decay counting can be used to quantify abundances of short-lived radioactive isotopes. However, for radioactive isotopes with half-lives longer than a few thousand to tens of thousands of years, only a small number of atoms undergo radioactive decay during the counting period resulting in poor precision of isotope abundances. Furthermore, a number of geochronometers rely on stable, albeit radiogenic, progeny which cannot be measured by decay counting. Therefore, isotope ratios are more commonly determined by mass spectrometry where potentially all of the atoms present in the sample can be counted. Geochronological methods using K-Ar, Rb-Sr, Sm-Nd, Lu-Hf, Re-Os, U-Pb, and U-Th decay schemes take advantage of atom counting by mass spectrometry to provide precise measurements of relative isotope abundance. Other methods for measuring mass ratios exist; however, this entry focuses on mass spectrometric methods that are most commonly employed in geochronological studies.

Determination of isotope ratios by mass spectrometry involves (1) introduction of the sample into the mass spectrometer either as a gas, liquid, or solid and ionization of the element or elements of interest, (2) separation of ions on the basis of their mass-to-charge ratios, and (3) detection of those ions by measuring currents for large signals or by ion counting for smaller ones. Methods by which material is introduced and ionized allow mass spectrometers to be classified into different types, each of which has strengths and weaknesses. However, all methods take advantage of the physical response of moving charged particles through a strong electromagnetic field and conversion of the beam of separated ions into an electronic signal that is directly proportional to the number of atoms

*Email: jbpaces@usgs.gov

detected. Output takes the form of a mass spectrum of peak intensities that are indicative of the relative abundances of isotopes present in the sample, which can then be interpreted to represent age information through application of various decay schemes and dating models. More detailed explanations of the general principles and various methods of mass spectrometry are readily available (Faure 1986; Dickin 2005; Goldstein and Stirling 2003; Faure and Mensing 2005; Gross 2011; Ireland 2013; White 2013).

History

The initial development of mass spectrometry closely followed the discovery of radioactivity in the middle to late 1890s. The first demonstration that isotopes could be separated on the basis of their masses came in 1913 when J.J. Thomson constructed a spectrometer at the University of Cambridge Cavendish Laboratory that used a photographic emulsion to show that neon gas produced two spectral lines of differing intensities representing ^{20}Ne (90.48 %) and ^{22}Ne (9.25 %). Modifications of the original design made shortly thereafter by A.J. Dempster at the University of Chicago in 1918 and F.W. Aston at the Cavendish Laboratory in 1919 included addition of 180° sector magnetic fields enabling directional refocusing, separate thermal ionization filaments to produce and accelerate ions, source and exit slits to better refine the ion beam, and a separate electric field to remove the velocity spread and yield point images (Fig. 1a). Even though early instruments had low-mass resolution and sensitivity, they were capable of identifying all of the naturally occurring isotopes of the light elements as well as their relative abundances.

Fig. 1 Historical mass spectrometer designs. **(a)** Cross-sectional schematic of Dempster's first thermal ionization instrument which included an analyzer chamber *A*, constructed from a brass tube fitted with iron plates *B*, an entrance slit *S1*, exit slit *S2*, and defining aperture *D*. The source consisted of an electron-emitting filament *F* and a heating element *H*. Ion currents were detected by the electrometer fitted in an ebonite plug, *E* (Figure modified after Dempster 1918). **(b)** Cross-sectional schematic of Nier's 1940 thermal ionization mass spectrometer consisting of widely separated source and collector whose slits *S2* and *S3*, respectively, are collinear with the center of curvature of the flight tube (Modified after Fig. 2 of Nier 1940). The flight tube passed through a 60° magnetic sector analyzer and had a length of 58 cm between *S2* and *S3*. The basic design has remained similar after more than 70 years of improvements

Fig. 2 Diagram depicting the Lorentz force law operating in magnetic sector mass analyzers. **(a)** Oblique schematic view of the magnetic pole pieces designed to provide a uniform magnetic field B . The resulting force (F) operates at right angles to both the ion velocity vector (v) and the magnetic field vector (B) at any point along the flight path. **(b)** Plan view showing the paths of ions of different masses (m) affected by the Lorentz force to different degrees. Ions with heavier masses ($m + 1$) follow less curved paths than ions with lighter masses ($m - 1$)

In 1940, Alfred Nier at the University of Minnesota revolutionized mass spectrometry by developing a design that utilized a 60° sector-field magnet and moved the ion source and ion collectors away from the influence of the electromagnet (Fig. 1b; Nier 1940; De Laeter and Kurz 2006). Nier also completely redesigned the ion source and introduced the electronic measurement of ion beams. These fundamental changes made production and operation of magnetic sector mass spectrometers more efficient and reliable and opened the field of isotope geosciences far beyond the initial scope imagined by earlier physicists. Many modern instruments still use Nier's designs.

Subsequent improvements in mass spectrometer performance are more related to incorporation of digital operation and control, refinement of various electronic and vacuum technologies, and innovation in sample introduction into the ion source. Improvements in instrumentation coupled with the use of clean-laboratory conditions to minimize contamination were stimulated by the lunar sample return missions in the late 1960s and early 1970s and the accompanying interest in understanding solar system evolution by studying meteorites with low elemental abundances for many of the geochronological systems. The development of the plasma source coupled to a multicollector magnetic sector system represented another major wave of improvements in the mid-1990s, allowing the measurement of isotopic ratios for nearly any element in the periodic table.

Principles of Mass Spectrometry

Mass spectrometers are designed to separate ions based on their mass-to-charge ratio. To do this, atoms or molecules of interest in a sample must become charged forming an ion cloud, extracted from that cloud by applying an acceleration voltage (typically 1–10 kV), and focused into a narrow beam using a series of source plates that constitute the ion optics of the instrument. Ions in the accelerated beam have kinetic energy that is equal to the electrostatic field produced in the source ($\frac{1}{2}mv^2 = qV_E/d$; where m = mass, v = velocity, q = charge, V_E = extraction voltage; and d = distance over which the acceleration takes place). The beam thus produced is introduced into a mass analyzer where dispersion takes place using magnetic fields (magnetic sector instruments), rapidly cycling electric fields (quadrupole instruments), or velocity selection (time-of-flight instruments).

Magnetic Sector Instruments

An ion with mass and charge traveling at velocity through a uniform magnetic field (B) will experience a centripetal force that imparts a circular motion. As a result the ion will follow a curved path having a radius (R) within a plane perpendicular to the magnetic field ($F = qvB = mv^2/R$). Magnetic sector mass spectrometers take advantage of this principle (Lorentz law) by using electromagnets specifically designed to produce a homogeneous field that is positioned at right angles to the path of the ion beam (Fig. 2). Ions traveling through the magnetic field will follow an arc with a radius proportional to its mass ($R = mv/qB$). As other factors are held constant, ions of different masses follow paths with different radii through the magnetic field, with heavier ions being deflected less than lighter ones.

To steer beams of lighter and heavier ions into the collector slit on a single-collector spectrometer, either the magnetic field or the velocity of the ions (via changes to V_E) can be varied to alter the radius of curvature via the Lorentz law. In practice, the magnetic field is more precisely monitored using a Hall probe that senses the field strength and adjusts the magnet power supply as necessary (Dickin 2005). In multicollector instruments, a number of faraday cups and ion counters are positioned to simultaneously measure multiple dispersed beams, thus avoiding temporal variability in the signal due to ion beam instabilities. Recent advances in magnet design feature poles set at oblique angles to the exiting beam in order to use fringing fields for better focusing. Because this design also increases the distance from the magnet to the ion focal point, it is referred to as “extended geometry.” This design allows increased ion transmission and greater dispersion, which, in turn, facilitates additional collectors. Ion transmission in magnetic sector instruments can be close to 100 %, whereas multiple-sector instruments commonly have lower transmission.

High-precision measurement of isotope ratios needed for geochronology requires that magnetic sector mass spectrometers maintain very high vacuum throughout the ion path in order to avoid reduced velocities or loss caused by inelastic collisions with ambient air molecules. Pressures within the flight tube (ion path between the source and collector) typically are between 10^{-9} and 10^{-8} mbar. High vacuum is maintained by continuous pumping using a combination of turbo pumps (momentum transfer pump that uses high-speed rotating blades to capture gas molecules) backed by positive displacement mechanical pumps, cryotrap (cold fingers), and ion getters (entrapment pump that uses electrical fields to ionize gas molecules that are then captured on a charged solid substrate).

Quadrupole Instruments

Although magnetic sector mass spectrometry is the most common method used for measurements of high-precision isotope ratios, dispersion of isotopes on the basis of mass-to-charge ratios also can be accomplished by applying electric fields to two pairs of metal electrodes forming a quadrupole mass analyzer (Miller and Denton 1986). Opposing pairs of rods are electrically connected, and a combination of fixed DC and alternating RF (radio frequency) potentials are applied such that two rods have oscillating positive and negative voltages. Ions are extracted from an inductively coupled Ar plasma source and introduced at one end of the quadrupole. Oscillations of charges on the electrodes cause complex ion trajectories where only ions with the proper mass-to-charge ratio for a given set of voltages can traverse the length of the quadrupole. All other ions will have unstable trajectories and be neutralized by collisions with the electrodes. Ions that enter the collector slit at the far end of the quadrupole are measured as described above.

Quadrupole mass spectrometers benefit from the ability to switch masses very quickly allowing collection of data from the entire periodic table during a single, rapid analysis. They require only modest vacuum conditions and are not as complex or costly as magnetic sector instruments. These

attributes allow quadrupole instruments to excel in determination of elemental concentrations in either solution mode or attached to a laser ablation system. However, quadrupole instruments are not as sensitive nor as stable as magnetic sector instruments and are typically operated at unit mass resolution, which typically restricts their use to low-resolution applications (Gross 2011). Therefore, they cannot produce the same level of high-precision, isotope-ratio data compared to magnetic sector instruments and are not widely used in geochronological studies.

Time-of-Flight Instruments

Time-of-flight (TOF) mass analysis relies on the fact that heavier ions are accelerated more slowly than lighter ions of the same charge in the same potential field. TOF instruments are designed to measure differences in arrival times of ions that are generated during a discrete event. In practice, a group of ions is typically generated using a pulsed laser shot, a pulsed beam of primary ions, or a pulse generator coupled with a plasma source. Mass separation is accomplished in the flight tube as ions in the pulse are separated into individual packets defined by mass number. Additional mass dispersion can be accomplished by extending the path length through incorporation of reflection geometries.

Time-of-flight analysis has been primarily used to produce elemental and molecular maps of solid surfaces as well as depth profiles in material-science applications. Benefits include a theoretically unrestricted mass limit, analysis of a complete mass range for a single ionization pulse, high ion transmission, and extremely small sample requirements ($<10^{-18}$ mol). However, time-of-flight analyses generally do not produce fully quantitative data and, as such, have not yet been used to produce geochronological information.

Double-Focusing Instruments

Production of ions in mass spectrometers using plasma sources or secondary ion sources results in ions with a range of kinetic energies as well as mass-to-charge ratios. Dispersal of ion energy results in poor mass resolution due to beam spread and increased tailing. In order to narrow the spread of ion energies and improve mass resolution, both an electrostatic analyzer (ESA) and a magnetic sector analyzer are used in series, resulting in a double-focusing mass spectrometer (Fig. 3). The ESA consists of a set of two concentric curved plates held at different potentials to filter and focus the ions traveling through them, regardless of their mass. The ESA may be placed before (forward geometry) or after (reverse geometry) the magnetic sector. The use of double-focusing designs is critical for

Fig. 3 Schematic depictions showing the ion beam paths (in blue) passing through two types of double-focusing mass spectrometers. Designs employ both magnetic sector analyzers for mass dispersion and electrostatic analyzers (ESA) to compensate for energy dispersion inherent in inductively coupled plasma and secondary ion sources. (a) Forward geometry where the magnetic sector precedes the ESA and (b) reverse geometry where the ESA precedes the magnetic sector (Modified after Fig. 3 of Ireland (2013))

obtaining the high-precision measurements required for geochronological studies when using plasma source instruments or ion microprobes; however, an ESA is not required for thermal ionization instruments (see descriptions of different mass spectrometers below).

Other types of tandem geometries have been employed, including double- or triple-focusing designs with multiple magnetic sectors (de Hoffman 1996). These designs result in increased abundance sensitivity and high selectivity but suffer from increased complexity, cost, and transmission losses.

Ion Detection

Two general types of detectors are commonly used to measure ion-beam intensity. For large beam currents up to 10^{-10} A, a deep, narrow faraday cup positioned behind the collector slit captures the incoming ions. The incident ions are neutralized by electrons from the ground that flow through a large resistor (10^{10} – 10^{12} Ω). The potential across the resistor is amplified and read by a digital voltmeter. Signals of several millivolts up to 50 V can be reliably measured using faraday cups.

At lower ion beam currents, electrical noise becomes a substantial component of the total signal present in the cups. In order to measure beam currents smaller than about 10^{-13} A, collectors that use signal multiplication are needed. The two types most commonly employed are Daly detectors and secondary electron multipliers (SEMs). A Daly detector consists of a polished metal “knob” placed under a large negative potential (Daly 1960). Incoming positively charged ions are attracted to the knob and, upon impact, release a shower of secondary electrons. These electrons are accelerated toward a nearby positively charged phosphor screen where they generate light pulses that are amplified and measured by a sensitive photomultiplier. SEMs consist of either discrete-dynode or continuous-dynode (channeltron) designs that rely on secondary electron emission after initial collision of an ion on the dynode surface (Allen 1947; Poenisch 1976). Release of additional electrons causes a cascade effect, multiplying the initial collision by gain factors of 10^4 – 10^8 (Gross 2011). Electrical output for Daly and SEM detectors is typically given in counts per second that must be calibrated (at least at the upper end of the range) against voltages produced for the same beam on a faraday cup.

Charge-coupled device (CCD) detectors, a relatively new type of silicon-based electronic device capable of detecting multichannel arrays of electromagnetic radiation, are capable of measuring impinging ion currents and have been used as detectors on miniaturized spectrometers (Sinha et al. 2011). However, these detectors have not yet been incorporated into instruments used for high-precision geochronological work.

Data Collection

Data collection in modern computer-controlled mass spectrometers involves measurement of multiple scan cycles in order to attain high-precision results. Single-collector instruments require magnet cycling from low to high-mass, counting intensities at each mass (and background positions) before returning to the low-mass peak to repeat the cycle. This form of analysis is referred to as dynamic peak-jumping mode and requires stable ion beam intensities to achieve precise isotope ratios. Multicollector instruments running in static mode do not require changes in magnet current and can therefore tolerate short-term beam instability because ion beams for all masses of interest are measured simultaneously. Static multicollection methods still gather data in separate blocks that allow statistical treatment and correction for instrument drift and beam growth or decay. However, static multicollection requires that corrections for electronic biases between detectors and amplifiers must be made by running collector gain calibrations with some frequency. Alternatively, high-precision measurements can be made on multicollector instruments using a multi-dynamic analysis

Table 1 Distribution of masses steered to different collectors that have been positioned at single atomic mass unit spacing for three types of data collection (dynamic peak jumping, static multicollection, and multi-dynamic triple jumping) for Sr-isotopic compositions (^{84}Sr , ^{86}Sr , ^{87}Sr , and ^{88}Sr) while monitoring ^{85}Rb to correct mass 87 for ^{87}Rb

Analysis type	Magnet jump	Collector number						
		Lo-3	Lo-2	Lo-1	Axial	Hi-1	Hi-2	Hi-3
Dynamic peak jumping	1	–	–	–	84	–	–	–
	2	–	–	–	85	–	–	–
	3	–	–	–	86	–	–	–
	4	–	–	–	87	–	–	–
	5	–	–	–	88	–	–	–
Static multicollection	1	–	–	84	85	86	87	88
Multi-dynamic triple jumping	1	–	–	84	85	86	87	88
	2	–	84	85	86	87	88	–
	3	84	85	86	87	88	–	–

that involves double or triple magnet jumps that measure the same isotope ratios in sequential sets of collectors. This method is capable of canceling out beam growth or decay, correcting for collector/amplifier bias, and applying a power law mass fractionation correction. An example of these three types of data collection schemes intended to determine the isotopic composition of Sr is shown in Table 1. Total length of analysis time depends on signal intensity and desired precision but can take from a few minutes to several hours for the highest-precision results. A variety of other corrections are necessary to produce the most precise and accurate data including baseline subtraction, detector linearity, and isobaric interference.

Mass Resolution

One of the main performance considerations in mass spectrometry is the ability of an instrument to distinguish two peaks having different mass-to-charge ratios. This is easier for lower-mass elements where differences in isotope masses are large relative to total mass, but becomes increasingly difficult for high-mass elements or for different species having similar masses (for instance, ^{29}Si vs. $^{28}\text{Si}^1\text{H}$ or ^{87}Rb vs. ^{87}Sr). Mass resolution is specified as the overall mass under consideration divided by the difference between masses being considered ($m/\Delta m$). For instance, a mass spectrometer needs a mass resolution of only 87 to resolve ^{86}Sr from ^{87}Sr ($87/[86.9089-85.9083]$) but a value of about 3,500 to resolve ^{29}Si from $^{28}\text{Si}^1\text{H}$ ($29/[28.9765-28.9848]$) and more than 200,000 to resolve ^{87}Rb from ^{87}Sr ($87/[86.9092-86.9089]$). Modern magnetic sector mass spectrometers have mass resolutions ranging from 300 to more than 5,000.

Mass resolution can be determined by noting the Δm for the closest spacing of two, equal-intensity peaks separated by a minimum signal less than a specified fraction of peak height (typically 10 % or 50 %). A more common and easily measured determination of mass resolution uses the width of a peak (in Δm) measured at a stated fraction of the peak height (commonly at 1 %, 10 %, or 50 %, the latter of which yields full width at half maximum, or FWHM; Fig. 4). Ideally, peaks obtained by scanning the ion beam across the collector slit will have flat tops and steeply sloping sides that allow minor mass drift without affecting ion beam intensity. Width at the base of the peak is approximately the sum of the widths of the source and collector slits, whereas the width of the peak flat is related to the ratio of the collector slit width to the ion beam width. A narrower collector slit will result in higher mass resolution, but will reduce the width of the peak flat. Reducing the

Fig. 4 Schematic depiction of an instrumental scan across an isotope of mass m , showing a trapezoidal-shaped peak with a flat top at a fractional intensity of 1 (*thick, gray line*). Peak width measured at 50 % of the peak height represents the collector slit width (c) and the width of the peak slope (s) represents the width of the demagnified source slit. Mass resolution at the 10 % peak height is given by $m/\Delta m$ (Modified after Fig. 6 of Ireland (2013))

width of the source slit will also result in higher mass resolution along with increased peak flat, but will cause a reduction of ion beam transmission. Therefore, mass resolution is often a compromise between the ability to effectively separate peaks with similar masses and the ability to acquire high-precision isotope data from those peaks.

A concept related to mass resolution is the amount that the tail of one peak may contribute to the signal of an adjacent peak. This measure is called abundance sensitivity and represents the ratio of the maximum ion current measured at a specified mass divided by the maximum ion current present for the same species measured at an adjacent mass. It is commonly measured at mass 237 (no natural isotope) while running a large ^{238}U signal. Tails arise from collision of ions in the flight tube with residual gas molecules resulting in a loss of energy and a shift toward the lower-mass side of the peak. Abundance sensitivity is therefore related to the quality of the vacuum in the instrument. Flight tube pressures in the low 10^{-9} mbar range commonly yield abundance sensitivities of ~ 0.000002 (2 ppm), although this can be improved by up to two orders of magnitude by addition of an energy filter in front of the collector or by designs incorporating multiple magnetic sectors.

Chemical Separations

In order to reduce the number of isobaric interferences and to improve precision and reproducibility of the measurements, samples used for geochronological purposes are commonly reduced to pure chemical forms using cryogenic separation for noble gases (Ar) or liquid chromatography after acid digestion for solids. Only the purified elements of interest are then introduced into the ion source of the mass spectrometer, reducing or eliminating interferences associated with complex matrices typical of geologic material. Consequently, mass resolution requirements are simplified to unit mass differences, and isobaric interferences from combinations of lower-mass molecules are dramatically reduced.

Chemical separations are usually performed under cleanroom conditions involving highly filtered airflow and the use highly refined reagents. Cleanroom conditions are designed to reduce the potential contaminants added during processing, which in turn results in reduced amounts of materials not present in the original sample (known as “blank”). Low chemical processing blanks allow more accurate analysis of substantially smaller-sized samples, which facilitates dating of rocks using isochrons derived from mineral separates, or when total sample size is very limited. Analysis of solid materials (rocks and minerals) requires quantitative digestion using high-purity

hydrofluoric, nitric, and hydrochloric acids. Complete dissolution of a known amount of sample allows the addition of a “spike” consisting of a solution containing a known amount of purified tracer isotope. Once the tracer is isotopically equilibrated with the sample, it can be used to monitor and correct for mass fractionation that occurs during the isotope analysis or for quantifying the concentration of the element of interest in an unknown through a procedure known as isotope dilution (Dickin 2005; Faure and Mensing 2005).

Mass Spectrometry Used for Dating

Principles described above are common to a variety of mass spectrometers used to collect isotope ratios for geochronological purposes. The following groupings are largely based on differences in how ions are produced. Comparisons between these mass spectrometric methods applied to radiogenic elements used for dating rocks and minerals can be found in a number of textbooks and review articles (Goldstein and Stirling 2003; Faure and Mensing 2005; Dickin 2005; Siebel and van den Haute 2007; Ireland 2013).

Thermal Ionization Mass Spectrometry

Thermal ionization mass spectrometry (TIMS) relies on thermal energy to produce ions from a sample placed on a thin ribbon (filament) of a highly purified refractory metal. Solid samples are prepared by acid digestion followed by chemical separation processes that are specific to the individual elements of interest. After separation, the resulting purified salt is loaded as a small drop of liquid onto a filament of rhenium, tantalum, or tungsten, either by itself or along with an activator such as Si-gel, Ta-oxide, or carbon suspension that helps stabilize or enhance ion emission. Depending on the ionization characteristics of a given element, samples can be loaded onto a single filament that produces both evaporation and ionization or on double- or triple-filament assemblies where separate filaments control evaporation and ionization. Loaded filaments are placed in the TIMS source, which is evacuated to pressures of $\sim 10^{-8}$ mbar, and then heated by passing a current of about 1–5 A. Heating under these conditions yields filament temperatures of 800–3,500 °C, which is sufficient to cause sample evaporation and at least partial ionization of a number of elements. Ions are extracted from the evaporation cloud in front of the filaments and accelerated through the source optics into the mass analyzer (Fig. 5a).

TIMS analyses of natural, nonvolatile radioactive isotope systems have been the historical standard in geochronology studies for more than 60 years. This includes dating systems such as U-Pb, Rb-Sr, Sm-Nd, and more recently Lu-Hf, Re-Os (in negative-ion mode), and U-Th disequilibrium studies. Advantages of TIMS analyses are in part derived from the careful chemical preparation which reduces mass-resolution requirements. The fact that different elements evaporate at different temperatures can also be used as an advantage for eliminating unwanted interferences to a certain extent (i.e., removal of ^{87}Rb at low temperature prior to analysis of ^{87}Sr at higher temperature) or for combined runs from the same filament (i.e., single-grain zircon or opal dating with no chemical separation where Pb data are collected at low temperature, U at intermediate temperature, and Th at high temperature). Thermal ionization also results in ions with a low energy spread allowing TIMS instruments to be relatively simple, relying only on single-focusing designs (magnetic sector). The main disadvantage of TIMS is that many elements have low to very low ionization efficiencies resulting in detection of only a small fraction of the total atoms present on the filament. Variations in matrix composition can also affect sample chemistry, resulting in poor ionization for impure separates. These shortcomings can be overcome by improving chemical

Fig. 5 Schematic diagram depicting designs of modern commercially available magnetic sector instruments consisting of a single-focusing solid-source thermal ionization mass spectrometer (**a**), and a double-focusing inductively coupled plasma mass spectrometer with forward geometry (**b**). Note that the two instruments are identical past the beam isolation valve (Diagrams courtesy of Thermo Fisher Scientific, Inc.)

separations and, in some cases, by adding an enhancer to the filament along with the sample load to increase the ionization efficiency without adding blank. TIMS analysis times are lengthy (several hours to obtain the highest-precision results), and total throughput can be low due to arduous chemical preparations.

Inductively Coupled Plasma Mass Spectrometry

Inductively coupled plasma–mass spectrometry (ICP–MS) uses a plasma source utilizing Ar as the plasma support gas (Fig. 6). A Fassel-type torch with automated radio-frequency matching allows the aerosol gas to punch a hole through the plasma. The Fassel torch uses relatively low gas flow and can be used for aqueous samples using either a peristaltic pump or Meinhard nebulizer, or, for “dry” samples from which most of the liquid has been removed, by desolvation using a microconcentric nebulizer. The nebulizer converts the solution into an aerosol that, while passing through the plasma source, is desolvated, dissociated, and ionized. The interface region of the instrument usually consists of two cones, separated by a very small distance that is being pumped by a rough pump. The whole interface region is made from material that dissipates heat easily such as copper or aluminum that is also cooled by circulating chilled water to reduce the effects of the high-temperature plasma (up to 8,000 °K) on the cones. The first cone, known as the sampler cone, typically has an orifice of 0.8–1.2 mm internal diameter, while the second cone, the skimmer cone, has a much smaller orifice (0.4–0.8 mm). The cones are usually made of Ni, although different materials, such as Pt, can be used depending on the element being ionized and the aggressiveness of the matrix. The role of the interface region is to transport the ions efficiently, consistently, and with electrical integrity from the plasma, at atmospheric pressure, to the mass spectrometer analyzer region, where pressure is at $\sim 10^{-7}$ or $\sim 10^{-8}$ mbar. When the ions emerge from the skimmer cones, they are directed through the ion optics that will focus the beam into the analyzer region of the mass spectrometer (Fig. 5b).

The advantage of the ICP source is that it can ionize nearly all elements in the periodic system, and when combined with a multicollector system as described above, it allows for the measurement of isotopic compositions of many more elements than TIMS methods, especially those that are difficult to ionize by thermal methods. This opened up the analysis of many useful systems in geochronology,

Fig. 6 (a) Photograph of the source area of an inductively coupled plasma mass spectrometer showing the layout of major components (*left*) and the sample and skimmer cones (*right*) which are attached to the liquid-cooled interface. (b) Schematic diagram of the main components shown in photograph (a)

such as Al-Mg, Fe-Ni, Mn-Cr, Pd-Ag, and Hf-W as well as allowing for more precise analysis of Hf and Pb isotopic compositions.

The ICP source can also be coupled to a laser ablation (LA) system that allows in situ production of ions while imaging the sampling process (Košler and Sylvester 2003; Longerich 2008; Koch and Günther 2011). LA-ICP-MS has been used extensively for U-Pb dating of zircons, as well as on other mineral matrices when a detailed understanding of sample texture and composition is required. Laser ablation adds more complexity to ICP-MS systems such as the effects of laser wavelength and pulse length on formation of aerosols, processes of elemental fractionation during lasing and in the vapor stream, adequacy of reference materials and calibration of the system using age standards, sampling strategies and analytical protocols, and data collection and reduction strategies (see numerous chapters in Sylvester 2008). Despite these complexities, LA-ICP-MS represents a successful and powerful dating tool with a growing number of applications.

There are strong matrix effects in ICP-MS that tend to reduce the reproducibility and accuracy of the analysis. To overcome this disadvantage, the element of interest can be carefully separated from its matrix through ion exchange while insuring a maximum yield (>95 %) through the process. The major limiting factor on the precision of multicollector-ICP-MS isotopic analyses stems from the instability of the plasma. An ESA is used to clean up the energy dispersion inherent in the plasma source and make it match the dispersion of the sector analyzer. In addition, mass fractionation associated with ionization in the ICP source is significantly larger than that observed in TIMS.

However, instrument-induced mass biases are usually constant during the analyses allowing for proper correction, either by sample-standard bracketing or by the addition of another element of comparable mass range such as Tl to monitor Pb mass bias. Finally, because the ICP source is capable of ionizing all constituents introduced into the plasma, corrections for spectral interferences that may overlap the masses of interest must be made.

Noble Gas Mass Spectrometry

Radiogenic noble gases including ^4He and ^{40}Ar can reside within certain minerals over geologic time scales and are often used in research applying geochronology and thermochronology. Noble gas mass spectrometry requires extraction and purification of exceedingly small fractions of gas from mineral grains under ultrahigh vacuum systems and is generally done using a high-temperature furnace or infrared laser. Heating can be done incrementally, such that gas fractions having different isotopic compositions can be separated. In some cases, step heating may provide information constraining the thermal evolution of the sample. Gases released from minerals during heating are isolated using chemical and cryogenic traps. The noble gas of interest is introduced into a gas-source mass spectrometer through an inlet port. Positive ions are created when the gas interacts with a heated filament causing ejection of an outer electron, and the resulting ions are accelerated through the source optics into a single-focusing magnetic sector mass spectrometer. The noble gas isotopes are typically measured in static mode.

Secondary Ion Mass Spectrometry

Secondary ion mass spectrometers (SIMS) were developed to provide in situ elemental and isotopic compositions on samples at high spatial resolution (Ireland et al. 2008). To do this, a primary beam of energetic ions is focused onto a small spot on the sample (typically 10–50 μm). Bombardment of the sample surface causes ablation and generates a variety of metal ions and more complex species that can be extracted to form a secondary ion beam. Chemically active elements, such as O^- and Cs^+ , are most commonly used for the primary beam because of their enhanced ability to generate secondary ions. Because secondary ions generated in this manner have a large range of both energies and mass-to-charge ratios, SIMS instruments employ a dual-focusing design with either forward or reverse geometries (Fig. 3). They also require high-mass resolution in order to discriminate between numerous secondary ion species that may have similar masses. To accomplish this, these instruments employ large magnetic and electrostatic sectors and long flight paths.

In the last 30 years, SIMS analyses of the U and Pb isotopic compositions of zircon have become a critical tool for dating igneous and metamorphic rocks and for providing age data used in sedimentary provenance studies. Although individual ages are not as precisely determined as those analyzed by TIMS, SIMS has the distinct advantage of being able to analyze distinct spatial domains within a single grain that may be related to separate geological events. Furthermore, in situ SIMS analyses eliminate the involved and time-consuming step of chemical processing required by TIMS. Additional elements can be added as part of the same SIMS spot analysis (i.e., rare-earth and high-field-strength elements in zircon) allowing petrologic interpretations to accompany age data (petrochronology). Other minerals besides zircon have been dated using SIMS by both U-Pb and U-series methods (monazite, xenotime, titanite, baddeleyite, rutile, and opal). Unlike LA-ICP-MS, the SIMS primary beam is used both to sample the target and to simultaneously generate ions from resulting volume. The SIMS “sputtering” process is much less aggressive than vaporization via laser ablation and evacuates sample volumes that are only several micrometers rather than several tens of micrometers deep. Consequently, SIMS analyses require longer data acquisition times but are less likely to incorporate zones of disparately aged material at depth. Mass-dependent fractionation is

also less pronounced in SIMS analyses, and isotope ratios require less elaborate correction procedures.

Summary

Over the last 100 years, mass spectrometry has become a critical aspect of geological science by providing ages from isotope–ratio measurements of natural radioactive decay. Mass spectrometry has also provided isotopic compositions of a myriad of solids, liquids, and gases that have been invaluable for understanding earth science processes, the rates at which they occur, and the characterization of the compositions of numerous geochemical reservoirs.

Mass spectrometry is based on the principle that charged particles moving through electromagnetic fields are affected in ways that allow the dispersion of ions of different masses into separate signals that can be measured independently. All mass spectrometers consist of three main components: (1) a source of ions and a means of imparting velocity, (2) a mass analyzer that separates the moving ions on the basis of their mass-to-charge ratios, and (3) a collector system that can quantify the intensity of separated ion beams. Most mass spectrometers used for geochronological studies must be able to produce high-precision isotope–ratio measurements of stable ion beams and therefore make use of a magnetic sector mass analyzer. Because it is possible to generate ions and introduce them into the mass analyzer by various means, several types of mass spectrometers have been developed. These instruments can provide precise and accurate measurements on a wide range of isotope systems using a spectrum of different materials and analytical strategies.

Sea Level Change (U-Series)

Christina Gallup*

Department of Earth and Environmental Sciences, University of Minnesota Duluth, Duluth, MN, USA

Synonyms

Quaternary sea level change; Sea level variations; U-series disequilibrium dating; U-Th dating

Definitions

U-series dating: A method for determining the age of material based on the changes in amounts of various isotopes within the decay chains of uranium-238 or uranium-235 due to radioactive decay.

Sea level change: Changes in global mean ocean level over time, usually associated with climatic changes.

Introduction

One of the most dramatic applications of uranium-series dating has been the quantification of past changes in late-Quaternary global sea level through U-Th dating of fossil corals and speleothems (cave deposits). Large-scale changes in Quaternary sea level result from changes in the volume of ice on land associated with the ice ages. This is because the water that formed the great ice sheets of past glaciations came from the ocean. As sea level changes, the location and elevation of coral growth and speleothem formation in coastal caves also must change.

Corals make excellent indicators of sea level because reef forming corals require sunlight and so must grow near the sea surface. A typical coral reef has a reef crest; behind the crest is the back reef or lagoon, and in front of the crest is the fore reef that slopes down into deeper water. Reef-crest corals make excellent sea level markers, such as *Acropora palmata* in the Atlantic Ocean (Goreau 1959), which grows predominantly within a few meters of the sea surface. In the Pacific Ocean, it is more common to have an assemblage of corals that indicate growth on a reef crest (Huston 1985). When a coral reef becomes exposed on land, either due to dropping sea level or tectonic uplift, the reef becomes a terrace, with the reef crest forming the lip of the terrace. Many fossil coral terraces around the world have been sampled and dated with U-series techniques, resulting in data that forms the backbone of our record of Late-Quaternary sea level (see references in Medina-Elizalde 2013).

Speleothems also help to constrain past sea level changes. Speleothems are cave deposits, many of which formed from water flowing or dripping into vadose cavities. Caves often form in bedrock near sea level because of the corrosive quality of the groundwater where fresh water meets sea water. When these caves are exposed to air and dripping water after sea level falls, speleothems form. When sea level rises and floods the cave again, speleothems stop growing. The growth of speleothems in these types of caves thus means that sea level was below the elevation of the cave at the time the

*Email: cgallup@d.umn.edu

speleothem grew. Dating such speleothems with U-series methods provides a history of periods during which sea level was below a certain elevation (see references in Edwards et al. 2003).

Vertical movement caused by tectonic forces can cause fossil corals and speleothems to be moved from their original elevation. This can be an advantage, such as when tectonically uplifting coastlines cause corals or speleothems that grew below modern sea level to be exposed on land and more easily sampled.

Obtaining sea level information from a fossil coral or a speleothem deposit requires knowledge of the deposit's elevation and age. If the deposit is on a tectonically stable substrate, then the measured elevation indicates the elevation of sea level when the deposit was formed. If the deposit is on a tectonically active substrate, then one must correct the measured elevation for the amount of tectonic movement that occurred since the deposit was formed. The tectonic uplift or subsidence rate is needed for this correction and is usually determined by measuring the elevation of a deposit that was formed at a known elevation in the past. For sea level studies, the deposits formed during the last interglacial period, when sea level was ~6 m higher than present (Kopp et al. 2009), are often used to determine tectonic uplift or subsidence rates. Local sea level can also vary due to changes in the shape of the earth (called isostatic changes) due to changes in the weight of the ice sheets and the oceans resulting from the ice ages.

U-Th dating can provide precise age determination of fossil corals and speleothems. The precision in ages is important not only because it determines the precision of the sea level record but also because the sea level record is used to test the current theory for the cause of the ice ages, the Milankovitch Theory (Milankovitch 1941). This theory states that the ice ages wax and wane due to the amount of solar insolation reaching 65° N latitude. When summer insolation is low, ice will build up from year to year, causing a glaciation. When summer insolation is high, ice will melt, causing an interglacial period. The changes in summer solar insolation at 65°N are caused by changes in the orbit of the Earth around the sun. These changes can be calculated with a precision of about 1 ka (1,000 years) (Berger 1978). To test the Milankovitch Theory, it is necessary to date geologic records of the ice ages to a similar or better precision.

Dating Systematics and Analytical Methods

U-Th dating is based on the radioactive decay products of ^{238}U : ^{234}U and ^{230}Th . ^{234}U has a half-life of 245,250 years and ^{230}Th has a half-life of 75,690 years (Cheng et al. 2000). Uranium is weathered out of the continental rocks, and because it is soluble, it is transported through surface waters to the oceans. Thorium is also weathered out of continental rocks, but because it has very low solubility in natural waters, it has very low concentrations in most water on Earth. When corals grow in the ocean, they incorporate approximately 3 µg/g of U into their skeleton, which is made of the mineral aragonite. When speleothems crystallize from dripping water, they incorporate U also, though the concentration is much more variable. Thorium produced by the decay of uranium is essentially absent from corals and speleothems due to its very low solubility, unless the sample has incorporated clay-rich or organic-rich sediments, which can have significant amounts of thorium in them. After the coral or speleothem forms, the uranium in these deposits will decay, producing ^{230}Th . The amount of ^{230}Th increases at a predictable rate with time, providing a chronometer. Ages calculated from the ingrowth of ^{230}Th are called ^{230}Th ages, which can, in principle, be used to date materials as young as 3 years and as old as 600,000 years (Edwards et al. 1987; Edwards 1988). There is also

a chronometer based on the decay products of ^{235}U (present in all uranium in a ratio of 1 part ^{235}U to ~138 parts ^{238}U), which includes ^{231}Pa (protactinium) with a half-life of 31,000 years (Cheng et al. 1998). Protactinium has very similar chemical properties to thorium, and so the ingrowth of ^{231}Pa in a sample provides a chronometer. Ideally, the ^{230}Th and ^{231}Pa ages on the same sample should be the same (often called concordant) within error. ^{231}Pa ages are not commonly available because the measurements are difficult to make.

For fossil corals, the isotopes ^{234}U and ^{238}U are also important. When uranium is weathered from the continents, the ^{234}U atoms are dissolved more easily because their chemical bonds have been damaged by the radioactive decay process. This means that the oceans have a higher activity ratio (atomic ratios normalized by the ratio of their decay constants) of ^{234}U to ^{238}U than they would have due to decay in a chemically closed environment. The ^{234}U to ^{238}U activity ratio due to the long-term decay process is 1.000 (i.e., in secular radioactive equilibrium), whereas the ratio in the ocean water is 1.147. The activity ratio of ^{234}U to ^{238}U is often expressed as $\delta^{234}\text{U}$ in delta units ($\delta^{234}\text{U}_{\text{sample}} = [({}^{234}\text{U}/{}^{238}\text{U}_{\text{sample}} \div {}^{234}\text{U}/{}^{238}\text{U}_{\text{standard}}) - 1] \times 1,000$, where ${}^{234}\text{U}/{}^{238}\text{U}_{\text{sample}}$ and ${}^{234}\text{U}/{}^{238}\text{U}_{\text{standard}}$ are expressed as activity ratios and ${}^{234}\text{U}/{}^{238}\text{U}_{\text{standard}}$ is equal to the secular equilibrium value of 1.000). The modern ocean $\delta^{234}\text{U}$ value is 147 ± 1 per mil (‰) (Stirling and Andersen 2009). Evidence suggests that this ratio has remained relatively constant during the last 400,000 years (Henderson et al. 1993), consistent with the long time that uranium resides in the ocean. The ^{230}Th age of a fossil coral can be used to calculate the initial $\delta^{234}\text{U}$ value. How closely the value matches the modern ocean value provides a measure of the coral's quality of preservation.

Analytical methods for measuring uranium and thorium isotopes have improved dramatically since the first ^{230}Th ages were measured in the 1950s (Barnes et al. 1956). The first ages reported were measured using alpha counting techniques, where the alpha particles given off during radioactive decay were detected and counted. A typical measurement of a 125,000-year-old (last interglacial age) sample had a precision (2σ) of 10,000–20,000 years in age and 20–40 per mil in $\delta^{234}\text{U}$ value. Thermal ionization mass spectrometry (TIMS) replaced alpha counting as the preferred method of analysis in the late 1980s. TIMS methods involve measuring atoms of the various uranium and thorium isotopes rather than just those that decay during the measurement period using heat to ionize the atoms, a sector magnetic analyzer to separate the isotopes by mass, and a secondary electron multiplier to measure the ions collected (Chen et al. 1986). A typical measurement of a 125,000-year-old sample had a precision of 500–2,000 years in age and 1.5–8 per mil in $\delta^{234}\text{U}$ value. Magnetic sector inductively coupled plasma mass spectrometry (MS-ICPMS) became the preferred method of analysis in the late 1990s (Shen et al. 2002). This method differs from TIMS in the manner in which the isotopes are ionized before being separated by the magnet. ICPMS uses a very hot gas (plasma) to ionize the sample, which is introduced into the plasma as a liquid nebulized into tiny droplets. The precision ranges from 300 to 1,000 years for a 125,000-year-old sample and 1–3 per mil in $\delta^{234}\text{U}$ value. The greater ionization efficiency of the plasma results in a higher percentage of ions reaching the collector and the increase in precision relative to TIMS measurements. The sample size in this technological progression decreased from grams to 10s of micrograms, and the time involved decreased from weeks of counting decays to hours of counting atoms. There is also the option of using large samples (grams) to run samples on MS-ICPMS with very high intensities, where the ions are measured on faraday cups instead of a secondary electron multiplier, which results in precisions of 100–200 years for 125,000-year-old samples and 0.2 per mil in $\delta^{234}\text{U}$ value (Stirling and Andersen 2009; Cheng et al. 2013).

Preservation and Location

Fossil corals from all over the world have been collected and analyzed. Initially, all data were considered exciting and encouraging, as the timing of high sea level events was found to match the predictions of the Milankovitch Theory (Broecker et al. 1968). As more corals were analyzed and the precision of the measurements improved, it became clear that many of the samples had been altered such that their uranium and thorium isotopic composition did not provide a perfect clock.

There are two main indicators of alteration in fossil corals. One is the presence of calcite, which has the same chemical formula (CaCO_3), but a different arrangement of atoms, than aragonite. Calcite is the more stable configuration of atoms of the two minerals. Rain water percolating down into the fossil coral reef can cause the rock to dissolve and reprecipitate, often resulting in a change from aragonite to calcite. Calcite accommodates less uranium in its structure than aragonite, so it is likely that recrystallization causes a disruption of the uranium-series isotopes in the fossil coral. Samples are often measured for calcite content prior to uranium-series analysis to avoid measuring altered samples. The second indicator is an initial $\delta^{234}\text{U}$ value that is higher than the modern marine value. Even with lower precision, early studies noted that many samples did not have initial $\delta^{234}\text{U}$ values near the modern value of about 150 but had values between 160 and 200, and a smaller number of samples had values well in excess of 200. The trend toward higher initial $\delta^{234}\text{U}$ values was noticed to be accompanied by a trend toward higher ^{230}Th ages in the late 1970s (Bender et al. 1979) and later quantified (Gallup et al. 1994). For every increase of 4 per mil in initial $\delta^{234}\text{U}$ value, the ^{230}Th age increased about 1,000 years in samples from Barbados, making it clear that some process was mobilizing uranium resulting in shifts in ages. Since this trend was quantified, many studies have adopted a cutoff for how far above the modern value the initial $\delta^{234}\text{U}$ value can be and still provide acceptable ages. This cutoff, or criterion, has varied from 0 (meaning that the initial $\delta^{234}\text{U}$ value must be within error of the modern value; Gallup et al. 2002) to 10 per mil (Medina-Elizalde 2013). As precision has improved, the initial $\delta^{234}\text{U}$ criterion has become more useful. Not all samples conform to this trend (e.g., data from New Guinea); data without these trends are much harder to evaluate. There are other methods to evaluate the quality of coral data, such as the uranium and thorium concentrations in the fossil coral and a holistic evaluation of the data set to see if it makes sense in terms of the geologic deposit.

Several workers noted that the observed trends in initial $\delta^{234}\text{U}$ value and ^{230}Th age are consistent with what might happen if the decay process itself caused the mobilization of uranium and thorium isotopes (Henderson and O’Nions 1995; Thompson et al. 2003). Most steps in the decay chain between ^{238}U and ^{230}Th are by alpha decay, where the equivalent of a helium atom is released during decay. Each time an alpha decay occurs, there is a physical movement called alpha recoil, where the atom can be dislodged from its site in the mineral structure. Thompson et al. (2003) used a mathematical model to show that alpha-recoil processes can produce the types of trends observed in Barbados corals and elsewhere. He further used the model to develop model ages, where the effects of this alteration can be corrected and produce a corrected ^{230}Th age. These model ages are very useful for checking a data set to see if the samples from a given deposit converge on a narrow age range when corrected, as alteration tends to spread the ^{230}Th ages out toward higher values. The model ages are only appropriate where the uranium and thorium isotopes display the type of trend produced by alpha recoil.

Fig. 1 Comparison between sea level elevation determined from fossil coral data and the stratigraphically continuous deep-sea oxygen isotope record (Lisiecki and Raymo 2005) spanning the last 400 ka (Reprinted from Medina-Elizalde (2013) with permission). Panel **a** contains all of the coral relative sea level (RSL) data in the compilation ($n = 897$) (blue squares). Panel **b** contains selected coral RSL data based on initial $\delta^{234}\text{U}$ values within the 137–157 ‰ (red squares) and 146–148 ‰ (green squares) ranges (See Medina-Elizalde (2013) for the references to data in this figure)

Late-Quaternary Sea Level Record from Fossil Corals and Speleothems

A recent compilation of three decades of work using uranium series dating of fossil corals provides a comprehensive documentation of sea level changes (Medina-Elizalde 2013). Much of the data for high sea level comes from locations with no to slow tectonic uplift, such as Barbados, Australia, the Bahamas, Hawaii, and Henderson Island (in the Pacific ocean), while much of the low sea level data comes from locations with high uplift rates, such as New Guinea, or from submerged samples obtained from ocean drilling, such as from Barbados and Tahiti. Figure 1a shows the data that has been collected, regardless of signs of alteration, superimposed on a record of deep-sea oxygen isotope changes as recorded by shells of foraminifera (Lisiecki and Raymo 2005). Because ice sheets preferentially incorporate light oxygen isotopes, the values of marine oxygen isotopes vary mainly as a function of ice volume. Sea level in the Late Quaternary also varies mainly due to changes in ice volume. Therefore, records of deep-sea oxygen isotopes and fossil coral sea level should reflect similar fluctuations.

It is clear from Fig. 1a that there is quite a bit of scatter and conflict in this graph of coral data. Figure 1b shows two applications of the $\delta^{234}\text{U}$ criterion, one in red with values accepted between 137 and 157 per mil and one in green with a much narrower range of 146–148 per mil. The strictest criterion reduces the number of data points significantly, but conflicting data points remain. One

conflict occurs during the last interglacial high sea stand (about 120,000–128,000 years ago) where multiple data sets suggest that sea level was higher than present, whereas data sets from New Guinea for this same period suggest a much lower sea level. The source of this discrepancy is unclear. The prevalence of data showing high sea level during the last interglacial period suggests that sea level did remain above the present value for most of the period. Another area of conflict is the many different sea level elevations reported for the high sea stand 80,000 years ago.

Despite these issues, the coral data generally follow the marine oxygen isotope record fairly well, with a few notable exceptions. The coral record suggests a much higher sea level around 80,000 years ago, a much longer last interglacial which remains high until roughly 115,000 years ago, and a much higher sea level 170,000 and 200,000 years ago. Model ages (Thompson et al. 2003) from the data that meet the 137 to 157 per mil initial $\delta^{234}\text{U}$ criterion do reduce the scatter in Fig. 1b (see Fig. 3b in Medina-Elizalde 2013), but do not remove the conflicting sea level data or change the relationship with the marine oxygen isotope record. The reasons for the scatter and conflicts in the data even after it has been screened for its initial $\delta^{234}\text{U}$ value and modeled to correct for alpha-recoil effects are likely many, including isostatic changes, uncertainties and/or inaccuracies in tectonic corrections, uncertainties in the water depth at which corals grow, and dating uncertainties and/or inaccuracies.

Medina-Elizalde (2013) performed a statistical analysis on the coral data that meet the 137–157 per mil initial $\delta^{234}\text{U}$ criterion to form a best fit record of sea level through time with a 95 % confidence level based on uncertainties in the sea level and the measured age. Figure 2a shows the results of this analysis superimposed on the data it is based on, and Fig. 2b shows the results superimposed on two, deep-sea oxygen isotope records (Lisiecki and Raymo 2005; Waelbroeck et al. 2002) and one oxygen isotope record from the Red Sea (Rohling et al. 2009). The coral sea level curve agrees broadly with the other sea level records. However, the coral record (a) shows higher sea level about 80,000 years ago, (b) does not show a drop between the last interglacial 125,000 years ago and the next high sea level event at about 100,000 years, (c) shows a high sea level about 140,000 years ago that is not present in the other records (though this is based on very sparse data), and (d) shows sea level much higher between 160,000 and 200,000 years ago (though this is based on very sparse data).

Edwards et al. (2003) assembled sea level data for the last 210,000 years (Fig. 3) based on speleothems and fossil corals that had an initial $\delta^{234}\text{U}$ within error of the modern seawater value and, where available, concordant ^{230}Th and ^{231}Pa ages. The data in Fig. 3 are connected by a line that is the best estimate (unlike the statistical method of Medina-Elizalde) of sea level based on the available data. For the sea level rise since the last glacial maximum 20,000 years ago, the line is based on drill core data from Barbados (not shown). For the period between 20,000 and 70,000 years ago, the line is based on an analysis by Chappell (2002) of ^{230}Th dates and coral terrace elevations from New Guinea. The speleothem data is shown with gray symbols accompanied by a downward facing arrow, indicating that the speleothem constrains sea level to have been below the plotted elevation. The speleothem data are generally consistent with the coral data, though the data at 200,000 years ago are only barely consistent within error. The estimated sea level records from Figs. 2 and 3 are very similar in overall shape and timing. There are some differences, as Fig. 2 has a higher estimate for sea level 80,000 years ago and 140,000 years ago and suggests a more detailed and variable sea level record between 80,000 and 130,000 years ago.

Fig. 2 Monte Carlo 95 % confidence intervals (*red curve*) based on sea level benchmarks calculated from samples having initial $\delta^{234}\text{U}$ values within the 137–157 % range. The Monte Carlo analysis is based on 1,000 runs and takes into account a sea level uncertainty of 6 m (1σ) and age uncertainties at a 2σ level (Reprinted from Medina-Elizalde (2013) with permission). The original coral RSL data used in this statistical analysis are also plotted (**a**, *blue circles*). The continuous sea level proxies are shown for comparison in (**b**) with references based on oxygen-isotope data as indicated in the figure

Finally, Fig. 3 makes it possible to evaluate how the uranium-series record of sea level compares with the timing of the orbital cycles that drive the glacial cycles according to the Milankovitch Theory. The peaks in the top curve in Fig. 3 are times when summers are warm in the northern high latitudes and when sea level should be high due to low glacial activity. While it is true that periods with high sea level almost always coincide with times of high 65°N summer insolation, it is also true that periods of high insolation do not necessarily result in high sea level. There are fewer low sea level data points, but what data there are show that low sea levels coincide with periods of low 65°N summer insolation. Thus, the uranium-series sea level data generally support the Milankovitch Theory for the ice ages. However, there are many unexplained relationships between the orbital cycles and the sea level data, such as the observation that higher 65°N summer insolation does not necessarily correspond to higher sea level and the observation that high sea level periods often continue well into periods of declining 65°N summer insolation.

Fig. 3 Direct sea level data (210,000 years to present) from corals (*solid symbols*) and speleothems (*gray symbols*). The *gray symbols* represent maximum possible sea level based on speleothem growth. The marine oxygen isotope stages are indicated by numbers, where even numbers are glacial periods and odd numbers are interglacial periods. The line segments above the last interglacial high stand (125,000 years ago) are different estimates of the timing and duration of peak last interglacial sea level from corals and from direct dating of the marine oxygen isotope record. The placements of the line segments have no significance in terms of sea level elevation. The curve between 65,000 and 35,000 years is from Chappell (2002). Note that the curve disagrees with a $^{231}\text{Pa} - ^{230}\text{Th}$ concordant point at about 50,000 years. This indicates that either the curve or the point are in error, or that the curve does not capture the full range of sea level variability in this time range. July summer solar insolation at 65° north latitude is depicted in the top panel (Berger 1978). The vertical gray bars indicate times of high insolation and are intended as aids in comparing the curves

Thermal Ionization Mass Spectrometer (TIMS)

Roland Mundil*

Berkeley Geochronology Center, Berkeley, CA, USA

A thermal ionization mass spectrometer (TIMS) consists of (1) an ion source (here a solid source), (2) a magnet (analyzer) that splits the ions depending on their mass to charge ratio (momentum filter), and (3) one or multiple collectors that measure the magnitude of the ion beams such that isotopic ratios of a given element can be computed (Nier-type spectrometer, Nier 1940).

Prior to analysis, a solution containing the purified sample is loaded on a metal filament (Re, Ta, Pt, or W) and dried down. In the evacuated source, ions are generated using the process of surface ionization by thermally heating the filament to ca. 1,200–1,800 °C. In a single-filament configuration, ions are directly emitted from the loaded sample; in a double- or triple-filament configuration, the sample is loaded on one or both of the side filaments where volatilization takes place followed by ionization using the center filament that is heated to a significantly higher temperature. Depending on the element, the use of various emitter substances can be used to enhance and stabilize the ionization. Most elements are analyzed as positive ions and some as negative ions (e.g., OsO_3^- , WO_3^-). Ionization efficiency depends on the work function of the filament material, the first ionization potential of the sample, and the temperature (Saha-Langmuir equation). Efficiencies range from 0.01 % (e.g., Hf) to ca 100 % (e.g., Rb) but are <1 % for most elements. The ionized portion of the sample is then accelerated and focused in a potential field (up to 10 kV) applied to an electrostatic lens stack (collimator) before entering the evacuated flight tube.

For large ion beams, the field of the magnet is typically held constant, and several masses are measured simultaneously using multiple collectors (static mode). For small ion beams, the magnetic field is typically cycled through the individual masses of a given element, which are measured sequentially using a single collector (dynamic mode, peak hopping).

Collectors include the following: (1) Faraday cups which accurately measure the current generated by an ion beam and therefore can be used in parallel; however, they require a significant noise correction and are thus only suitable for sufficiently large ion beams; (2) various types of multipliers (e.g., discrete or continuous dynode) for analysis of small ion beams, but in many cases, they are limited by a short life span and challenges involving intercalibration with other collectors.

A TIMS is often optionally fitted with an energy filter that results in a monoenergetic ion beam that enhances the abundance sensitivity by reducing tailing effects of major masses on adjacent minor masses.

The measured raw isotopic ratios must be corrected for the effects of mass fractionation and instrument-induced mass discrimination. The correction is typically between 1 % (for light elements) and 0.1 % level (for heavy elements) and can be done internally, using a known ratio of two or three isotopes (of either natural isotopes or added tracer isotopes) or externally by applying corrections observed on reference materials. In ideal cases isotopic ratios can be measured to a precision of <0.001 %.

Geochronometers that are commonly analyzed using a TIMS include U-Th-Pb, Rb-Sr, Sm-Nd, Lu-Hf, Re-Os, and U-series disequilibrium.

Thermochronology, Landform Evolution

Thibaud Simon-Labric*

Institute of Earth Surface Dynamics (IDYST), Université de Lausanne (UNIL), Lausanne, Switzerland

Definition

The use of thermochronometers having closure temperatures less than 200 °C that allow evaluation of the timing of geomorphic events or rates of landscape change caused by processes such as uplift, incision, exhumation, erosion, transport, and sedimentation.

Introduction

Continental topography links to some of the most fundamental questions about earth processes and history. Some modern topographic features, such as the Altiplano, Himalaya, or Tarim basin, are among the most striking physical features on the planet. Understanding the timing and processes that created these topographic spectacles would seemly provide profound insight into planetary dynamics. Topography is also central to interactions between a wide range of phenomena, including mantle circulation (e.g., Cazenave et al. 1989; Forte et al. 1993), ocean chemical evolution (e.g., Raymo et al. 1988), biota and biotic evolution (e.g., Dietrich and Perron 2006), and weather and climate on both local and global scales (e.g., Ruddiman and Kutzbach 1989; Molnar and England 1990). The ability to reconstruct paleotopography would lead to improved understanding of all these phenomena and their interactions.

Although thermochronology cannot directly constrain paleoelevation, it can provide estimates of the form, location, and scale of paleotopographic relief, as well as its change through time. Unique thermochronologic perspectives on paleotopography come from (1) spatial patterns of surface and subsurface cooling ages or cooling histories that reflect either spatially focused erosion (including incision) or the influence of topography on subsurface isotherm warping, and (2) the age-elevation relationship in paleolandscapes that may be preserved in the distributions of detrital cooling ages.

Low-Temperature Thermochronometers

Thermochronology begins with the measurement of ratios of isotopes, elements, or nuclear tracks that compose a parent-daughter radioisotopic decay system. These ratios reflect the thermal history of the sample in which they were measured. This is possible in commonly used thermochronologic systems because retention of the radiogenic (daughter) products, which “keep time,” varies inversely with temperature. A simple example is a bulk crystal parent-daughter ratio, which relates to age through a radioactive-decay equation. This age can be interpreted as the time elapsed since the crystal cooled below a critical temperature at which point daughter retention switched from nearly nil, due to diffusive or annealing loss, to essentially complete, due to a lack of thermal energy required to drive diffusion or annealing. This hypothetical temperature can be thought of as the

*Email: thibaud.simon-labric@unil.ch

closure temperature (T_c) (Dodson 1973), though in reality both the concept of closure and the mechanics of the increasing retentivity with decreasing temperature are more complicated. The thermochronometers used in studies about landscape evolution are called low-temperature thermochronometers and are characterized by closure temperatures or retentive zones cool enough to be impacted by valley incision or to be deflected by the Earth's surface topography. Widely used low-temperature thermochronometers include fission tracks and (U–Th)/He dating, both on apatite, which have closure temperatures of ~ 110 and ~ 70 °C, respectively.

In slightly more sophisticated applications, thermochronology involves measurement of a series of parent-daughter ratios and their inferred or observed distribution within a sample. This distribution reflects something more complex and potentially powerful about the thermal history of the sample and can be modeled as a finite time-temperature path, rather than a specific point in a monotonic cooling history. These approaches include fission track length distributions and $^4\text{He}/^3\text{He}$ diffusion experiments combined with (U–Th)/He dating.

Thermochronological Record of Valley Incision

Low-temperature thermochronologic studies of major river gorges in Eastern Tibet and the western Andes have been used to interpret the timing and rates of rapid fluvial incision on the flanks of large orogenic plateaux and, by inference, the timing and rates of plateau uplift. Kirby et al. (2002) used multiple thermochronometers to model the cooling histories of samples near the edge and in the interior of the Tibetan plateau. They noted that samples near the southeast margin of the plateau experienced rapid cooling from roughly 200 °C to less than ~ 70 °C in the late Miocene (~ 5 –12 Ma), whereas interior samples showed older ages for a given thermochronometer and more gradual cooling histories. To the south of the Kirby et al. (2002) study area, Clark et al. (2005) compared apatite He ages to their depths in fluvial valleys below the local plateau surface. The resulting composite age-elevation relationship show a break in slope in the late Miocene (9–13 Ma) consistent with rapid incision by rivers throughout the region. Indeed, age-elevation profiles, i.e., sets of thermochronological ages collected from different elevations within a spatially restricted domain, have been widely used to infer exhumation histories of specific areas (e.g., Wagner and Reimer 1972; Fitzgerald et al. 1995). A third spectacular example comes from the western flanks of the planet's second largest subaerial orogenic plateau (the Altiplano-Puna) in the Peruvian Andes. There, Schildgen et al. (2009) determined apatite He ages collected along strike of a major river canyon and interpreted the results as evidence for onset of ~ 2.4 km of rapid incision beginning at ~ 9 Ma (Fig. 1).

The lowest-temperature thermochronometer in wide use is apatite (U–Th)/He, which has a closure temperature of ~ 70 °C. Consequently, unique (U–Th)/He constraints on the timing of an erosional event require that the episode be of sufficient magnitude (at least 2,300–3,500 m of denudation in areas with geothermal gradients of 20–30 °C/km) such that apatite ages from rocks in a vertical transect can reveal the timing of unroofing. New and still developing techniques such as $^4\text{He}/^3\text{He}$ (Shuster and Farley 2003) and optically stimulated luminescence (OSL; Herman et al. 2010) thermochronometers provide the potential to constrain even lower magnitude denudational events. An illustration of the power of these new techniques comes from samples collected in alpine landscapes in mountain ranges that have been affected by glacial erosion. Apatite $^4\text{He}/^3\text{He}$ step heating results from samples in the 2-km deep, glacially carved, Rhône Valley in Switzerland show that this valley deepened by about 1–1.5 km over the past one million years (Valla et al. 2011). Results record an approximately twofold increase in local topographic relief at around

Fig. 1 (a, b) Location maps showing Ocoña canyon in southwest Peru and thermochronologic sample sites for apatite (U–Th)/He dating. Topography in (b) is illustrated by a 30 m resolution semitransparent DEM colored by elevation draped over a hillshade layer. *White shading* indicates the relict surface over which a spline surface was fit to determine surface topography prior to surface uplift and incision. Depths of samples below the paleosurface are indicated by 1,000 m contour lines. (c) Apatite (U–Th)/He data plotted against depth beneath reconstructed paleosurface (Data and illustration modified from Schildgen et al. (2009))

one million years ago and imply that the onset of intense glaciations and rapid valley incision within the European Alps correlates with the global mid-Pleistocene climatic transition from symmetric 41,000 year to strongly asymmetric 100,000 year glacial/interglacial oscillations. Valla et al. (2011) further proposed that this major climatic change may have enhanced glacial conditions by permitting larger, more erosive, and longer-lived alpine glaciers to develop. As a result, valleys could be lowered by glacial incision while still preserving high-elevation landscape elements.

Reconstruction of Paleotopography Using Topographic Bending of Isotherms

Topographic effects on thermochronological age-elevation profiles result from the fact that near-surface isotherms are not horizontal but are deflected by the topography (Fig. 2). The intensity of this perturbation and its depth of penetration are governed by the amplitude and wavelength of the topography (Braun 2002a). Different approaches used to exploit the topographic deflection of isotherms in order to derive quantitative and independent estimates of both denudation and relief histories are presented in the three following sections.

Fig. 2 Synthetic model simulating the upper-crustal thermal structure for a steady-state sinusoidal topography with wavelength $\lambda = 20$ km, amplitude $A = 4$ km and a constant 1 km/Myr denudation rate. *Black circles* denote synthetic samples collected along an elevation profile (Figure from Van der Beek et al. 2010)

Fig. 3 Plots of elevation (*lower*) and apatite He age (*upper*) for samples from a north-to-south transect along the western Sierra Nevada Range, California. Samples collected near major valleys have older ages than samples collected at the same elevation but farther from valleys. Major features include the Yosemite (Y), San Joaquin (SJ), and Kings (K) canyons. The *upper* panel shows the Along with individual apatite (U–Th)/He ages, and the *upper* panel also shows a running average age (*stepped curve*). The data suggest that samples collected near major canyons passed through their closure isotherms earlier than samples away from the canyons because of the downward warping of isotherms beneath wide valleys (Adapted from House et al. 1998)

The House et al. (1998, 2001) Sierra Nevada Studies

One of the earliest, if not the first, application of these principles to detecting paleotopography was the work of House et al. (1998, 2001) in the Sierra Nevada of California. House et al. showed that samples collected at about the same elevation along the Sierra Nevada Range had very different apatite (U–Th)/He ages, depending on their proximity to major valleys such as the Yosemite and San Joaquin canyons. As shown in Fig. 3, samples near canyons had much older ages. The simplest explanation for those results is that as samples were exhumed, they passed through their closure temperatures at depths that depended on the overlying topography, as suggested in Fig. 2. If true, the major range-traversing canyons seen today must have been present in roughly the same positions between 60 and 80 million year ago.

Spectral Approaches

Because the interpretation of low-temperature thermochronological age data is difficult and relies on the knowledge of local parameters that are usually poorly constrained, notably, the geothermal gradient (House et al. 1998, 2001), Braun (2002b) developed a new methodology, called the “spectral method,” to interpret thermochronometric data that does not suffer from this drawback. Spatial variations in erosion rate that result in changes in topographic relief will therefore be preserved in age-elevation relationships. Specifically, age-elevation relationships over different topographic wavelengths contain information about relief change at various scales, as well as the mean erosion rate over the whole landscape. In general, the spectral approach is most sensitive to the most-recent relief changes and those that occur over the longest topographic wavelength. The spectral method requires several important assumptions including a steady and uniform (except as perturbed by topography) geothermal gradient, stationary landforms that may grow or shrink over time, and no horizontal advection of rock (which would result in a phase shift of the gain function) (Braun 2002b). Most importantly, because this approach implicitly associates age variations over long wavelengths with transient topography, it requires uniform rock uplift rates throughout the domain used in the analysis. If active structures or isostatic rebound partition uplift over the landscape domain, age variations over long wavelengths may reflect erosion rate variations that are not associated with relief change. Young cooling ages in the core of a mountain range, relative to the flanks, for example, may not necessarily be caused by decreasing relief of the range. Instead, those younger ages may reflect high rates of rock uplift in the core due to focused crustal strain or isostatic rebound of a deep crustal root.

Numerical Models and Inversion of Thermochronological Ages

Important assumptions required by the House Sierra Nevada studies and spectral methods have led to a major challenge: can we describe or predict the temperature structure in the Earth’s upper crust with sufficient accuracy to infer exhumation rates from cooling rates? This challenge is further complicated when one realizes that the process of exhumation itself perturbs the temperature structure, as does the finite amplitude topography that we wish to measure or date. Other challenges inherent to any modeling exercise that attempts to reproduce data include incorporation of available knowledge of the physical and geological processes (i.e., faulting, sedimentation, magmatism, fluid circulation) that can affect the thermochronological age during cooling of the rock sample, as well as uncertainties contributing to noise in the data. Consequently, sophisticated 3D numerical methods have been developed to quantify landscape evolution from thermochronological data. Braun et al. (2012) developed a numerical model, called PECUBE, designed to predict the 3D thermal structure of the crust in regions subject to complex exhumation and landform evolution histories (Fig. 4). The model is coupled with an age-prediction model that produces synthetic thermochronologic ages. Predicted ages can be compared to data from samples collected in the region.

Recent studies (e.g., Braun and Robert 2005; Herman et al. 2007) have combined PECUBE with an inversion scheme based on the neighborhood algorithm to search the parameter space and extract best-fitting scenarios for denudation and relief histories from the data (Braun et al. 2012). Glotzbach et al. published a nice example of inversion of a thermochronological dataset collected along the Mont Blanc tunnel, crossing the Mont Blanc external crystalline massif in the Western Alps (Glotzbach et al. 2011). Inverse PECUBE modeling was used to better quantify the Neogene exhumation and relief history of the Mont Blanc Massif. Results of the inversion shown in Fig. 5 suggest that the most probable scenarios are characterized by an approximate doubling in relief

Fig. 4 Basic philosophy of the PECUBE model. Shown is a crustal block, subjected to a uniform uplift rate and assuming a time-varying, finite amplitude surface topography. The sides of the block show the thermal structure (note the compression of isotherms near the surface as a result of rapid rock advection). In *black* are shown the isotherms corresponding to various thermochronometers (Figure from Braun et al. (2012))

starting at 0.9 ± 0.8 Ma and a consequent increase in local (but not regional) exhumation rate at the same time (Fig. 5a, b).

Tracer Thermochronological Approaches

As presented above, thermochronological ages can be used to quantify landscape evolution over long time scales ($>10^6$ years) and thus tend to represent regional-scale erosion rates given that geomorphic processes tend to migrate spatially on shorter time scales. Dating of detrital minerals in the sediment load of river drainages provides an alternative for examining erosion processes. The tracer thermochronology method uses detrital cooling ages as a tracer, which links modern stream sediment to upstream bedrock sources. For example, Vermeesch (2007) used cooling ages to constrain the source of alluvial boulders to upstream bedrock sources. At the drainage scale, Stock et al. (2006) used a tracer method to argue for above-average erosion rates in the upper reaches of a drainage because of the abundance of old cooling ages in the fluvial sediment. McPhillips and Brandon (2010) established a statistical basis for the tracer thermochronology approach and used this approach to examine relief change in two major Sierra Nevada drainages: the Kings and the San Joaquin. The detrital cooling ages from the Kings River drainage show an excess of young ages relative to what would be expected from uniform erosion, whereas the San Joaquin River drainage shows an excess of old ages. These thermochronology results were interpreted to indicate increasing relief in the Kings drainage. The results from the San Joaquin drainage were more difficult to interpret, but were ultimately interpreted to indicate steady or declining relief in the basin.

Fig. 5 Exhumation and relief evolution path of the Mont Blanc massif. Probabilities and corresponding 2σ (*gray*) and 1σ (*black*) confidence intervals are constructed using re-sampling of the dataset. **(a)** Most probable relief evolution and **(b)** total exhumation history (i.e., including both regional exhumation and local valley carving) for a valley sample. A value of 0 of the relief amplification factor implies a flat paleosurface at the present-day highest elevation and 1 implies paleo-relief equal to the present-day relief (Modified from Glotzbach et al. (2011))

Summary

Spatial patterns of ages that correspond to cooling through low-temperature characteristic of the shallow crust can be used to infer paleotopography in several ways. Multiple thermochronometers or age-elevation profiles collected along areas of large topographic relief, such as valleys incised into orogenic platforms like the Tibetan and the Andean plateaux, can be used to date their incision ages (Kirby et al. 2002; Clark et al. 2005; Schildgen et al. 2009). The recent development and application of lower-temperature thermochronometers such as $^4\text{He}/^3\text{He}$ (Shuster and Farley 2003) and OSL (Herman et al. 2010) techniques provide the potential to constrain lower magnitude denudational events, such as the incision of glacial valleys (Shuster et al. 2011; Valla et al. 2011). The antiquity and amplitude of long-wavelength topographic development can be estimated by dating samples collected across the landform at similar elevations and then exploiting superimposed short-wavelength topography, as in the House et al. (1998, 2001) studies. Sophisticated 3D numerical models that simulate the thermal structure of the Earth can be used to invert thermochronological data and separately quantify rock uplift and relief histories (see Braun et al. 2012, for a recent review of this approach). Finally, thermochronological ages can also be used as tracers in modern fluvial sediments to repartition areas of greater or lesser erosion in a catchment (Stock et al. 2006; Vermeesch 2007; McPhillips and Brandon 2010).

As with any analytical technique, the application of thermochronology for understanding landscape evolution must overcome distinctive challenges that can complicate interpretations. Indeed, quantifying paleotopography requires important assumptions, not the least of which is that the thermal field in the shallow crust is affected mostly by topography and not by variations in advection

by fluids, heat production, arc magmatism, or other factors. Another important assumption for most approaches involving spatial variations of surficial bedrock cooling ages is that rock uplift beneath a landscape is uniform, a postulation that is most likely met over short wavelengths in tectonically inactive settings.

Biostratigraphy

Marie-Pierre Aubry*

Department of Earth and Planetary Sciences, Rutgers University, Piscataway, NJ, USA

Introduction

Biostratigraphy (from Gr. *bios*, life; L. *stratum*, bed; Gr. *grapho*, write (Brown 1991)) is arguably one of the most broadly used stratigraphic methods in Earth Sciences and concurrently one of the most misrepresented/misunderstood disciplines. In a strict sense, biostratigraphy is the *objective* subdivision of the stratigraphic record based on its paleontological content for the purpose of relative dating and correlation, and, as such, it is described in international stratigraphic guides and national codes. In the broadest sense, biostratigraphy encompasses the whole spectrum of disciplines that reconstruct various facets of Earth history from its sedimentary record, for academic and industrial purposes. In this view, biostratigraphy is central to the reconstructions of paleoceanographic and paleoclimatic history, the formulation of evolutionary theories, the description of sedimentary architecture and of sea level history, and, foremost, the discovery of geological time (or geochronology). This has been emphatically demonstrated by McGowran (2005) who illustrated the unprecedented role of microfossil biostratigraphy in the discovery of Earth history.

In this entry, biostratigraphy is discussed as a method, and I define its components and discuss the biostratigraphic correlations. This leads to the problem of diachrony and the importance of biostratigraphy in determining the occurrence of stratigraphic gaps in sedimentary sections. Finally I examine the significance of integrated biostratigraphy to soundly interpret stratigraphic successions and discuss a few examples of its role as a means to *interpret* the paleontologic record. The vertical succession of strata constitutes a clear evidence of the passage of geological time, as Steno (1669) discovered, leading to the formulation of the three principles that would become the cornerstone of Earth Sciences. But what are the relations of strata to time? Is there a one-to-one relationship between rock and time, so that any stratigraphic interval (thickness, measured in meters [m]) can be readily converted into an equivalent amount of time (duration (for distinction between Ma and Myr, the reader is referred to Aubry (2009)), measured in million years [Myr]), and any stratigraphic level (positioned with reference to Meter 0) converted into a geological date (positioned as a point expressed as mega-annum [Ma])? Or is the stratigraphic record discontinuous, with concealed unconformities that complicate the extraction of information about time from stratal successions?

Biostratigraphy and Paleontology

Biostratigraphy is intimately related to paleontology. This is because biostratigraphy involves mostly the study of *extinct species*, and for this reason, it was first known as *paléontologie stratigraphique* (stratigraphic paleontology) (D'Orbigny, 1852).

Species have a *life span*, which is the collective life span of all the specimens in it, from the moment when the species evolved to the moment when it became extinct. Most of the species that

*Email: aubry@rci.rutgers.edu

ever lived are now extinct, but many are known from their fossils, which are named based on the Linnaean nomenclature of genus and species names just as any living species. Not all fossils are of skeletonized organisms, but the majority are, which results in biostratigraphy being only compulsory for the relative dating and correlation of the Phanerozoic sedimentary strata. Its usefulness extends, however, to the strata just below the Cambrian, assigned to the Vendian series, in which soft-body animals and traces of their activities (burrows in particular) are common and diverse.

The vertical extent over which a species occurs in sedimentary rocks is called its *range*, which is representative of the life span of that species in the area where its fossils are found. The range is delineated between two stratigraphic horizons (Fig. 1). A species (e.g., species D in Fig. 1) is absent below the lower (and older) stratigraphic horizon but is present above it. It is also absent above the upper horizon but is present below it. Stratigraphers refer to the presence of a taxon at a stratigraphic level as *occurrence* (the meaning of “occurrence” seems to have changed through time. The Roget’s II, 1980 (p. 645), gives three definitions for occurrence: (1) “something that happens” [= circumstance]; (2) “something significant that happens” [=event]; and (3) “the condition or fact of being present” [= presence]. In contrast, the Roget’s II 2014 (<http://thesaurus.com/Roget-alpha-index.html>) gives two definitions of occurrence: (1) “the action, fact, or instance of occurring” and (2) “something that happens: event, incident”. I stress here that “stratigraphic occurrence” should be understood as “stratigraphic presence”). Thus, the lower (older) horizon contains the *lowest occurrence (LO)* of the taxon, which is the *oldest stratigraphic level in a section* where the species is present, while the upper (younger) horizon contains the *highest occurrence (HO)*, which is the *youngest stratigraphic level in the same section* where the species is present. LOs and HOs are *biohorizons*. The LO of a macrofossil such as an ammonite species may appear significant enough to qualify as a biohorizon, whereas the LO of a 5 µm coccolith may seem rather insignificant. Yet, the same principle applies to microfossil (~63–250 µm) and nannofossil (<63 µm to 2 µm) taxa as to macrofossils. LOs and HOs are stratigraphic terms, positioned in a section with respect to a specific point of reference.

Fossils were first treated as unrelated objects, as buttons are, for instance, some sharing similar ranges, whereas others would not. The concept of *faunal succession* (Smith, 1815) was derived from this basic observation and prior to the acknowledgement of the evolution of organisms. But fossils are related to one another through organic evolution, which explains their enormous morphologic diversity and the organization of this diversity in specific stratigraphic intervals marked by the success of particular groups or clades (thus the “Age of Fishes,” those “of Reptiles,” “of Dinosaurs,” and “of Mammals”) and the arrow of time that is perceived through the unfolding of this diversity. The arrow of time confers upon biostratigraphy its uniqueness: it is the only *non-iterative method* of relative dating and the counterpart of the radioisotopic methods in numerical dating. Biostratigraphy is the only means of relative dating that is self-sufficient, although its integration with other stratigraphic means (magnetostratigraphy, isotope stratigraphy, sequence stratigraphy) enhances its potentialities.

The ideal species in biostratigraphy are those with abundant and widespread geographic occurrences during their life, regardless of latitudes and depth of deposition (Table 1). They are marine planktonic species, among which are the Paleozoic graptolites (up to several mm long,

Fig. 1 An example of biostratigraphic subdivision of a section based on the range of selected species. Biostratigraphic subdivision is arbitrary in the sense that a few species are selected among many to construct a biozonal framework. In this example, the HO of *Sp. F* may have been chosen rather than the LO of *Sp. H* to delineate biohorizon B8

Hemichordata), the phosphatic conodont elements (~200 µm to 5 mm; Chordata), the Paleozoic and Mesozoic cephalopods (Mollusca), and the minute Mesozoic and Cenozoic planktonic protists that belong to unrelated clades but are preserved together in deep-sea sediments and among which the

Table 1 Main taxonomic groups involved in biostratigraphy. Biostratigraphy relies on eukaryotic organisms, those that have evolved a diversity of skeletal morphologies, and these comprise protists, invertebrates and vertebrates animals, and (mostly) vascular plants. It can be readily inferred from this that not all fossils have equal potential with regard to biostratigraphic usefulness. Species that, alive, had a narrow geographic distribution, as most benthic species did, do not constitute good stratigraphic markers, at least not over long distances. (The term biomarker does not designate stratigraphic markers but chemical molecules characteristic of specific organisms.) Benthic invertebrates, such as bivalves and echinoderms, are biostratigraphically useful, but only regionally. This is true also of benthic protists such as large benthic foraminifera (e.g., the Paleozoic fusulinids, Mesozoic *Orbitoides*, Cenozoic *Nummulites*) of warm water epicontinental deposits and of green algae such as charophytes in brackish and lacustrine deposits. The distribution of vertebrates and vascular plants is also limited by climatic barriers. Fossilized parts (shells, tests, gyrogonites, teeth, leaves) of these organisms usually serve for regional biostratigraphic subdivision, but their trace fossils (burrows, foot tracks) may occasionally be helpful as well (Olsen et al., 2002)

Biological group	Lifestyle	Phyla/groups	Biostratigraphic applications
Invertebrate animals	Benthic	Brachiopoda	Regional
		Echinodermata	
		Mollusca	
	Planktonic	Hemichordata (graptolites)	Broad
Vertebrate animals	Terrestrial		Regional
	Marine	Chordata (conodonts)	Global
Nonvascular plants	Brackish lacustrine	Charophyta	Regional
Vascular plants	Terrestrial		Regional
Unicellular organisms (“protists”)	Marine, benthic	Large benthic foraminifera	Regional
	Marine, planktonic	Coccolithophores	Global
		Diatoms	High latitudes
		Dinoflagellates	Epicontinental
		Foraminifera	Global
		Radiolarians	Low latitudes

planktonic foraminifera and coccolithophores occupy a prominent role. Both are abundant in deep-sea oozes and chinks, and they also occur in epicontinental deposits; additionally, coccoliths constitute the fine fraction of many such deposits. Examples in the following discussion are borrowed from these two groups, because they have contributed more to biostratigraphic thinking than any other group, but the same principles and concepts in biostratigraphy apply to all paleontological groups.

Basic Concepts in Biostratigraphy

The use in any form of fossils for relative dating and correlation is part of biostratigraphy. For instance, morphologic trends in a genus or differences in optical properties among closely related species may be used to characterize specific chronostratigraphic intervals (Figs. 2 and 3). These methods result, however, in broad age assignments. Greater resolution is achieved with the

Fig. 2 Morphologic trends in coccoliths (here discoasters) and relative age assignment. Each morphologic group is symbolized by a species (*left*) (Modified after Martini, 1971b, Fig. 39.1). Occasionally, when preservation in a stratigraphic section is poor, there are no other means than broad morphology to determine its relative age. Also anomalous mixture of morphologies (e.g., morphologies represented by *E. surculus* and *H. multiradiatus*) is indicative of reworking (or contamination, depending on circumstances)

subdivision of stratigraphic succession into biostratigraphic zones (Figs. 1 and 4, Tables 2 and 3) based on the stratigraphic ranges of selected species or other selected criteria. Occasionally, poor preservation of fossil assemblages hampers fine resolution, leading to the recourse of less satisfactory methods (Figs. 2 and 3).

Biozone

Concept

The basic unit of biostratigraphy is the *biostratigraphic zone*, or *biozone* for short, which is a stratigraphic interval measured in terms of thickness (generally in meters and its derivatives; occasionally feet in the industry) and characterized by selected aspects of its fossil content. A biozone is delineated between two biostratigraphic surfaces (biohorizons) that determine its *base* and *top*. Most horizons are the LOs and HOs of chosen taxa (see above). However, other biohorizons may be used, such as a surface across which the abundance of a species considerably increases or across which a taxon is seen to have arisen from an ancestral species. Superposed biozones are separated by *zonal boundaries* so that the top of the underlying zone is also the bottom of the overlying zone. A sequence of biozones based on the same paleontological group is referred to as a *biozonation* or *biozonal scheme*.

Fig. 3 The use of the optical properties of some coccoliths (here ceratoliths) helps delineate three biostratigraphic intervals that are correlatable to chronostratigraphic units. This may be useful when coccolith assemblages have been strongly affected by dissolution. The three biostratigraphic intervals can be regarded as assemblage zones, the older one comprising only species of non-birefringent ceratoliths (genus *Amaurolithus*) and only them; the younger zone comprising only species of birefringent ceratoliths (genus *Ceratolithus*) and only them; and the intermediate zone comprising species of both birefringent and non-birefringent ceratoliths. Note that the lower two intervals could also be described in succession as follows: (1) lowest occurrence interval zone (between the LO of the oldest species of *Amaurolithus* [A. sp. 1] and the LO of the oldest species of *Ceratolithus* [C. sp. 1]) and (2) concurrent-range zone (from the LO of C. sp. 1 to the HO of the last representative of the genus *Amaurolithus* [A. sp. 2])

Types of Biozones

Biozones differ from one another in two aspects. One is the means used for defining boundaries, in which the base and the top of a zone may be characterized by LO(s) and HO(s) of a taxon (or taxa). The other is the content of the zone itself, including occurrence and abundance of one or several taxa. The combination of both characters results in ten types of biozones distributed in two categories (interval and range zones, Fig. 4). In assemblage and abundance zones, the emphasis is placed on the content of the zone. In lineage and interval zones, the emphasis is placed on the boundaries, whereas in concurrent-range, Oppel, and taxon-range zones, it is placed on both content and boundaries. The number of taxa involved in the definition of biozones varies from a single one (abundance and taxon-

range zones) to several (assemblage and Oppel zones). Three species are involved in the definition of a lineage zone (or phylozone) and a partial range zone. A minimum of two species is needed for defining concurrent-range and interval zones. Each type of zone has strengths and weaknesses (see below), and it is important to know the type of zone used for biozonal assignment in order to evaluate its reliability.

Biozones are (or should be) established based on morphologically characteristic species whose LOs and HOs can be consistently delineated in sections over broad geographic areas. They may be subdivided into *subzones* and regrouped into *superzones* (Fig. 5). A biozone is subdivided into subzones when species involved in the subzonal definition have inconsistent occurrences, for instance, exhibiting consistent LO, HO, or both in some sections although not present in others. Superzones are introduced when the older and the younger boundary of the oldest and youngest biozones, respectively, are particularly prominent (easily identified and geographically consistent).

Naming a Biozone

Biozones (and super- and subzones) are *formally defined and named* stratigraphic units. The procedures for their establishment are explained in the *International Stratigraphic Guide* and do not need repetition here. However, it is important to emphasize that the naming implies that each biozone is unique and should be used as defined. Its designation includes the type of zone that is being defined and the name(s) of the species that serves for its definition. The (Miocene) *Eudiscoaster quinquerramus* Taxon-Range Zone (Martini, 1971a), the (lower Eocene) *Pseudohastigerina wilcoxensis*/*Morozovella velascoensis* Concurrent-Range Zone (Berggren and Pearson, 2005), and the (Cambrian) *Trichophycus pedum* Assemblage Zone (Landing et al., 2013) may serve as examples.

Long taxonomic names in Latin do not, however, ease communication among scientists other than specialists of the groups whose species are involved in zonal definitions. Thus, the most commonly used biozonations are codified with acronyms representing the interval, taxonomic group, and/or geographic area concerned by a specific zonal scheme, associated with a number corresponding to the position of the zone in the numerical succession of zones as counted in stratigraphic succession (Table 4). The Zone NP1 to Zone NP21 and Zone NN1 to Zone NN21 of Martini (1971a) and the Zone P1 to Zone P4, Zone E1 to Zone E16, and Zone O1 to Zone O6 of Berggren and Pearson (2005) are among the most commonly used in deep-sea stratigraphy. Examples of biozonations are given in Figs. 6 and 7.

Biostratigraphic zones are equivalent, in their own category, to lithostratigraphic and chronostratigraphic units, but they are not as strictly established. Whereas the latter require stratotypes, citations of reference section are only encouraged for biostratigraphic zones. Composite reference sections are generally necessary for zonations that cover a large chronostratigraphic interval. In contrast, it is highly recommended that the taxa used in zonal definitions be described as clearly as possible and illustrated (see below).

Fig. 4 Types of biostratigraphic zones. An assemblage zone (AZ) is a stratigraphic interval characterized by the co-occurrence of several taxa in combinations that may vary laterally and vertically. The taxa may be long ranging, with only one or two having its LO or HO in the zone. AZs are mostly defined in shallow water or land deposits on macrofossils. An abundance zone (AZ) is a stratigraphic interval characterized by the notable abundance of a specific taxon. The placement of the zonal boundaries may be a matter of discussion, and the percentage of a taxon in the zone may vary broadly, depending on its usual frequency. A taxon-range zone (TRZ) is defined by the total range of a taxon. A lineage zone (LZ) is defined between two horizons that record the evolutionary transition of the species from its ancestor (base of the zone) to its descendent (top of the zone). TRZ and LZ are similar in being characterized by a single taxon, but differ fundamentally in the nature of their boundaries. A concurrent-range zone (CRZ) is the interval defined

Biohorizons

Just as a stratigraphic horizon is “an interface indicative of particular position in a stratigraphic sequence” (Hedberg 1976, p. 14), a biohorizon is a “surface, or interface across which there is a significant and distinctive change in biostratigraphic characters” (Salvador, Ed., 1994, p. 56). The LO and HO of each species are potential biohorizons. However, only a few such stratigraphic occurrences achieve the status of useful biohorizon. There are many reasons for this. To qualify, species must be common where they occur, their morphology must remain sufficiently stable under different environmental conditions for the species to be identifiable in different settings, and their stratigraphic range with respect to broadly co-occurring taxa must be consistent. Thus, the most prominent biohorizons serve as zonal boundaries. However, as stratigraphic investigation continues and as attention is given to specific taxonomic entities, new biohorizons are delineated, which increases the biostratigraphic resolution within zones and subzones. Biohorizons may be the LOs and HOs of additional species, but also any prominent morphologic change (in size, shape, or ornamentation) or abundance change (of a species or in diversity; or between two taxa, the abundance of one species increasing while that of the other decreasing [the crossover biohorizon in nannofossil stratigraphy]) are recorded over long distances.

Biostratigraphic Correlations

The method of *biostratigraphic correlation* consists in recognizing in lateral sections biohorizons that have been formally defined in a reference section and to draw lines of correlation between them on this basis. In this manner, biozones are extended laterally to locations as far as the biohorizons can be identified. Beyond the furthest locations, the biozonation is no longer applicable. In practice, however, it is one thing to define a biozonal scheme based on well-preserved fossils of species in an extended section and another to recognize the same zonal scheme in sections elsewhere. When the species have been soundly selected and preservation is as good in the lateral sections as in the reference section, the characterization of the biozones and delineation of their boundaries are made with high confidence. However, this is not always the case, and difficulty may increase with increasing geographic distance and in particular across latitudes even with planktonic organisms (Fig. 7). Also each type of biozone has its own set of strengths and weaknesses that cause uncertainty in its lateral extension, recognition, and correlation (Table 5). An insufficiently recognized problem is that the possible combinations between the seven commonly used types of biozone do not number 49 as statistics would imply, but much fewer (12). The most reliable types are the taxon-range and the concurrent-range zones because they are defined by content and boundaries (see above). However, the two cannot be in immediate succession, but are necessarily separated either by a highest occurrence interval zone, a highest to lowest occurrence interval zone, or a partial range zone, which are less reliable (Figs. 8 and 9). In other words, the least dependable types of biozone

Fig. 4 (continued) between the LO of one taxon and the HO of another taxon. A CRZ is marked by the co-occurrence of two species. An Oppel zone is a hybrid between a concurrent-range and an assemblage zone in that it is comprised of several taxa (as an AZ) whose ranges are mostly restricted to the zone (unlike an AZ and unlike a CRZ which may be comprised of two long-ranging taxa but whose respective lower and upper ranges overlap). Oppel zones were mostly used in ammonite-based stratigraphy. Interval range biozones (IRZ) are those defined by the range of one taxon to the exclusion of another one and may correspond to the interval between (1) the HO of one species and the HO of another species, (2) the LO of one species and the LO of another species, and (3) the HO of a species and the LO of another species. A partial range zone (PRZ) is defined by the occurrence of a selected species between the HO of a species and the LO of another species. A PRZ is a constrained interval zone of the latter type

Table 2 Classification of biostratigraphic zones in the *International Stratigraphic Guide* (1976, 1984) and the *North American Stratigraphic Code* (2005). Note the change in position of the lineage zone, from a type of range zone in Hedberg (ed., 1976) to an independent type in Salvador (ed., 1994), the abandonment of the Oppel zone, and the agreement between the current guide and code (North American Commission on Stratigraphic Nomenclature, 2005). Although the term is not used in Hedberg (ed., 1976, p. 61), the concept of partial range zone is explicit in it, and Salvador (ed., 1994, p. 60) refers to its introduction in the report of the Stratigraphical Code Subcommittee, Geological Society of London, 1967, p. 85

Fig. 6 Examples of calcareous nannoplankton biozonation. Martini's zonation (1971a), here represented for the lower Eocene (*partim*) through Oligocene, is still in broad use. NP = nannoplankton Paleogene. The names of the zone and their code are given together with the types of biohorizons that are defined by species ranges

Aside from the latitudinal effect on correlation potentials and the uneven reliability within most biozonal schemes that is inherent to the very types of component zones, two categories of difficulties may arise in extending zonal boundaries away from the reference sections. In the first category are general difficulties that have been discussed in detail by Pearson (1998; Table 6). It can be added that the use of more than one taxon to define a zonal boundary introduces an uncertainty in its location because it is rarely the case that two species have precisely the same LOs or HOs in normal stratigraphic successions. In short, the greater the number of species involved in defining a zonal boundary, the greater the chance of characterizing it generally, but the less the precision in its delineation. This is a common problem with coccolithophore stratigraphy, for example. In the second category are difficulties relative to taxonomy.

It cannot be overemphasized that the concept of biozone is strictly dependent of the taxonomic concept(s) of the species used to define it (e.g., Hedberg, 1976, p. 55). Yet, taxonomy is a main source of uncertainty in stratigraphic correlation, and the more so that there is a general tendency to minimize this fact, in concert with the general disregard for taxonomic work in many circles today. The taxonomic problem is about consistency: (1) how to consistently recognize a species throughout its spatial and temporal range and (2) how to consistently place biohorizons so as to enhance precision in correlation.

Pearson (1998) and McGowran (2005) addressed the first question by discussing the conflict between the typological concept in paleontology and the population concept in biology. Species are not morphologically stable in the sense that no two individuals are alike, which is as obvious in fossil assemblages as it is in living populations. However, studies of living populations are mainly concerned with spatial variations, whereas studies of extinct species are concerned with both spatial *and* temporal variations. Morphologic evolution has been documented for very few protistan species (e.g., Hull and Norris, 2009; Knappertsbusch, 2000, 2007). These studies have shown complex evolutionary patterns, but with long intervals of morphologic stasis interrupted by brief intervals of high morphologic variability (in close agreement with the theory of punctuated equilibrium, see Gould and Eldredge, 1993) which lends credence to the application of the typological approach to biostratigraphy.

The second question is answered differently in the different disciplines of biostratigraphy, depending on the morphological characteristics of the fossils, as shown by the following two examples:

1. The archetypal shape in the planktonic foraminifera is a sphere, and the chambers that constitute the test are modified spheres arranged around an axis. This is the cause for an “infinite” morphologic diversity in the group and high intraspecific morphologic variability within lineages and species. Except at high rank, taxonomy in this group is dominated by morphology over structure. Specialists of foraminifera are thus confronted with a broad morphologic diversity whose significance in terms of evolutionary history must be determined. Pearson (1998) has thus advocated the use of biohorizons reflecting the evolutionary history of lineages: dispersal, extinction, pseudospeciation, and pseudoextinction biohorizons (Fig. 10).
2. Coccoliths are the articulated or loosely arranged skeletal pieces of the coccospheres of coccolithophores. Their shape varies little, but their structure differs markedly between lineages, so that taxonomy down to the genus level can be rigorously based on structure, species determinations being based on small morphological differences. The specialist here is confronted with having to determine the range of tiny fossils that may be few in the lower part of their range (possibly during species dispersal), reworked in its upper part, and whose identification is made ambiguous by poor preservation. Specialists have thus introduced semiquantitative methods

Fig. 7 Examples of planktonic foraminiferal biozonal schemes. Note the loss of biostratigraphic resolution with increasing latitude. In general, maximum biozonal resolution is obtained at low latitudes where species diversity is highest. Species diversity decreases with increasing latitudes, resulting in the loss of marker species in high-latitude stratigraphies. In this example of middle Miocene to lower Pliocene planktonic foraminiferal zonations for different latitudes, more than half of the biohorizons are lost between low and high latitudes. The upper Serravallian–lower Tortonian stratigraphic interval can be subdivided into seven zones and eight biozones at low latitude (M7–M13) but in only three biozones at mid latitudes and one biozone at high southern latitudes (Modified from Berggren et al., 1995, Fig. 5)

(Backman and Shackleton, 1983, Fig. 11), where abundance patterns help determine reliable biohorizons. The methodology is broadly applied but encourages a cumbersome terminology that may obscure its benefit (Table 7). It also raises a conundrum. If the typological definition of species is used in biostratigraphy and if the intraspecific variability of species is not known, how can abundance patterns be reliable? There can only be a large amount of subjectivity involved in taxonomic determination. This will need to be addressed, particularly in view of the existence of pseudocryptic species (Fig. 12).

Table 5 Strengths and weaknesses of specific types of biozones (From Hedberg 1976; Salvador, ed., 1994; North American Commission on Stratigraphic Nomenclature, 2005)

Biozone type	Definition	Strength	Weakness
Taxon-range zone TRZ	= Range of a species	Presence of species required	
Concurrent-range zone CRZ	= Overlap between the older range of one species and the younger range of another species	Presence of both species required	
Lowest occurrence interval zone LOIZ	= Interval between the LO of a species and the LO of another species	One of the types needed between a TRZ and a CRZ Successions of LOIZ associated with times of increasing diversification	
Highest occurrence interval zone HOIZ	= Interval between the HO of a species and the HO of another species	Useful in drilled material. One of the types needed between a TRZ and a CRZ Successions of HOIZ associated with times of decreasing diversification	
Highest to lowest occurrence interval zone HLOIZ	= Interval between the HO of a species and the LO of another species	One of the types needed between a TRZ and a CRZ	Identification is difficult, based on the whole assemblage, if isolated sample is to be dated or if section encompasses only one or two zones
Partial range zone PRZ	= Partial range of a taxon between the HO of a species and the LO of another species	The introduction of a third taxon constrains the HLOIZ	
Lineage zone LZ	= Interval between the two phylogenetic transitions	Potentially best first-order means of chronostratigraphic correlations	Taxonomy may be subjective. Requires quantification of lineage between species
Abundance zone AZ	= Interval marked by the abundance of a taxon		Abundance may vary between regions; strict quantification is not possible

Biostratigraphy and Stratigraphic Interpretation

Biostratigraphy is not only the most readily available means of relative dating and correlation of sedimentary rocks, it is also the cheapest and the fastest. For this reason, micropaleontologists are the first specialists onboard ship or on-site to receive sediments retrieved from core catchers during scientific and industrial drilling. Biostratigraphy also provides control on the identification of iterative stratigraphic information such as magnetostratigraphy and sequence stratigraphy

Fig. 8 Biostratigraphic zonations based on: (a) lowest occurrence interval zones, (b) highest occurrence interval zones, and (c) lineage zones. Any one type allows construction of a full biozonal scheme. This is different from concurrent-range zones and taxon-range zones that can only be used in combination with other biozones (Fig. 9)

(Fig. 13). At the same time, their integration results in significant refinement of biostratigraphic assignment and correlations (Fig. 13). This procedure is at the root of the ever-growing role of biostratigraphy in geochronology, which is the development of a chronology (a calendar indeed) in which biohorizons are converted into biotic events. In this manner, the LO and HO of species, both measured in terms of height/depth in a stratigraphic section, are converted into evolutionary events—e.g., evolutionary appearance and extinction—expressed in terms of dates (from which durations are derived). It is highly suitable that a dual terminology be used for biostratigraphy and biochronology, the former being the product of observation and the latter an inference (Fig. 14 and Table 8).

The fundamental problem in biostratigraphy is the temporal significance of biohorizons. Does every biohorizon record a specific event that can be singled out in the life span of a species? For instance, does every LO and HO correspond to, respectively, an FAD or an LAD? With Hedberg (1976, Ed., p. 63), we must recognize that “Biostratigraphic correlation is not necessarily time correlation.” This touches on the common problem of diachrony (=diachroneity) that has plagued biostratigraphy by casting doubt on its reliability. Diachrony concerns delayed LOs and premature HOs (or other biostratigraphic events) in stratigraphic sections (see McGowran, 2005, for a thorough discussion). The dispersal of species may not be instantaneous, or the geographic range of a species may contract or expand momentarily (Fig. 10). Latitudinal diachrony generally leaves a clear

Fig. 9 Taxon-range and concurrent-range zones cannot be in consecutive order, but are necessarily separated by either a highest–lowest occurrence interval zone (HLOI zone, shown in *a*) or a partial range zone when only one zone separates them or by a combination of a HLOI and one lowest or highest occurrence interval zone when two zones separate them. An HLOI zone or a highest occurrence interval zone (*b*) necessarily intervenes between them and an overlying zone of any type (*c*). Note that LO in (*b*) might be the biohorizon defining the base of the taxon-range zone or the concurrent-range zone in (*c*)

Table 6 General difficulties encountered during biozonal correlations (Compiled from Pearson (1998))

Criteria	Problem	Consequences
Samples	Density is too low	Insufficient stratigraphic resolution
	Size is too small	Insufficient fossil recovery
Preservational biases	Fossils are scarce	Marker species are not found
	Extraction of fossils is very difficult	
	Preservation variable between beds in same section	Dissolution, abrasion, internal and external molds
	Variable between sections	
Displacement	Reworking	HOs are difficult to delineate
	Displacement by fluids	Dubious occurrences
Contamination	In the field	Anomalous occurrences
	In the laboratory	
	Downhole contamination during drilling	

Fig. 10 Dispersal, extinction, pseudospeciation, and pseudoextinction biohorizons in a taxon-range zone (Modified after Pearson, 1996, Fig. 5.4 and 5.7). **(a)** Relationship of a taxon-range zone (species S) to space and time. Allopatric speciation of species S is followed by broad dispersal, itself followed by regional geographic stability or contraction, and finally geographic contraction until extinction of the species. In this model, the moment of speciation can only be known from one location; whereas the dispersal of the species constitutes a diachronous biohorizon (or a series of discrete biohorizons), as does the contraction of the biogeographic range. The extinction of species S is also known from a single location. **(b)** Possible relationships between typological species and evolutionary lineages. *(a)* As a first approach, ranges of morphospecies are linked in a dendrogram to show possible phylogenetic relationships. *(b)* Subsequent analyses show that transitional forms momentarily occur between morphospecies (*blue shading*). *(c)* Phylogenetic reconstructions, showing when cladogenetic and extinction events occurred. Combined, the cladogram and dendrogram allow distinction of pseudospeciation and pseudoextinction events that, although meaningless with regard to evolutionary patterns, may be useful as biohorizons

signature, and it involves long durations measurable in million years (Table 9), whereas ecological diachrony related to different water masses is of less amplitude. Tests allow determination of diachrony (Fig. 15), and orbital chronology is used to measure it (Table 9).

Diachrony is a rationalized process that immediately comes to mind to explain unexpected biostratigraphic patterns. However, unconformities produce patterns that mimic diachrony

Fig. 11 Abundance patterns of coccoliths of the genera *Diantholitha* and *Lithoptychius* in the upper Danian section at Zumaia, Spain. Abundance patterns may be expressed as number of specimens/area (of a smear slide, prepared in a way similar to a blood sample) or as percentage of a species in a whole assemblage. Note that the same biohorizons are delineated based on qualitative and semiquantitative methods when the qualitative analysis has been rigorous. Red crosses: reworked specimens. Note that species may be rare in the lower part of their range (Data from J. Criscione, personal communication, January 2014)

Table 7 Biohorizons defined on the basis of abundance patterns

Biohorizon	Acronym	Definition
Highest occurrence	HO	Youngest horizon where the species has been recorded
Highest common occurrence ^a	HCO	Horizon above which the species does not occur consistently (continuous and/or common)
Reentrance ^a	RE	Horizon where a species re-occurs
Temporary high occurrence ^b	THO	Level above which a species is anomalously absent
Crossover in abundance	X	Shift in dominance of one taxon relative to another
Paracme end ^a	PE	Horizon below which a species is temporarily absent or present with scattered single specimens
Paracme end ^a	PB	Horizon above which a species is temporarily absent or present with scattered single specimens
End of acme ^a	AE	Horizon below which a species exhibits peaks in abundance
Beginning of acme ^a	AB	Horizon above which a species exhibits peaks in abundance
Lowest common occurrence ^a	LCO	Horizon above which the species occurs consistently (continuous and/or common)
Lowest continuous common occurrence ^c	LCtO	Horizon above which the species occurs consistently but in low to very low numbers
Lowest rare occurrence ^c	LRO	Horizon above which the occurrence of the species is rare
Lowest occurrence	LO	Oldest horizon where the species has been recorded

(Aubry, 1995, Fig. 16), and failure to decipher unconformities leads to misinterpretation of biohorizons, which leads, in turn, to miscorrelation and incorrect age assignments and dating. Methodologies in two categories have been devised to delineate unconformities in stratigraphic sections. The first category, reviewed by Gradstein (2004), comprises deterministic and probabilistic quantitative methods that are applicable to all Phanerozoic stratigraphies and are generally used where classical biostratigraphic means are not applicable, in particular in industry. Graphic correlation (Shaw, 1964; Edwards, 1984) is classical among them (Fig. 17). The other methodologies are based on the analysis of sedimentation rates curves, in which terraces are indicative of stratigraphic gaps (Fig. 18). Terraces are formed at stratigraphic levels where LOs and HOs are juxtaposed although they markedly differ in age. This is at the origin of the method of temporal interpretation (Aubry, 1995) in which stratigraphic sections are projected into a temporal framework so that the duration (hiatus) represented by unconformities is fully accounted for.

The best documentation of evolutionary histories concerns the planktonic protists, and this can be attributed to their abundant, generally well-preserved, broadly distributed (the ocean occupies ~70 % of the surface of the planet) fossil record. In contrast, reconstitution of the evolutionary history of marine invertebrates and, to a lesser extent, benthic protists, has been problematic, largely because of their narrow dependence on specific environmental parameters. Their paleontologic records are biased by several factors, including artificial range truncation and stratigraphic gaps,

Fig. 12 Species and pseudocryptic species. Integrated morphologic and genetic studies of coccolithophores have shown that living species are in fact an aggregate of several pseudocryptic species (e.g., Saez et al., 2003; Hagino et al., 2009). This implies that the broad intraspecific variability attributed to single extinct taxon may in fact represent the cumulative variations of several extinct pseudocryptic species (the extinctions of which may constitute the pseudospeciation biohorizons of Pearson, 1998). Size may be a good indicator of pseudospeciation. Counts according to size class minimize the subjectivity involved in semiquantitative analysis of abundance patterns

which has led to formulation of models to predict their evolutionary patterns (e.g., Signor and Lipps, 1982; Holland, 1995; Springer, 1990). The method of temporal interpretation has permitted illustration of the role of unconformities in altering the record of paleobiological events as suspected by paleontologists and has shown that temporal resolution does not necessarily match stratigraphic resolution (Fig. 19). It has also strongly indicated that unconformities at sequence boundaries on continental margins extend to the deep sea (Aubry, 1991; 1995), which has notable implications for the documentation of paleobiological events among marine invertebrates (Fig. 20). Sequence stratigraphy postulates that the hiatus associated with sequence boundaries decreases along a coast to basinal transect so as to be nonexistent at the correlative conformity (e.g., Van Wagoner et al., 1998; Catuneanu et al., 2009). If the model of sequence stratigraphy is correct in this, paleobiological studies along depth transects on continental margins will help verify or supplant

Fig. 13 Integration of magneto- and biostratigraphy. Although magnetic reversals occurred iteratively through time, each can be characterized by a particular species or group of species that existed or coexisted only during individual magnetochrons. Thus, biozone B2 may be a taxon-range zone defined by species A that lived only from late Chron Cyn to mid Chron Cxn. Assignment of a magnetozone associated with this biozone to any other chronal succession would be erroneous. In turn overlap between stratigraphic means allows to determine more precisely the relative age of the section. Based on paleontological group 1 alone (*a*), the section covers interval Ia; based on integration of paleontological groups 1 and 2 (*b*), it covers only interval Ib; adding magnetostratigraphy (*c*), it is reduced to interval Ic

Fig. 14 Relationship between rock and time

Table 8 Biostratigraphic and biochronologic terminology. The dual stratigraphic versus temporal terminology shown here is recommended although it is not always followed. The term “biohorizon” is also referred to as surface, horizon, level, limit, boundary, band, marker, index, datum, datum plane, and key horizon. First and last appearance data (FAD, LAD) are commonly used in synonymy with biohorizon. However, *first* and *last* are temporal terms (in opposition to *lower* and *upper* that are stratigraphic terms) and are more appropriately used to designate temporal events, such as evolutionary appearance and extinction (see discussion in Aubry (1995) and (2007))

Stratigraphic terminology	Temporal terminology	
<i>Terms</i>	<i>Terms</i>	<i>Synonyms</i>
Biozone	Biochron	
Biohorizon	Bioevent	
Highest occurrence (HO)	Last appearance datum (LAD)	Extinction of taxon
	Last occurrence datum (LOD)	Cases of pseudoextinction
Lowest occurrence (LO)	First appearance datum (FAD)	Evolutionary appearance of a taxon
	First occurrence datum	Dispersal, cases of pseudospeciation
Abundance	Acme	
Stratigraphic event	Evolutionary event	Speciation, extinction, cladogenetic divergence
	Biogeographic event	Contraction/expansion of geographic distribution
Range	Span	

Table 9 Examples of diachrony exhibited by species of planktonic foraminifera (Wade et al., 2011) and coccolithophores (Backman et al., 2012; Raffi et al., 2006; Aubry, 1992). For reference (Raffi et al., 2006), only reliable (“A”) data are cited. Note that although ages in different works cited are based on different time scales and should not be compared, the amplitude of diachrony varies little between time scales. *LOD* last occurrence datum, *FOD* first occurrence datum, *EM* Eastern Mediterranean; (Aubry, 1992): latitudinal diachrony. Other works: different water masses at low latitude sites (Wade et al., 2011; Backman et al., 2012; Raffi et al., 2006; Aubry, 1992)

Fig. 15 Testing for diachrony. In this classic example, a paleontological event (extinction event) is considered diachronous because of its inconsistent relationship to a formational boundary (a). However, the finding of an ash layer of characteristic mineral composition (one of the shortest possible time markers) indicates that the extinction level is synchronous, whereas the lithological contact is diachronous (b)

models of evolutionary patterns (Fig. 19a, b). However, if the model of sequence stratigraphy is incorrect with regard to the decreasing hiatus down dip, tests of evolutionary models through studies of selected transects will not yield decisive information (Fig. 19c).

Conclusions

Biostratigraphy is the only non-iterative method of relative dating. Based on firm foundations, capable of evolving through the developments of new techniques, the rise of new concepts and their integration with other stratigraphic means it is the most dependable means of stratigraphic correlation and dating available to the stratigrapher. It is at the root of biochronology, and it makes possible insights into the rates at which earth and life processes occur on geological time scales. As such it is a major part of the framework upon which the history of the Earth system is being deciphered.

Some immediate and fundamental problems that biostratigraphy can help address concern the completeness of stratigraphic sections. Although Ager (1973) cautioned that the sedimentary record is highly discontinuous everywhere, overconfidence is increasing, unchallenged, that

Fig. 16 Comparison between diachronous stratigraphic patterns and patterns resulting from unconformities (Modified after Aubry, 1995). Consider six sections (A–F) assigned to biozones BZ1 to BZ3, zone BZ2 being a taxon-range zone defined by the range of the planktonic species *Aglae xanthos*, which is abundant and equally well preserved in all sections. Zones BZ1 and BZ2 are interval range zones. *Aglae xanthos* had a life span of 2 Myr, between its FAD at 54 Ma (=T₁ in figure) and its LAD at 52 Ma (=T₂; FAD and LAD as defined in Table 8). The range of *A. xanthos* in section A represents the whole life span of the species, so that the LO and HO in the section correspond to the FAD and LAD of the species, at 54 and 52 Ma, respectively. The LO of *A. xanthos* is delayed in section B and even more in section C, whereas its HO occurs prematurely in the two sections, so that neither stratigraphic event corresponds to the FAD and LAD of the species. The LO is <54 Ma in section B and >> 54 Ma in section C, and the HO is >52 and >> 52 Ma in sections B and C, respectively. This stratigraphic pattern is typical of diachrony, the delayed occurrence in sections B and C corresponding to dispersal following evolutionary divergence or to ecologically forced expansion of the species, whereas the premature regional extinction results from contraction of the geographic distribution of the species. *Algae xanthos* exhibits a stratigraphic pattern in sections D to F that mirrors the diachronous pattern in sections A to C, but this latter results from truncation of its stratigraphic range in sections E and F. The important point here is that the biohorizons in sections B and C have significance with regard to the evolutionary and/or biogeographic history of the species and represent regional events (first and last occurrence), whereas the same biohorizons in sections E and F do not carry any evolutionary or paleobiogeographic significance. Blue arrow indicates migration; red arrow indicates contraction of biogeographic distribution

Fig. 17 Method of graphic correlation. Distance between stratigraphic events in a section is compared to their distance in a standard reference section. Note the terrace indicative of a stratigraphic gap. Numbered *circles* and crosses represent LOs and HOs, respectively [base and top in the method] (Modified from Miller, 1977, Text-Fig. 5)

Fig. 18 (continued)

Fig. 18 Method of sedimentation rate curves. Sedimentation rate curves are constructed by comparing thickness between biostratigraphic events to duration between biochronologic events. When sedimentation is continuous, the thickness of biozones is essentially proportional to duration, and changes in rates result in changes in the slope of the curves. Stratigraphic gaps are marked by terraces (as in graphic correlation) corresponding to the overlap at the same stratigraphic level of multiple biohorizons. (a) Lower–middle Eocene section recovered from Deep Sea Drilling Site 612 (From Aubry, 1995) and (b) lower–middle Miocene section from an exploration well (From Sanchez et al., 2014)

Fig. 19 Stratigraphic resolution versus temporal resolution and pseudo-diachrony. Consider three stratigraphic sections of different thicknesses, exhibiting a major paleobiological event [PB]. PB occurs in zone BZ2 in *sections A and B*, but in the middle of the zone in *section A* and in its lower part in *section B*. PB occurs at the BZ2/BZ3 zonal boundary in *section C*. Whereas at face value event PB is diachronous, temporal interpretation (cf. Fig. 18) of the sections using integrated magnetobiostratigraphy shows that correlative unconformities in *sections B and C* and associated with different hiatuses are responsible for apparent diachrony. Note also that the temporal resolution considerably differs in the three sections (Modified from Aubry, 1998, Fig.)

Fig. 20 Integrated magnetobiostratigraphic studies of sections carefully located along the sequence boundaries should, in principle, help resolve evolutionary patterns among organisms living on epicontinental shelves. In this example, if the hiatus associated with a sequence boundary decreases basinward, study of a continuous (temporally complete) section across the correlative conformity will allow determination of stepwise (a) or abrupt (b) extinctions. However, if the hiatus increases or remains constant basinward, the event cannot be constrained (c)

biostratigraphic records are reliable markers of time, seismic patterns are chronostratigraphic, and evolutionary modes of life can be restored from direct recovery of stratigraphic patterns and without tests of temporal continuity. These are fundamental questions that biostratigraphic studies must continue to address in the future.

Acknowledgments

I am most grateful to Jack Rink for inviting me to contribute to this entry on biostratigraphy; to W. A. Berggren, D. Bord, P. N. Pearson, W. Si, and J. A. Van Couvering for the discussion and their review of this entry; and to Sarah Klingler for the artwork.

Uranium–Lead Dating

Randall Parrish*

Department of Geology, University of Leicester and NERC Isotope Geosciences Laboratory, British Geological Survey Keyworth, Notts, UK

Definition

Uranium–Lead dating is the geological age-determination method that uses the radioactive decay of uranium (U) isotopes (^{238}U , ^{235}U , and also in this entry ^{232}Th) into stable isotopes of lead (Pb) (^{206}Pb , ^{207}Pb , and ^{208}Pb , respectively). U–Pb geochronology is the science of both the methodology but also the application of these methods to geological problems.

U–Pb Decay System and Age Calculations

The accumulation of Pb in U-bearing minerals according to known decay rates of radioactive parent isotopes of U and Th forms the basis of this dating method. One measures the amount of *radiogenic* (i.e., produced from radioactive decay) Pb relative to the amount of radioactive parent isotope. As there are three radioactive isotopes (^{238}U , ^{235}U , and ^{232}Th) that decay into stable “daughter” isotopes of Pb, one can calculate three ages in this manner, two of which have the same (i.e., U and Pb) elements forming parent and daughter. The decay systems, decay constants (λ), and half-lives ($T_{1/2}$) are

The isotope ratio of uranium, $^{238}\text{U}/^{235}\text{U}$, has been recently determined to be 137.818 ± 0.045 (Hiess et al. 2012); a compilation of data from Hiess et al. (2012) from all terrestrial materials shows a variation from 137.71 to 137.96 with low-temperature earth materials having distinctly more variation as a result of the oxidation characteristics of uranium.

There are a number of intermediate isotopes in the decay chain that must first decay before stable Pb isotopes are produced. The most important ones for U–Pb dating are ^{234}U and ^{230}Th in the ^{238}U decay system and ^{231}Pa in the ^{235}U system, all of which have half-lives between 30,000 and 250,000 years. These intermediate isotopes produce complications to the interpretation of U–Pb dates that can be very important for young (i.e., Neogene) ages and particularly minerals with high Th/U such as monazite or allanite. Also there are a few cases where the effects are very dramatic and

*Email: rrp@nigl.nerc.ac.uk

which may involve ^{231}Pa excesses in the ^{235}U – ^{207}Pb decay chain (Oberli et al. 2004; Anczkiewicz et al. 2001).

The basic age equation is

$$T = (1/\lambda) * \ln(1 + D/P),$$

where T is the age, D refers to a molar quantity “daughter” isotope of Pb (^{206}Pb , ^{207}Pb , and ^{208}Pb), and P refers to the respective molar quantity of a parent isotope of Uranium (or Thorium), and where λ is the decay constant for each respective radioactive parent isotope (^{238}U , ^{235}U , ^{232}Th).

Published studies have used this dating system for materials ranging from the age of the solar system (4,567 Ma) to less than 1 Ma. A unique aspect of this decay system is that the two parent isotopes of U, with contrasting decay constants, become two isotopes of Pb; as a result, the radiogenic $^{207}\text{Pb}/^{206}\text{Pb}$ isotope ratio is a strong function of age, and it can be used to provide an additional date, based on the measured radiogenic Pb isotope ratio alone. This Pb isotope ratio can be measured very precisely, and this property allows uncertainties for ancient samples to be much smaller than would otherwise be the case, as little as 1 part in 10,000 of the age of a sample. The equation for this Pb isotope age calculation is:

$$\frac{^{207}\text{Pb}}{^{206}\text{Pb}} = \frac{^{235}\text{U}}{^{238}\text{U}} * \frac{\exp(\lambda_{235}T - 1)}{\exp(\lambda_{238}T - 1)},$$

where T is time and $^{235}\text{U}/^{238}\text{U}$ is the current isotope ratio of uranium ($= 1/137.818$).

When the measurements are made, dates are calculated by measuring a daughter/parent ratio ($^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$, $^{208}\text{Pb}/^{232}\text{Th}$) and a radiogenic lead isotope ratio ($^{207}\text{Pb}/^{206}\text{Pb}$), resulting in up to four calculated dates, three of which are part of the U–Th–Pb system of decay.

In the U–Pb system, a calculated date using one of the equations above does not necessarily result in the most valid interpreted age of a mineral, partly because some minerals have a tendency to lose Pb as a result of volume diffusion and/or diffusion via radiation damage and partly because some accessory minerals can have multiple age components during their formation (e.g., cores overgrown by younger rims). These combined effects are often referred to as “open-system” behavior, referring to cases where a date does not simply reflect a single growth domain where the parent and daughter isotope ratio has changed only through radioactive decay. Age patterns within single grains of zircon and monazite, in particular, can be quite complicated because of these factors and require careful analysis in the petrographic context, especially in metamorphic rocks (Cottle et al. 2009).

A method of visually displaying measured isotope ratios to better interpret potential complexities resulting from open-system behavior can be attributed to Wetherill (1956), who devised the Concordia diagram. This diagram graphically interrelates all three ratios of the U–Pb system whereby the X and Y axes are $^{207}\text{Pb}/^{235}\text{U}$ and $^{206}\text{Pb}/^{238}\text{U}$, and the inverse gradient of any point drawn through the origin is proportional to $^{207}\text{Pb}/^{206}\text{Pb}$. In this diagram, a curve originating at the origin, termed the “concordia curve,” defines the $^{207}\text{Pb}/^{235}\text{U}$ and $^{206}\text{Pb}/^{238}\text{U}$ values where the calculated dates of these ratios are identical, using the age equations above. Any measured analysis of a mineral that plots within uncertainty of the Concordia curve is considered “concordant,” having its $^{207}\text{Pb}/^{235}\text{U}$ and $^{206}\text{Pb}/^{238}\text{U}$ calculated dates the same within uncertainty. If falling off this curve, either above or below, an analysis is termed “discordant,” with measured dates not in agreement.

A variant of the Concordia diagram, termed the Tera-Wasserburg diagram (Tera and Wasserburg 1972), plots $^{207}\text{Pb}/^{206}\text{Pb}$ as Y and $^{238}\text{U}/^{206}\text{Pb}$ as X and is particularly useful when measurement of the small ^{204}Pb isotope is imprecise or not possible. Both of these diagrams offer a graphical method

of making a correction for disturbances to the U–Pb system arising, for example, from a single moment of Pb loss or a second phase of mineral growth well after a mineral's formation, in order to calculate the original time of mineral growth. Further variations of the Concordia diagram involve $^{208}\text{Pb}/^{232}\text{Th}$ plotted against $^{207}\text{Pb}/^{235}\text{U}$ or $^{206}\text{Pb}/^{238}\text{U}$ to illustrate behavior involving U, Th, and Pb isotopes. The use of two parent U isotopes and two daughter Pb isotopes is a very useful property; it allows a correction for disturbed systems and recovery of the initial age of a mineral, a feature unique to the U–Pb dating method among all isotope geochronometers.

A correction for initial or “common” lead, that is, the lead incorporated into a material at its time of formation, is implicit in calculation of ages. The theory of this is well-developed in many geochemistry or geochronology textbooks and is not detailed herein.

Historical Development of the Method

The discovery of radioactivity of uranium was a pivotal event, with recognition that transformation of uranium into other elements was inevitable. Early on, lead was suspected of being the ultimate stable end product of this decay (Boltwood 1907). Even before the discovery of isotopes by Frederick Soddy in 1913 (Soddy 1913), U–Pb ages of geological materials were calculated, using initial estimates of the half-life or decay rate of uranium. Although Boltwood (1907) was the first to calculate the age of a mineral based on its U–Pb ratio, Arthur Holmes (Holmes 1911), under the guidance of his supervisor R J Strutt, determined dates of a suite of igneous-related Devonian minerals of variable U–Pb ratio in Norway by measuring the atomic U–Pb ratio in minerals with improved methods. This study used a combination of appropriate geological samples with clever methods of classical wet chemistry and radiochemistry. The dates calculated, approximately 370 Ma, were within 5 % of the correct ages determined later. Holmes also recalculated Boltwood's dates with a better decay constant, having sought information on the geological context of Boltwood's samples from the US Geological Survey. These were of real importance because this began the first numerical calibration of the geological timescale as well as proving that the Earth was much older than 1 Ga.

The discovery of isotopes by Soddy had little impact initially to U–Pb dating because the development of mass spectrometry capable of measuring U or Pb isotopes was only achieved decades later. This changed dramatically in ~1935 with advances in technology. Alfred Nier, among the most brilliant of all mass spectrometrists of the twentieth century, designed instruments and ion signal amplification devices that could measure accurately and relatively precisely the isotope composition of U and Pb; indeed, his measurement of U isotopes were pivotal in demonstrating that ^{235}U was the isotope capable of fission by thermal neutron irradiation (Nier 1939). His measurements of Pb isotopes allowed U–Pb isotope ages of U ore minerals to be calculated and a $^{207}\text{Pb}/^{206}\text{Pb}$ age of 2.6 Ga to be determined on monazite (Nier et al. 1941). Some years later, Claire Patterson (1956) published accurate and precise measurements of primordial lead in troilite (an iron sulfide with negligible U) from the Canyon Diablo (Meteor Crater, Arizona) Ni–Fe meteorite that allowed an age of ~4.55 Ga for the age of early solar system meteorites to be established.

One of the most important collateral outcomes of atomic energy research was the accurate and precise method of isotope quantification known as isotope dilution. In this method a known quantity of an enriched isotope of an element (i.e., ^{235}U , ^{208}Pb) is added to a sample prior to dissolution, and the concentration of natural U and Pb isotopes in the sample are calculated using the measurement by mass spectrometry of the isotope composition of the resultant mixture. This method is an

extension of the original method using radioactive tracers invented by George de Hevesy in 1913, for which he was awarded the Nobel Prize in 1943.

This procedure is simple and superbly reliable. To illustrate how this works, imagine a bucket of unknown quantity of colored balls that are black and white in a ratio of 2:1 black–white (representing the natural isotopes in a sample). If one adds 100 red balls (representing the enriched tracer) and mixes the balls up and then measures a ratio of red–black of 0.5 (by isotope ratio mass spectrometry of a portion of the sample), then one can easily work out that there are 50 black and 25 white balls in the original sample. One does not have to count all the balls to know this; one only needs to know the number of tracer balls added and the ratio (i.e., isotope ratio) of the mixture.

This methodology was developed and applied to a wide range of elements and sample materials. It still represents the most accurate and precise manner of isotope quantification in geological samples. One of the finest early papers to date accessory minerals by these methods is the *tour de force* of Tilton et al. (1955) in which various minerals were dated in a Precambrian granite; the paper presents tedious but elegant analytical methods, including not just U–Pb but also Th–Pb, and is a required reading for all U–Pb geochronologists who wish to appreciate the fundamental work of the early pioneers of the methods we now use so routinely. This was the standard method of U–Pb geochronology until the mid-1990s and is still widely used today.

Evolution of Methods 1955–1980

In the isotope dilution method of U–Pb dating, decomposition of samples into a homogeneous solution is a requirement so that tracer and sample isotopes can fully mix prior to chemical separation and isotope analysis by mass spectrometry. During the period prior to ~1970, dissolution of various silicate minerals useful for U–Pb geochronology (i.e., zircon) was tractable only with flux melting followed by HCl acid dissolution, and it required a large quantity of sample material. This was a hindrance to widespread application of the U–Pb dating method partly because of the time and expense involved in the procedure but also because zircon commonly loses Pb due to radiation damage of its crystal lattice. When large quantities of zircon were analyzed by this flux method, this inevitably resulted in many discordant dates being produced because of the prevalence of Pb loss in some of the grains; analysis of tiny amounts of high quality zircon was simply not generally possible. This frustrating reality proved to be a strong motivation to find a better way – to be able to analyze much smaller quantities of zircon and ultimately single grains that were of very high quality not subject to significant Pb loss.

In the late 1960s and early 1970s, two young geologists – Tom Krogh and James Mattinson – devised a solution to this conundrum while doing work early in their careers at the Carnegie Institute of Washington. Using the availability of Teflon™, which fortuitously had been discovered by Roy Plunkett of DuPont Corporation in 1938 during refrigerant research, Krogh and Mattinson made several key breakthroughs in geochemical research: (1) the ability to dissolve refractory minerals like zircon in HF acid at high temperatures (~220 °C) in steel-jacketed Teflon™ pressure vessels, (2) the ability to clean Teflon™ vessels so as to introduce very little additional lead contamination, and (3) the development of sub-boiling distillation of acids in Teflon™ to produce ultrapure acids with low lead contamination. Together with the silica gel Pb ionization method on a re-thermal ionization filament, it became possible to analyze single grains of zircon or other minerals; a practice that is routine today. Despite these improvements, the issue of Pb loss in zircon still hindered high-precision age determination. Krogh (1982) addressed the problem of zircon discordance by inventing the air abrasion technique to remove the discordant outer part of

zircon crystals, which resulted in production of vastly improved concordance (i.e., closed-system behavior) of zircons. In 1985–1987, R Parrish worked with Tom Krogh and J C Roddick (Parrish and Krogh 1987; Roddick et al. 1987) to synthesize a significant quantity of the artificial isotope ^{205}Pb for distribution to world laboratories and devised an efficient method to dissolve multiple individual zircon samples in a single steel-jacketed pressure vessel. All of these analytical advances conspired to facilitate a very significant growth in the number of U–Pb laboratories and the quantity of high-accuracy, high-precision zircon dates. Using U–Pb zircon dating with $\leq \pm 4$ Ma uncertainty, Precambrian volcanic chronostratigraphy became a commonplace in the 1980s–1990s, especially in Canada. A great advance in Precambrian continental orogenic evolution then proceeded, especially in the Canadian Shield. This made possible seminal papers on continental evolution, such as Paul Hoffman's United Plates of America synthesis (Hoffman 1988).

At the same time, when these methods were applied to complicated igneous and metamorphic zircon, the complexity in zircon U–Pb systematics became apparent, including the phenomenon of zircon inheritance and multiple metamorphic zircon growth periods during high-grade metamorphism. In such cases, single-grain analysis produced consistently discordant data, and the determination of precise ages of metamorphism or igneous events proved to be a challenge in many samples. Complex zircon growth and alteration were imaged using electron microscopy, suggesting that the complexities in U–Pb data were the result of a combination of lead loss and multiple zircon age domains within single grains. The paper by Corfu et al. (2003) illustrates the variation in textures elegantly. The analysis of zircon on the micron scale became an obvious tantalizing goal, but it presented major technical challenges and was impossible at the time for multi- or single grain zircon analysis by ID-TIMS. One way forward using ID-TIMS came from accessory minerals like monazite with less inheritance and Pb loss to determine igneous and metamorphic ages (Parrish 1990).

With more work applied by ID-TIMS methods to alternative minerals, the effects of chemical fractionation of the intermediate daughter isotopes ^{230}Th and ^{231}Pa relative to ^{238}U and ^{234}U became better documented (Schärer 1984; Parrish 1990; Anczkiewicz et al. 2001). As a result of this effort on alternative minerals, excess ^{206}Pb in monazite and other Th-rich minerals, sometimes of huge relative magnitude, was documented, and smaller magnitude ^{206}Pb deficiencies and much more rare ^{207}Pb excesses (Anczkiewicz et al. 2001) were documented in zircon; all of these features were shown to exist by early work of Mattinson (1973).

Notwithstanding the advances made by laboratories using the ID-TIMS method, efforts to develop in situ methods of U–Pb analysis were accelerating, building on advances in secondary ion mass spectrometry (SIMS).

In Situ Methods of U–Pb Analysis

In this article, in situ U–Pb dating refers to the measurement of age of a mineral in a solid state using microbeam sampling techniques, and it includes first SIMS and later LA-ICP-MS methods, as well as the less-used electron microprobe chemical dating method, all of which are described briefly below.

Among other scientists involved in SIMS (secondary ion mass spectrometry) techniques, William Compston of the Australian National University (ANU) led a team to develop SIMS methods for the analysis of very small ($<50\text{ }\mu\text{m}$) regions of zircon for the purpose of U–Pb dating. The SIMS method consists of firing a primary highly focused ion beam (oxygen or cesium ions) onto the surface of polished zircon in order to produce secondary sample ions which are then accelerated and focused

into a beam which could be analyzed by a mass spectrometer. However, in SIMS zircon analysis, a wide range of molecular ions are produced during the primary sputtering process where the beam interacts with the sample. Many of these molecular ions have very similar masses in relation to the Pb isotopes that are of interest for dating, and which occur in very small quantities. In order to cleanly separate and measure the molecular ions from the Pb ions of interest, larger radius (>1 m) double-focusing high mass resolution SIMS instruments had to be designed and built. In the U–Pb trade, these methods have been loosely termed “ion microprobe” methods, and the ANU instrument was termed “SHRIMP” (Sensitive High Resolution Ion Microprobe) and was built in the early 1980s; an analogous instrument was built in France by Cameca Instruments in the early 1990s. In 1984, the first SIMS zircon age was published by Compston et al. (1984), and it determined an age of 4.36 Ga for zircons in lunar breccia sample 73,217 returned from Apollo 17. This development heralded a new period of exploration of zircon as a geochronometer, although the application of the SIMS zircon work to terrestrial rocks did not see wide application until the 1990s.

SIMS U–Pb methods cannot quantify accurately the ratio of Pb to U isotopes within a zircon or other accessory mineral directly. Instead calculation of a date relies on the analysis of a “standard” or “reference” zircon whose U–Pb isotope ratios must have been determined by the ID-TIMS method. Ion signals of unknowns are measured and compared to those of the reference zircons (the Pb–U ratio which is known) to establish a calibration relationship; this in turn is used to calculate the $^{206}\text{Pb}/^{238}\text{U}$ ratio of the unknown, then used for age determination. A series of zircon reference samples has evolved over the past ~30 years, with variable ages, U contents, homogeneity, and extent of concordance. The search for, and characterization of, suitable reference materials for isotopic and elemental analysis is an ongoing effort for in situ analysis, and not just for zircon.

Building on earlier work with quadrupole mass spectrometry and ionization using plasma sources, inductively coupled plasma ionization (ICP) was combined in the early 1990s with multiple-collector mass spectrometry (MC-MS) using an additional electrostatic analyzer to make the first ICP multi-collector mass spectrometer (ICP-MC-MS). This instrument combined the highly efficient ICP ion source with multiple collections of ion signals in a mass spectrometer of mass resolution similar to a normal TIMS instrument (mass resolution ~400). Shortly thereafter, laser ablation (LA) micro-sampling was attached to this type of instrument to deliver the first LA-ICP-MC-MS, with the measurement of U–Pb ages using a zircon reference sample. One of the more comprehensive early papers using this method was that of Horstwood et al. (2003) which also included a common Pb correction. Among other applications, this allowed hafnium (Hf) isotopes to be measured more time efficiently than by TIMS methods, and this was exploited by ID-TIMS zircon geochronologists to add Hf model ages to the zircon U–Pb evolution (Davis et al. 2005). These were the precursors to more widespread LA-ICP-MS instruments on the market now, which offer sufficient sensitivity and precision to compete directly with SIMS in situ analysis, but at less cost and with greater sample throughput, though with higher sample consumption. Both SIMS and LA-ICP-MS (including LA-ICP-MC-MS) instruments are dependent on one or more reference samples for date calculation.

SIMS U–Pb methods are very sensitive to surface polish quality and surface-charging characteristics and require a careful matching of the composition (matrix) of sample to the reference material. LA-ICP-MS methods, on the other hand, are more tolerant of surface irregularities, are less sensitive than SIMS methods to sample matrix matching, consume a larger quantity of sample, and have limited ability to measure the common Pb reference isotope ^{204}Pb due to the interference with ^{204}Hg in the carrier gas. Careful work using the most sensitive LA-ICP-MS methods, however, can deliver the same age accuracy and precision as SIMS methods with consumption of sample only a factor of 2–4× greater, with laser ablation pits as small as a few μm deep and ~20 μm in diameter. Depth

profiling by both methods is possible but is more controlled via SIMS analysis. As of the time of writing, international efforts are underway to improve interlaboratory inter-comparability of U–Pb data, but a fundamental limitation of both of these in situ methods is that accuracy and precision of the $^{206}\text{Pb}/^{238}\text{U}$ ratio in a sample appears limited to $\sim 1\text{--}2\%$ 2σ on weighted mean dates, which places a fundamental limit on the ultimate age precision measured by means of the $^{206}\text{Pb}/^{238}\text{U}$ ratio. The exact reason for this limitation is likely some combination of plasma chemical fractionation and laser ablation processes, perhaps compounded by matrix matching issues.

Unfortunately, a misunderstanding of the strengths and weaknesses of both isotope dilution methods and in situ SIMS or LA-ICP-MS methods traditionally led to tension between the two methodological communities. For example, SIMS dates claiming a precision of $<1\%$ of zircon age were published in numerous studies, and some were used to attempt a refinement of the geological time scale; several of these have been refuted and subsequently refined by careful isotope dilution methods. On the other hand, many papers contain published isotope dilution U–Pb zircon data that are discordant and yield non-unique and ambiguous interpretations of age on complex multiple growth-zoned zircons. More often than not, these complex and ambiguous interpretations are from metamorphosed rocks where multiple high-temperature events have produced complicated zircons. The primary lesson from these examples is that both methods have their strengths, and when used appropriately, rocks and events can be dated in the best possible way using one or both methods. All of these methods have their place in U–Pb geochronology.

Two further methodological aspects deserve mention. Electron microprobe U–Th–Pb analysis of monazite has been done since 1994 (Suzuki et al. 1994). This “chemical” (as opposed to isotope) method of dating was refined by Montel et al. (1996) and Williams and Jercinovic (2002) primarily in Precambrian rocks where monazite contains relatively large quantities of radiogenic Pb, sufficient to overwhelm any initial common lead, while preserving the petrographic context. Monazite U–Th–Pb *isotope* dating in thin sections is the only method able to reveal the ages of very young monazites of Mesozoic–Neogene age, however. Together, EMP, SIMS, and LA-ICP-MS methods offer significant insight into the P–T–t (pressure–temperature–time) conditions and paths of metamorphic rocks of all ages from Archaean to Neogene.

Two More Innovations to Remember

A further refinement was developed over many years by James Mattinson in a procedure loosely termed “chemical abrasion” or “CA-TIMS” (Mattinson 2005). Effectively this is a recipe involving high-temperature ($\sim 900^\circ\text{C}$) annealing of zircon, followed by a HF–HNO₃ acid partial dissolution of annealed grains, which effectively removes the discordant regions (zones, cracks, etc.) of a zircon grain, leaving undissolved zircon that has been a closed system since formation. When the residual zircon is analyzed, concordant analyses often result, allowing very precise concordant ages to be determined. This is such a profoundly important procedure that it has been adopted worldwide as the routine zircon procedure for ID-TIMS methods.

Finally, any U–Pb geochronologist will understand clearly the value in accurate and sophisticated data reduction, linear regression, and graphical plotting software to diversely illustrate and determine uncertainties in ages of U–Pb data, the latter being its most important attribute. The most commonly used software to plot data, termed Isoplot, was conceived, written and refined over several decades primarily by Ken Ludwig of the Berkeley Geochronology Center (Ludwig 1991). It is one of the most important underpinning tools that U–Pb geochronologists use.

Geologists and geochronologists, indeed humans in general, have a tendency to take for granted the technological advances that make our lives easier; it is important to remember the intellectual breakthroughs as well as the sheer effort of scientists who pioneered these advances. These breakthroughs have made the science of U–Pb geochronology as apparently routine as we know it today.

U–Th–Pb Geochronology: Applications to Earth, Planetary, and Environmental Science

Applications of U–Pb geochronology are incredibly varied, more so than with any other chronometer. Topics that have been addressed by U–Th–Pb geochronology include:

- The age of meteorites, the Moon, Earth, and the Solar System
- The age of igneous events throughout Earth history, plutonic and volcanic, mafic, alkaline, and felsic
- Earth differentiation and subsequent crustal evolution
- Age of the oldest continental crust and Earth materials
- The behavior of intermediate daughter radioactive isotopes and their impact on high-precision dating
- Rates of production of continental crust
- Continental reconstructions over time involving amalgamation and dispersal of continents
- Rates of tectonic events in arcs, collisional orogens, etc.
- Age of plumes and large igneous provinces and their global impacts
- Quantification of time in pressure–temperature paths of metamorphic rocks (P–T–*t* paths)
- Chronostratigraphy, in particular in Precambrian where biostratigraphy is absent
- Calibration of the geological time scale
- Rates of cooling of orogens and rocks by using U–Pb dates as *thermochronometers* in the context of closure temperatures
- Identifying the age of sources of igneous rocks by zircon and monazite inheritance
- Dating multiple growth zones in complex minerals even at micron-scale dimension
- Timing of diagenesis and cementation of sedimentary rocks
- Precise dating of extinction events facilitating the search for causality
- Dating of calcite and phosphate of Quaternary age for environmental reconstructions and human evolution
- Provenance of sediments, sedimentary rocks, dust, river sand, and ice-rafted glacial debris

Some of these topics are elaborated in chapters within this volume, but others are less well described. The following section highlights aspects of applications that are considered particularly interesting additions to complement the other chapters.

Minerals for U–Pb Dating

The inventory of minerals available for U–Th–Pb geochronology is vast; nearly any mineral that is capable of partitioning U or Th into its structure can be dated. The most commonly used minerals are, in approximate order of their use in geochronology:

- Zircon (ZrSiO_4)
- Monazite ($(\text{Ce}, \text{La}, \text{Th})\text{PO}_4$)
- Titanite ($(\text{sphene}, \text{CaTiSiO}_5)$)
- Baddeleyite (ZrO_2)
- Perovskite (CaTiO_3)
- Apatite $\text{Ca}_5(\text{PO}_4)_3(\text{F}, \text{Cl}, \text{OH})$
- Allanite ($\text{Ca}_2(\text{Al}^{3+}, \text{Fe}^{3+}, \text{Fe}^{2+})_3\text{Si}_3\text{O}_{12}[\text{OH}]$)
- Rutile (TiO_2)
- Xenotime (YPO_4)
- Uraninite (UO_2)
- Calcite/aragonite (CaCO_3)
- Thorite ($(\text{Th}, \text{U})\text{SiO}_4$)
- Pyrochlore ($(\text{Na}, \text{Ca})_2\text{Nb}_2\text{O}_6(\text{OH}, \text{F})$)

Of these minerals only uraninite, thorite, and monazite have $>1\%$ U and/or Th. Minerals most suitable for dating have little or no initial “common” Pb; this means that when dated the Pb contained in the mineral is primarily radiogenic. However, when common Pb is significant, either due to young age or low relative ratio of U/Pb (allanite, apatite, calcite, titanite), minerals can still be dated using an isochron approach, making a correction for the common lead isotope composition. Many of these minerals are amenable to either ID-TIMS or in situ SIMS or LA-ICP-MS dating methods, the latter requiring a reference mineral of the same type for the dating procedure.

Dating of Igneous Events and Related Applications

The early quest in U–Pb geochronology was mainly about determining the age of the Earth. By 1956, sufficient U–Pb ages documented Earth’s age to be >2.6 Ga, and work by Patterson (1956) on meteorite primordial Pb combined with information on terrestrial samples demonstrated that the Earth was ~ 4.5 Ga. Most work in U–Pb geochronology of the 1950s–1960s concerned dating igneous minerals – zircon and titanite – to constrain igneous events and populate the geological time scale and using the punctuated emplacement of felsic volcanic or plutonic rocks to constrain tectonic and orogenic events. These topics are dealt with in other chapters. Zircon became the mineral of choice mainly because it was realized early on that it was very refractory, resisted resetting, and could reveal igneous events in spite of subsequent alteration and metamorphism. Indeed, the work of Gulson and Krogh (1973) and Copeland et al. (1988) documented a phenomenon called “inheritance,” which is the survival (i.e., non-dissolution) of a preexisting phase – zircon and monazite – throughout a melting and magma crystallization event due to saturation of that magma in the mineral in question. These “inherited” grains are used extensively to deduce the age and geochemical characteristics of the source and/or country rock regions of the magmas. Beginning around 1990, the mineral baddeleyite (ZrO_2) began to be dated in diabase and gabbroic rocks by U–Pb methods (Heaman and LeCheminant 1993), allowing reliable and precise ages of mafic magmas, including ophiolites to be dated. This development was paired quickly with palaeomagnetism of such rocks (dyke swarms, major mafic igneous provinces) to more robustly reconstruct the whereabouts of continental fragments dispersed by rifting and to determine the positions of continents on the Earth more accurately throughout geological time. Kimberlite dating by U–Pb is dealt with in a related chapter using the minerals perovskite and baddeleyite. U–Pb

geochronology of igneous zircon and its application to geological problems are addressed in other chapters of this volume.

Meteorite U–Pb Dating

U–Pb geochronology of meteorites is a discipline in itself, requiring very rigorous sample preparation and chemical/isotope measurement procedures; a chapter is devoted to this topic in this volume. The antiquity of meteorites and the rapid change in the radiogenic $^{207}\text{Pb}/^{206}\text{Pb}$ ratio early in Earth history resulting from higher $^{235}\text{U}/^{238}\text{U}$ permit very precise dating of crystallization of the earliest materials of the solar system such as chondrules and CAIs (calciumaluminium inclusions). These materials contain relatively high U/Pb ratios, and it has been possible to date these 4,567 Ma old grains to better than ± 0.5 Ma uncertainty.

Earth's Oldest Zircons

In terms of the oldest materials identifiable on the Earth, the detrital zircons of quartzose metasedimentary rocks (Mt Narryer quartzite; Jack Hills conglomerate) of Western Australia have been a gold mine of information. Reasonably abundant ($\sim 3\%$ of detrital zircons) > 3.9 Ga zircons occur in these samples, and they have been dated extensively ($> 100,000$ zircon grains have been analyzed). The geochemical characteristics of these old grains (Hf isotopes, rare earth elements (REE) spectra, oxygen isotopes, Ti thermometry, inclusion mineral characteristics) have been researched at length (Amelin and Ireland 2013); these are mentioned in a related chapter. Among the most interesting conclusions of these studies are that the oldest zircons on Earth are ~ 4.36 Ga, significantly younger than the last stages of crystallization of the lunar magma ocean at ~ 4.42 Ga (Nemchin et al 2009). Hf isotope studies by many authors on these old zircons reveal that most if not all are derived from mantle reservoirs that are depleted to chondritic in composition, indicating that significant silicate mantle differentiation took place very early in Earth history. The extent to which this resulted in “continental” crust, as opposed to mafic crust, is very difficult to determine and no doubt will continue to be a topic of research well into the future. On the basis of existing work, it appears unlikely that zircons > 4.4 Ga will be found on Earth, even though it is certain that scientists will continue to search for them!

U–Pb Dating of Metamorphism and Quantifying Time in P–T Evolution

A related chapter describes the application of U–Th–Pb dating of monazite, xenotime, allanite, rutile, and titanite to the chronology of metamorphism. The chemistry of these accessory minerals makes it a challenge to relate their growth directly to the pressure and temperature conditions of metamorphism, since they do not form directly from reactions of P- and T-sensitive minerals like garnet, aluminosilicates, micas, etc. Nevertheless, studies of Smith and Barreiro (1990) showed how monazite grows in amphibolite facies conditions, appearing usually in the staurolite zone of Barrovian metamorphism, a generalization that still appears to hold. Other minerals such as allanite preserve reaction relationships to apatite and monazite and at times other more abundant rock-forming minerals. Because garnet is a major reservoir for yttrium (Y) and because Y can occur in significant proportions in monazite due to its solid solution with xenotime, Y-zoning is used as a

“monitor” of the presence/relative abundance of garnet during monazite growth. This allows monazite chemistry to be used to relate its growth to conditions of metamorphism defined by other pelitic minerals. Clearly, the textural relationships of these accessory minerals in relation to the fabric of other rock-forming minerals are crucial pieces of evidence concerning the relative age of accessory minerals. For example, inclusions of accessory minerals within other P–T-sensitive phases (garnet, coesite, diamond, etc.) can preserve the oldest prograde metamorphic ages. Phases that grow during decompression and retrogression, for example, titanite in rutile-bearing eclogite, can be used to date the exhumation/retrogression part of the P–T history. In these geological situations, the use of in situ methods is usually a requirement, along with data on mineral chemistry, phase equilibria, textural data, geological setting, and field relations. In situ methods need to measure wherever possible all U–Th–Pb isotopes, not just U–Pb, for monazite, due to the problem of excess ^{206}Pb in Th-rich monazite (Parrish 1990), in order to determine accurate ages in young metamorphic rocks. Often, multiple minerals dated in the same sample will reveal a richer and more complete metamorphic history. A particularly common characteristic, which is increasingly documented in detailed studies of metamorphic rocks, is that monazite growth takes place over a long period of time, including prograde, peak, and in part retrograde conditions. Examples published recently in the Himalaya and in the Cordillera have documented tens of millions of years of time in a rock’s P–T evolution. One of the challenges in doing this in situ work is that reference minerals of well-determined age suitable for age calibration may not exist, prompting the search for better mineral standards, for example, for rutile and allanite (Bracciali et al. 2013).

U–Pb Dates of Minerals as Thermochronometers

Although many minerals datable by U–Pb methods were initially regarded as having high closure temperatures, many of these can be effectively used as thermochronometers. In contrast to zircon and monazite, it has long been documented that the retention of Pb by titanite, allanite, rutile, and apatite is not complete during amphibolite facies conditions of metamorphism or reheating. Early work in case studies showed clearly that U–Pb dates on titanite, rutile, and apatite were generally younger than the peak of metamorphism, often much younger. When considered along with dates from other minerals (micas, hornblende) of known closure temperature, the Pb-retention temperature of these minerals was regarded as being in the range of 400–600 °C. More recent experimental diffusion studies have generally confirmed these estimates. Based on empirical and experimental data, the order of retention of Pb for these minerals from highest retention to lowest is allanite > titanite > apatite > rutile, with allanite and titanite being ~600–650 °C and apatite and rutile being closer to 500 °C. When combined with other thermochronometers (Rb–Sr mica, Ar–Ar hornblende and mica, fission track, U–Th–He), a full thermal history for metamorphic rocks can be established from ~700 °C to <100 °C, with U–Pb dating constraining the thermal and mineral growth history above 400–500 °C (Parrish 2001). Together with chemical and phase equilibria data, the P–t history (exhumation and /or burial) can also be constrained, but to a lesser degree of detail.

Provenance Applications of Detrital Mineral Dating

The identification of the source of clastic sedimentary rocks, or provenance analysis, enables a reconstruction of part of the geological history. The first lines of evidence are clast composition in conglomerate and the composition of grains (lithic, quartz, feldspar, heavy minerals) in sandstone.

However, without further information, few rocks can be proven to be derived from a specific source. U–Pb dating of detrital minerals provides probably the most important information allowing the discrimination of source areas for clastic rocks. Detrital mineral dating began to be tractable once single minerals could be dated. This work began in the mid–late 1980s using single-grain ID-TIMS dating, but the tedious aspect of the dating meant that few grains could be dated in a given study. The appeal of this type of data captured the imagination of geologists, and a new field of research increasingly gained momentum through the 1990s and in recent years. Some of these studies emphasized the desirability of systematically examining the detrital zircon signatures of formations in continents and in orogens, whereas other studies applied this single-grain dating technique to specific problems, for example, the determination of the maximum age of sedimentation of a Precambrian sedimentary rock for which few depositional age constraints existed. This field has exploded into what one might call “mass production” of detrital zircon data, covering most continents’ major sedimentary rock packages and including modern river detritus.

The proliferation since ~2000 of in situ U–Pb dating methods such as LA-Q-ICP-MS has encouraged many geologists to conduct this type of work as “users” who follow a standard, often somewhat unsophisticated, recipe for analysis in order to address provenance questions. This trend involves generating a huge amount of data often illustrated in probability distribution plots that show both uncertainties and abundance of data in only semiquantified form. Sometimes the data are not uniformly rigorously collected, some having no information about whether single zones in zircon are dated, whether data are concordant or nearly so, or whether the $^{206}\text{Pb}/^{238}\text{U}$ or the $^{207}\text{Pb}/^{206}\text{Pb}$ ages are being used for the interpreted age of a grain. Although the data is usually published in supplementary tables online, the interpretation of detailed data is a challenge to obtain as an interested reader. This can compromise the robustness of such datasets. A great variety of quality of data from such studies exists, and this diversity in quality continues to be published. Readers are cautioned to examine data thoroughly and question whether interpretations made are sufficiently rigorous!

Many geological questions pertaining to provenance of sediments simply cannot be answered by zircon single-grain dating alone. Approaches that use the most pertinent geochemical and dating methods are likely to be able to answer questions better, for example, by the use of additional detrital minerals (U–Pb dating of detrital monazite and/or rutile in sediments; Ar–Ar dating of detrital mica) and the use of isotope tracers of dated minerals (Nd in detrital monazite, Sr–Nd in detrital titanite and apatite, Hf isotopes in detrital zircon) (Najman et al. 2008). Excellent science demands a broad approach that is tailored to the question being addressed and which uses the most appropriate isotope methodology.

Sedimentological, Environmental, and Paleoclimate Applications of U–Pb Dating

A chapter on U–Pb applications to diagenetic events is part of this volume and presents methods for addressing this topic. A key part of this field is the application of U–Pb methods (both ID-TIMS and in situ methods) to carbonate (calcite, aragonite) and phosphate that occur as cement or as primary sedimentary materials deposited usually from marine or freshwater (fossils, cements, speleothems, lake carbonate, carbonate veins, hominin or other animal phosphate). While there are currently few extensive studies published, it is clear that this is a field that will grow rapidly in the near future.

U is partitioned into aragonite in marine fossils, and calcite includes sufficient U to also be dated, when the initial incorporation of lead into the mineral is low, as is often the case with precipitation of calcite from groundwater. Thus when a material has a high U/Pb ratio, these carbonate or phosphate minerals can be dated, by either ID-TIMS methods (Smith and Farquhar 1989; Rasbury et al. 1997; Richards et al. 1998) or by a combination of ID-TIMS and in situ methods (Woodhead et al. 2012). Indeed it is now tractable to apply LA-ICP-MS using high-sensitivity instrumentation to date calcite in situ even when the U content is not particularly high, via the use of a calcite standard. This field of research will likely explode in popularity and demand over the next 10 years.

Collaboration and Improvement of Methods

The field of U–Pb dating has come a long way since its inception by the work of Boltwood and Holmes about 100 years ago in the period immediately following the discovery of radioactivity. With the development of sufficiently sensitive mass spectrometry by Nier in the 1930–1940s and the availability of isotope tracers of U and Pb in the 1950s and 1960s, the field of ID-TIMS exploded with refinement of methods, use of Teflon acid distillation and mineral dissolution vessels and multi-collector high-sensitivity mass spectrometers. Recognition of complex zircon growth histories demanded the development of better ways to analyze concordant zircons and develop in situ methods, which in the past 20 years have exploded in availability and popularity. This has brought U–Pb geochronology within reach to geologists, some of whom never worked in a laboratory previously. Nevertheless, the advancement in methods is very impressive, both intellectually and technologically. Innovative applications of U–Pb dating to geological problems have generally kept pace with technology, because geological questions usually precede the availability of efficient and accurate instrumentation and methods. For example, widespread detrital single-grain dating had to wait until efficient in situ methods of analysis of large numbers of grains became available. The use of single grain rutile U–Pb dating in provenance studies will become more common following the recent development of rutile reference materials and sensitive LA-ICP-MS methods (Bracciali et al. 2013). Similarly, the availability of calcite U–Pb reference materials and sensitive mass spectrometry capable of measuring young ages precisely in minerals with low U contents is just now tractable; this will cause a rapid increase in demand and application of U–Pb dating to calcite and Quaternary materials, hardly addressed at the present time.

Collaboration among U–Pb laboratories has been essential because of the inherent ability of ID-TIMS methods to measure isotope ratios apparently more precisely than one can confidently calibrate isotope tracer solutions. The EARTHTIME project (www.earth-time.org) is one of these international efforts that has recognized the need for more collaboration and use of common solutions to monitor and measure interlaboratory data, to ensure that it is comparable, and to encourage laboratories to quote uncertainties that are accurate and realistic. For example, age solutions and mixed ^{233}U – ^{235}U – ^{205}Pb isotope tracers are available to world laboratories for the purpose of improving the precision and accuracy of data produced. This effort has been extended, for example, to U-series dating and to in situ methods of U–Pb dating, so that numerous world laboratories are able to compare data, assess their own performance against international standards, and share the best practice. This type of collaborative philosophy, combined with continued technological and method innovation, is the way forward for this important area of geochronology.

Luminescence Dating, Meteorites

Derek W. G. Sears*

NASA Ames Research Center, Mountain View, California, USA

Thermoluminescence is the light produced as a result of heating. In crystalline silicate rocks, there are a variety of possible energy levels at which electrons can reside, such as the valence band and the conduction band. Ionizing radiation passing through the crystals can transfer to the electrons sufficient energy to promote them from the valence band to the conduction band where they freely move through the crystal lattice. If they locate “traps,” they can remain at an elevated energy level. Traps are typically lattice defects or impurity ions, an important example being Mn^{2+} substituting for Ca^{2+} in a silicate lattice. Calcium is an abundant element, and Ca-bearing minerals are common in meteorites, most notably as the mineral plagioclase, a Ca aluminosilicate. The traps are typically an electron volt or so below the conduction band, and this energy has to be supplied to release them. One means of supplying the required energy is by heating the crystal. Once released, the excited electrons can find their way to the ground state by way of a “luminescence center” when their excitation energy is released as a photon, normally in the visible range. The number of excited electrons determines the intensity of light emitted, and the temperature at which it is emitted, as the crystal is heated, is determined by the depth of the trap below the conduction band. Deeper traps require higher heating temperatures. Being a solid-state property, there is a distribution of traps about some mean value, and the release of electrons from traps is governed by a probability function, e.g., the Arrhenius equation, so TL peaks are fairly broad. In addition, there are usually many kinds of trap in a typical crystal lattice, so there are multiple overlapping peaks in a typical experiment. The data are recorded as light emitted as a function of heating temperature, and the resulting plot is called the “glow curve.”

Meteorites have a wide variety of composition and mineralogy, but plagioclase is present in most of them and gives rise to their thermoluminescence. There are a few exceptions, in which plagioclase is absent and the thermoluminescence is produced by pyroxene, an Mg silicate. Pyroxene has at least two types of trap, one being Mn^{2+} substituting for Mg^{2+} , but pyroxene luminescence is “quenched” (destroyed) in the presence of Fe^{2+} which provides pathways for the electrons to reach the ground state without a visible transition. A recent review of the application of thermoluminescence to the studies of extraterrestrial materials is given by Sears et al. (2013).

The thermoluminescence mechanism enables several potential means of dating a meteorite. An early idea was that the traps were dislocations caused by radiation damage so that the number of traps built up with time and thus provided a “clock.” The basis of the idea was an observed correlation between induced TL and potassium-argon age (Komovsky 1961). Induced TL (sometimes referred to as “artificial TL” in the early literature) is the TL signal obtained by draining the meteorite of its natural TL and exposing the meteorite to a standard test dose of radiation in the laboratory. The idea of induced TL as a clock has not withstood the test of time, however, since exposure to radiation doses and fluencies greater than the meteorite experienced in nature do not change the induced TL response (Sears 1980). Instead, it seems that meteorites with low induced

*Email: derek.sears@nasa.gov

TL and too young potassium-argon ages have experienced severe shock-heating events that melted the plagioclase and caused the loss of Ar. Thus, while induced TL failed as a proposed chronometer, it succeeded as a new means of evaluating the shock-heating history of meteorites.

Thermoluminescence dating applications that have been proposed and developed in the literature and that have some degree of success are as follows.

Terrestrial Age Determination by TL Fading. Terrestrial age determination for meteorites, the time that has lapsed since their fall from space, has taken on particular interest with the discovery of large numbers of meteorites in the prairies, deserts, and Antarctic ice fields. A meteorite in space is exposed to large doses of radiation from internal radioactivities and cosmic rays, cosmic rays being the more important in the short term. The level of TL is determined by a competition between decay at ambient temperatures and buildup depending on the radiation dose rate. Once on Earth, the meteorite is shielded from the high dose of cosmic rays experienced in space and stored at a higher temperature on Earth than in space, so the TL level adjusts to the new environment by slowly fading to its new lower equilibrium level. Thus, one has the potential to determine how long the meteorite has been on Earth from the extent of fading. There are two issues to be resolved. One is that meteorites enter the atmosphere with a wide variety of natural TL levels, depending on the temperature of the object in space and the degree of “shielding” available to the sample, that is, how deeply it was buried within a larger body while in space. There is no way around this problem, and shielding is a problem shared with the isotopic methods for determining terrestrial age such as those using the decay of radiocarbon. The second issue is the effect of different storage temperatures on Earth, but these can be handled fairly well from knowledge of climate temperatures and theoretical modeling of the decay process. Several major studies of this process have been reported (Melcher 1981; Sears and Durrani 1980; Benoit et al. 1991; Sears et al. 2011), and it was one reason for routine natural TL measurements being incorporated in the US Antarctic Meteorite Program (Hasan et al. 1987).

Terrestrial Age by Buildup of TL in the Meteorite Just Under the Fusion Crust. This is sometimes referred to, somewhat misleadingly, as “fusion crust dating.” As a meteorite passes through the atmosphere, its surface is heated to the extent that a conspicuous melt crust is formed. The high heat capacities of silicate rocks and the ability of the melt to flow away from the meteorite mean that the heat of atmospheric entry does not penetrate far into the meteorite. However, for a few millimeters under the fusion crust, the meteorite will have been heated enough to drain the natural TL. Once on Earth, environmental radiations will cause the TL to build up again, and there is the potential to determine terrestrial ages using the same methods as used for dating pottery. The level of TL is measured and converted into an absorbed dose using laboratory calibration experiments. Then, the environmental radiation dose rate is determined by placing dosimeters in the field. Finally, absorbed dose is divided by dose rate to determine the age. Only a few studies have been made of this technique, but the results seem promising (Miono and Nakanishi 1994; Akridge et al. 2000).

Cosmic Ray Exposure Age by Natural TL Buildup. There has always been a sense that the thermoluminescence phenomenon should yield a means of determining cosmic ray exposure age, literally the time that has lapsed since the meteorite became exposed to cosmic rays. Consistent with this idea is the observation that the natural TL levels observed throughout large pieces of meteorite vary, reflecting the buildup and decay of primary and secondary radiations during cosmic ray exposure. However, it is only recently that quantitative efforts have been made (Biswas et al. 2011) in this direction, and the technique is in its infancy.

Luminescence, Soils

Arjun M. Heimsath*

School of Earth and Space Exploration, Arizona State University, Tempe, AZ, USA

Definition

Luminescence dating measures the time since quartz and feldspar mineral grains were last exposed to light. Dating soils with this method quantify the last time mineral grains sampled from within soil profiles were at the ground surface.

Soils can be defined in many different ways depending on the environmental context. For the purposes of this application, soils are defined as colluvial material produced from underlying parent material and being transported by various physical processes. Windblown soils, agricultural soils, and deep chemical weathering profiles are not considered here.

Introduction

Hilly upland landscapes are cloaked in a thin layer of soil derived primarily from the underlying parent material (Carson and Kirkby 1972; Dietrich et al. 1995; Heimsath et al. 1997) (Fig. 1). Understanding how the Earth's surface evolves under changing climatic, tectonic, or human land-use forces thus includes understanding how these physically mobile upland soils are produced and transported. Setting aside landslides, which are likely to dominate soil erosion in steep and mountainous terrain, soil moves slowly downhill by creep and slope wash. Observations from gently rounded hills show that soil thickness increases with distance downslope, supporting the view that creep occurs by diffusion-like processes with the amount of soil moving being linearly proportional to surface slope (Carson and Kirkby 1972; Heimsath et al. 1999; Young 1960). Such movement of individual soil grains could be caused by burrowing creatures (worms, ants, gophers, etc.) and by tree throw (trees uprooted, typically by high winds, often carry soil and bedrock attached to the root wad) coupled with localized slope wash. Field observations and laboratory studies also show that other processes may also transport the soil, including shear and depth-dependent viscous-like flow (Carson and Kirkby 1972; Fleming and Johnson 1975; Selby 1993; Young 1960). Tracking the transport paths of soil particles helps build our understanding of these processes (Fig. 2). Dating the last time soil minerals were at the ground surface can enable further quantification and establishing mathematical relationships capturing the essence of these processes. These relationships can then be used in models that can help predict soil sustainability, landslide frequency, and magnitude and also help develop water management and land-use development plans.

Other Methods for Dating Soils

Early thinking about how hilly, upland landscapes evolve with time recognized that landscape morphology likely reflects the long-term dominant process shaping the landscape (Davis 1892;

*Email: arjun.heimsath@asu.edu

Fig. 1 (a) Photograph of typical soil-mantled hillslope used for studies such as the ones covered in this chapter. This one is from Point Reyes, CA, during the late summer dry season. (b) Photograph of the well-mixed colluvial soil that mantles the same landscape enriched with organic matter and quite moist during the winter rains. Note the well-defined boundary between the physically mobile soil above (*dark layer*) and the underlying weathered bedrock that retains relict rock structure and is considered to be in place. *Holes* are from bulk density sampling

Fig. 2 (*Upper Panel*): The conceptual framework as used by Heimsath et al. (1997) and similar studies for vertical soil depth, h indicating that the slope-normal depth, H , is equal to the vertical depth times the secant of the slope angle. The change in soil mass in a column of soil with time is equal to the production of soil from the underlying bedrock minus the balance of soil transported past the column. (*Lower Panel*): Idealized displacement profile (a) showing how soil particles might move from a to b in a “laminar flow” path envisioned by Fleming and Johnson (1975) and later sketched in by Selby (1993). The *right-hand side* (b) shows Selby’s sketch of the commonly recognized “chaotic” flow path of soil particles that may be mixed while the soil profile is shrinking and swelling from changing water content

Gilbert 1909). Specifically, the observation that smooth hillslopes tended to steepen with increasing distance from the drainage divide led to the assumption that sediment transport flux, which must increase with increasing distance from the divide, is proportional to topographic gradient. This led to the writing of a linear transport relationship, which became known as the “diffusion equation” because of its similar form to Fick’s law of heat diffusion. Because creep processes were thought responsible for transport that could be modeled as “diffusive,” the term “diffusion” became synonymous with creep. Recently, more accurate terms such as “diffusion-like” or “linear transport relationship” are favored since soil particles are not actually diffusing downhill. They are, however, moving in a creep-like way as gravitational force imparts a downslope preference to any physical disruption of the soil. Quantifying the process necessitates dating or tracking the particles.

Physical Tracers

An innovative and not often repeated study attempting to quantify soil movement using physical tracers was published in *Nature* over half a century ago (Young 1960). The study recognized the importance of quantifying rates and processes of hillslope denudation and set about doing it by initially inserting metal pegs into the ground surface at regular intervals downhill from a bedrock outcrop, noting the distances carefully and tracking surface movement of clasts over time. The uncertainty involved with peg surface displacement was huge, and the problem with discerning surface transport from downslope movement occurring within the soil profile led to a modification of the method to develop what became known as a “Young Pit.” Despite two publications in *Nature* (Young 1960, 1963a), few studies have followed the lead of this challenge (e.g., (Finlayson 1981; Schumm 1967), including a modified approach (Richards and Humphreys 2010) that yielded results no less equivocal. Even the results of Schumm (1967), often cited as one of the few field-based studies quantifying soil transport processes, show considerable scatter and were collected over a 7-year period, longer than most are willing to devote to a single study. Given the results (or lack thereof) from the two most recent studies (Clarke et al. 1999; Richards and Humphreys 2010), few others have attempted to follow Andrew Young’s inspirational lead.

Tephra Deposits

Fortunately, geochemical methodological advances have enabled us to directly quantify processes and rates with significantly less uncertainty and physical effort. Another innovative approach that involves using a physical tracer that does not involve human disturbance (i.e., the digging of numerous Young Pits) is worth summarizing. Of course, this physical tracer method also involves using geochemistry, as the studies do rely on relatively precise geochemical dating (using calibrated ^{14}C dating) of tephra deposits in upland soils. Two recent studies documented profiles of tephra concentrations in hillslope soils and combined a detailed mapping of these concentrations with topographic derivatives to quantify soil transport processes (Roering et al. 2002; Walther et al. 2009). In both cases, one on a series of incised fluvial terraces along the Charwell River, South Island, New Zealand (Roering et al. 2002), and the other along a hillslope transect in the Blue Mountains, SE Washington state, USA (Walther et al. 2009), the tephra deposits are well dated and are treated as marker beds in the hillslope soils. Both studies involved extensive sampling of soil pits and auger profiles to quantify tephra distributions in the hillslope soils. Because the sample locations were located along profiles characterized by the topographic properties supporting linear transport relationships, the topographic derivatives were used with tephra distribution and concentration to provide calibrated transport relationships for each field site. Given the paucity of such field-based data supporting transport relationships, these studies are especially important. Given how difficult it

is to find such ideal field locations where there are both well-dated tephtras and hillslopes of characteristic form, such an innovative method is unlikely to be broadly used.

Short-Lived Isotopes (^{210}Pb and ^{137}Cs)

A technically less cumbersome approach involves using short-lived isotopes measured in bulk soil samples that can be collected without any disruption (i.e., by inserting tracers) and without any special site characteristics (i.e., dated tephtra layers). These fallout-derived radionuclides are used extensively in erosion and sediment transport studies on both agricultural and forested landscapes. Atmospherically delivered ^{210}Pb and weapons-derived ^{137}Cs can be used alone or simultaneously to quantify and trace erosional processes (Wallbrink and Murray 1996; Walling and He 1999a, b; Whiting et al. 2001). Relative rates of soil mixing can be evaluated through measurements of nuclide activities in soil profiles (Dixon et al. 2009; Dorr 1995; Kaste et al. 2007; Tyler et al. 2001). Because these isotopes are deposited at the soil surface, mixing processes can increase the dispersion of nuclides with depth and the overall downward transport rate. For example, on agricultural landscapes, where tilling homogenizes the soil to the depth of the plow layer, a unique, well-mixed ^{137}Cs profile captures the process (Walling and He 1999a). By measuring the vertical distribution of fallout radionuclides in soils and calculating diffusion-like coefficients, the sediment transport mechanisms and mixing rates are quantified over 10- to 100-year timescales.

Meteoric ^{10}Be

In addition to short-lived isotopes, fallout-delivered (or garden variety) ^{10}Be can be used to quantify hillslope sediment transport processes over longer timescales (Jungers et al. 2009; McKean et al. 1993; Monaghan et al. 1983). Meteoric ^{10}Be is a cosmogenic radionuclide well suited for use as a tracer of soil movement over geomorphic timescales. Spallation of oxygen and nitrogen in Earth's atmosphere produces the majority of ^{10}Be present in natural systems (Lal and Peters 1967). Following production, ^{10}Be is delivered to the Earth's surface at a rate most significantly proportional to regional precipitation fluxes. A smaller, but not insignificant, inventory of ^{10}Be falls from the atmosphere adsorbed to terrestrial dust. The timescale over which any radioactive tracer is useful is a function of the rate at which the isotope is produced and/or delivered to the natural system of interest and of the rate at which the radionuclide decays (^{10}Be has a half-life of 1.39×10^6 years) making it especially useful as a tool for quantifying rates of Earth surface processes that take place over thousands to millions of years. Additionally, ^{10}Be adsorbs quickly and strongly to soil particles and a soil mantle's total ^{10}Be inventory can reliably be accounted for if samples integrate from the soil-atmosphere interface to the contact between soil/saprolite and unweathered bedrock. Naturally, it follows that landscapes with relatively thin (0–150 cm) soil mantles are best suited to the task of capturing complete ^{10}Be inventories. Measurement of meteoric ^{10}Be is not trivial or inexpensive, however, and application of this methodology is limited.

Luminescence Dating of Soils

Rods, blocks, and flexible tubes inserted in the soil are too clumsy to examine grain scale sediment transport, which requires the use of labeled particles (Selby 1993). Insertion and detection of labeled grains throughout a soil mantle with microscale positional measurements would be a massive undertaking (Cox 1990; Cox and Allen 1987; Nichols 2004). Assuming, however, that grains brought to the surface by bioturbation and tree throw are buried again, vertical mixing at the grain scale may be determined by measuring the time since individual soil grains last visited the surface.

This was first done by single-grain optical dating, which is based on an optically stimulated luminescence (OSL) signal that accumulates within buried quartz grains and is reset to zero by exposure to sunlight (Heimsath et al. 2002).

OSL became the established successor to thermoluminescence (TL) as the means for measuring the time elapsed since a mineral grain's last exposure to sunlight (e.g., Aitken 1985; Aitken 1994; Duller 1996; Huntley et al. 1985; Roberts et al. 1990; Roberts et al. 1997). The OSL measurements from quartz and feldspar grains focus on the most light-sensitive electron traps, less readily measurable than TL. While exposure ages can be measured from both minerals, quartz is the dosimeter of choice because the microdosimetry in feldspar grains is complex and the stored dose decays unpredictably (Murray et al. 1995). The OSL dating initially used gram-sized samples of thousands of sand grains. The second stage of development involved the "small aliquot" methods, which used a few tens to a few hundred mineral grains per sample. Several recent reviews provide details of the methodology (Fuchs and Lang 2009; Madsen and Murray 2009; Rhodes 2011; Stockmann et al. 2013). The essence of the methodology applied to dating soils involves following detailed steps that are expanded upon in the above references.

While most applications of OSL dating of soils have been toward dating human artifacts and sedimentary deposits, the methodology can readily be used to quantify hillslope sediment transport rates and to distinguish between different transport processes. Optical ages of grains from different depths depend on transport processes: for example, grains moving in a surface layer would intermittently be exposed to sunlight, whereas grains never exposed at the surface should show "infinite" ages. Alternatively, mixing throughout the entire soil column would lead to finite-aged grains from the soil surface to its base, the boundary with the underlying saprolite, and the source of the mobile soil.

Downhill movement of any soil grain resolves into slope-normal and slope-parallel components. Only the slope-normal velocity of a grain can be derived from its optical age. Such methods cannot assess the slope-parallel velocity of individual grains, but the depth-averaged velocity can be calculated if the rate of soil production from rock weathering is known at all points and if the topography of the site is well constrained. Soil-production rates were previously determined from measurements of the in situ cosmogenic nuclides ^{10}Be and ^{26}Al (Heimsath et al. 2000) and were then used in a new way by Heimsath et al. (2002) to derive slope-parallel velocities. Additionally, modeling of the landscape evolution of the site (Braun et al. 2001) highlighted the need for more detailed field understanding of sediment transport processes active on soil-mantled landscapes. Unfortunately, the resource intensity of using OSL to date individual soil grains and attempt to fully quantify soil transport processes proves to be a significant hurdle.

More recent work expanded upon the methodology of Heimsath et al. (2002) by using OSL to derive soil-mixing rates for a set of soil pits from hilltop to base (Stockmann et al. 2013). Similar results led the authors to discern between soil grains that had been mixed throughout the soil column, ones that had never been to the surface and ones that were very recently bleached by the sun. The authors did not use the ages to determine or verify a transport relationship for the sediment transport at the site, but were able to quantify mixing rates and suggest that faunal mixing was less dominant than at other studied sites.

Summary and Conclusions

Establishing chronologies for profiles of soils and for young sedimentary deposits is an essential aspect of quantifying sediment transport processes and rates. Dating soils also enjoys wide

application to archaeology, land-use management, tectonic geology, and sedimentary geology. It is, however, exceedingly difficult to do and decades of work involving scores of researchers and a wide variety of methodologies have been devoted to it. Luminescence dating, specifically OSL and especially single-grain OSL, shows great promise as the leading methodology that enables both an accurate and precise dating tool that is ideally suited to the task. There are, however, essentially only two studies that have applied single-grain OSL dating to the rich problem of dating soils and using the dates to better understand erosional processes. The other applications of dating soils (sediments) have focused on the age of the deposit for archaeological needs rather than geomorphic. There are many challenges to overcome before this methodology becomes more widespread. First and foremost is the fact that sample collection is challenging and needs to be carefully tailored to the process geomorphology of the site in question. Second and related to the first because of the limits on sample numbers is that the method is relatively expensive, with each analysis approaching the cost of obtaining a cosmogenic nuclide age analysis. Third, there remain sources of significant uncertainty in establishing the particle flow paths such that interpreting the OSL age can be a challenge. Given the nearly endless list of exciting scientific problems that can be tackled using luminescence dating of soils, it is likely that these challenges will soon be overcome and this method will truly shine.

Luminescence Dating, Uncertainties, and Age Range

Jakob Wallinga^{a*} and Alastair C. Cunningham^b

^aSoil Geography and Landscape group, Wageningen University, Wageningen, The Netherlands

^bCentre for Archaeological Science, School of Earth and Environmental Sciences, University of Wollongong, Wollongong, Australia

Definition

Luminescence ages have an uncertainty of at least 4–5 %, mainly due to systematic errors in both dose rate (conversion factors) and equivalent dose (source calibration) estimation. In most cases, the uncertainty will be higher, due to random errors (e.g., spread in equivalent doses) or uncertainty in assumptions (e.g., water content fluctuations, burial history). Dating is possible for a wide age range of a few decades to about half a million years, although uncertainties are usually relatively large toward the extremes of this range.

Uncertainties

As with any method, results of luminescence dating contain errors or uncertainties. Adequate assessment of errors is important, for instance, to correctly assess rates of processes or leads and lags in natural or anthropogenic systems, or contemporaneity of different sites (e.g., Guerin et al. 2013). It is common practice in the luminescence community to present 1-sigma uncertainties, implying that there is a 68 % likelihood that the true answer is within the presented range. This of course only holds if all sources of uncertainty are adequately considered.

Error propagation in luminescence dating is not straightforward. Uncertainties in both dose rate and palaeodose estimation should be taken into account, as both contribute equally to the uncertainty in the final age estimate. Moreover, the errors should not only comprise the measurement uncertainties (e.g., counting statistics) but also the uncertainties in instrument calibration and parameters used in calculations. Finally, difficult-to-quantify errors may arise from assumptions made for equivalent dose or dose rate calculation. The most-important sources of uncertainty are discussed below, differentiating between random and systematic errors. The first arise mainly from counting statistics and may be reduced by additional measurements (i.e., longer duration, more samples, larger samples). The latter are usually related to instrument calibration, conversion factors used, or assumptions made and cannot easily be reduced.

Equivalent Dose Uncertainty

Statistical aspects of equivalent dose estimation have recently been discussed in detail by Galbraith and Roberts (2012). Here we provide a short summary of the most relevant information:

Individual Aliquots

Luminescence measurements for luminescence dating are carried out on subsamples; each of these aliquots consists of a single grain or a group of grains (up to many thousands for fine-grained dating).

*Email: jakob.wallinga@wur.nl

In the widely used single-aliquot regenerative dose (SAR) procedure for equivalent dose determination (Murray and Wintle 2000, 2003; Wallinga et al. 2000), repeated luminescence measurements are made on the same sample, to compare the natural luminescence signal to artificially induced signals and to monitor and correct for luminescence sensitivity changes during this procedure. For each of the luminescence measurements, the true luminescence signal is estimated based on the measured value. The uncertainty in the estimate is a function of the brightness of the signal and that of the associated background signal that is subtracted to obtain a net signal (Poisson statistics assumed). The uncertainty in the equivalent dose estimate of the aliquot should take the uncertainties in each of these individual estimates into account, as well as the uncertainties in fitting a dose–response curve through the data (see Duller 2007; Galbraith and Roberts 2012), and the additional error arising from instrumental uncertainty (e.g., Duller 2007).

Sample

In the next step, data obtained on the aliquots is combined to obtain the best estimate for the equivalent dose of the sample. For an ideal dataset showing a normal distribution around the mean and identical error terms, this can be done using the mean and standard error on the mean. Here the standard error (standard deviation divided by the square root of the number of measured aliquots) is used, as we are interested in how well we know the mean value. For estimates with widely differing uncertainties, it may be beneficial to use a weighted mean, where the best known estimates are given more importance than the lesser known points. However, use of the weighted mean assumes that there is a true burial dose to which all grains/aliquots belong, and the departure of the measured data from this value is due to the known uncertainties of measurement (i.e., the error term). In the real world this is not the case – even if the measurement uncertainties were infinitely small, the equivalent doses would not be identical.

The Central Age Model (CAM) (Galbraith et al. 1999) provides a better estimate of the burial dose. The CAM presumes instead that the single-aliquot equivalent doses are drawn from a log-normal distribution; the parameters of the distribution are then the “central age” (=burial dose) and the “overdispersion” (the relative standard deviation of the underlying log-normal distribution) and are determined by iteration or optimization. There is a straightforward estimate of the uncertainty on both parameters implemented in the model.

For datasets affected by heterogeneous bleaching, the true age is not represented by the mean or weighted mean, but is more likely to be at the lower end of the equivalent dose distribution. The correct estimate may be found using methods that distinguish dispersion in the data due to heterogeneous bleaching and dispersion from other sources. The Minimum Age Model (Galbraith et al. 1999) is most widely applied, although an alternative approach has been proposed by Thomsen et al. (2007); a study on young floodplain deposits from Australia yielded similar results for both methods (Sim et al. 2014). A crucial aspect in interpreting equivalent dose distributions is to quantify the spread due to sources other than heterogeneous bleaching. Such spread firstly comes from counting statistics, but this error can be adequately quantified and taken into account; it does not contribute to the overdispersion (Galbraith and Roberts 2012). There are two categories of overdispersion: (1) Intrinsic sources are the effect of experimental limitations and can be quantified using dose recovery experiments on uniformly gamma-dosed samples (Thomsen et al. 2007). (2) Extrinsic sources reflect true variation in burial doses, e.g., due to beta dose rate heterogeneity (e.g., Cunningham et al. 2012). Both sources should be quantified to accurately interpret equivalent dose distributions.

Arnold and Roberts (2009) report that 20 % overdispersion is typical at single-grain level for well-bleached samples, and Cunningham et al. (2011a) discuss how this value changes with aliquot size.

However, both intrinsic and extrinsic sources of scatter are likely to vary between samples (Arnold and Roberts 2009) and with absorbed dose (Thomsen et al. 2007, 2012). For this reason, it is advisable to include an uncertainty in the assumed overdispersion when adopting the Minimum Age Model. Such an approach has been proposed by Cunningham and Wallinga (2012); their bootstrapping approach provides reasonable uncertainty estimates for heterogeneously bleached samples, by linking uncertainty to the number of aliquots consistent with the minimum dose/age.

Calibration

The random errors in equivalent dose based on measurement uncertainties and spread in distribution may in principle be reduced by enlarging the dataset or improving the measurements. For the final error estimate, these sources of error should be combined with the systematic uncertainty in calibration of the radioactive source used for equivalent dose determination. Bos et al. (2006) have described a detailed calibration procedure and argued that the uncertainty in calibration is at least 2 %.

Other Errors

The premise of luminescence dating methods is that the dose–response of the natural luminescence signal can be reconstructed in the laboratory, allowing the burial dose to be inferred. Protocols like the SAR accomplish this by taking shortcuts: using preheats to simulate the effect of time on the OSL traps and high laboratory dose rates to simulate the low dose rates in nature. Subtle imperfections in this methodology can induce error in the equivalent dose. For example, the OSL signal may be sensitive to the rate at which the radiation dose is given, contributing to the poorer accuracy observed for older samples (Bailey 2004); the signal is also sensitive to the choice of preheat used (Wintle and Murray 2006). These sources of error are usually ignored, likely because it is very difficult to quantify the uncertainties associated with them. As a consequence, the errors are not reflected in the quoted uncertainty, but rather they define the practical limits of OSL dating. Anomalous fading of the feldspar signal also falls into this category of error; corrections for anomalous fading are sometimes made, but uncertainties associated with such corrections may be large and nevertheless are rarely addressed explicitly (e.g., Kars et al. 2012).

Total Equivalent Dose Uncertainty

For ideal samples, the total uncertainty in equivalent dose is dominated by the uncertainty in the calibration of the beta source and can be as small as 2 %. Measurement of limited number of subsamples and/or scattered equivalent dose distributions may lead to larger errors.

Dose Rate Uncertainty

Concentration Measurements

As with the equivalent dose estimate, there are multiple sources of error in the dose rate estimation. The sources of error depend on the method used for dose rate determination. Usually radionuclide concentrations are estimated either by measuring activity concentrations (e.g., gamma spectrometry) or by estimating radionuclide concentrations based on measured chemical concentrations (e.g., ICP, neutron activation analysis). The quoted errors should include both the random (counting statistics) and systematic (instrument calibration) errors. Minimal feasible relative errors are about 3 % (Murray and Olley 2002).

Conversion Factors

In the second step, infinite matrix dose rates are calculated from the radionuclide (activity) concentrations using conversion factors (Guerin et al. 2011). Unfortunately, neither Guerin et al. (2011) nor previous publications on this topic (e.g., Adamiec and Aitken 1998) discuss uncertainties in the conversion factors. Murray and Olley (2002) estimated an uncertainty of 3 % on the conversion factors, a value that is still reasonable for the updated conversion factors (Guerin, pers. com.).

Attenuation Factors

The third step involves the conversion of infinite matrix dose rate to dose rates in the grains of interest. This dose depends on the grain size due to partial shielding of the inside of the grains to beta irradiation. This effect, combined with effects of etching the surface of quartz grains during sample preparation, is taken into account in the beta attenuation factor (Brennan 2003). The uncertainty in beta attenuation factor is usually assumed to be around 2 % (Murray and Olley 2002). Then, the shielding effect of water should be considered (Aitken 1998), where 1 % by weight of water decreases the dose rate by about 1 %. Any uncertainty on the time-integrated average water content should be reflected in uncertainty in the water attenuation factor and hence the dose rate. Uncertainties in dose rate due to water content errors can be minor (<3 %) for sandy deposits, especially when the water content history is well established, e.g., because it is clear that the sampled material has always been above or below the groundwater table. However, for clay-rich sediments which can double in weight due to water uptake, uncertainties in dose rate due to poorly known water content history can be huge (>100 %). This is particularly relevant to lake-bed sediment, where water content can also change over time due to sediment compaction (e.g., Buylaert et al. 2013)

Cosmic Rays and Alpha Particles

Finally, the contribution of cosmic rays and internal alpha particles to the total dose rate should be considered. The cosmic dose contribution is well defined based on geographic location, height, and burial given by the present-day burial depth (Prescott and Hutton 1994; Madsen et al. 2005). However, in many cases, the burial history is not well established, leading to a relative uncertainty of about 10 % in the cosmic dose contribution. In most cases, the cosmic dose rate is a small portion of the total dose rate, and uncertainties will have a minor impact on overall uncertainties (<2 %). However, in exceptional cases of shallow deposits with low radionuclide concentrations (e.g., quartz-rich deposits), the cosmic dose may contribute up to 50 % of the total dose rate (e.g., Rink and Lopez 2010). The internal alpha dose is usually estimated based on literature information (e.g., Vandenberghe et al. 2008). Although the relative uncertainty in internal alpha dose is large (up to 50 %), the effect on total dose rate is usually limited (<2 %) due to the small relative contribution to the total dose rate.

Other Sources

In addition to the sources of error discussed above, additional uncertainties may arise for specific cases. When feldspar minerals are used, the dose rate should include the contribution from internal potassium and rubidium. Usually, concentration of these radionuclides is not known for the measured grains, and a standard value and uncertainty is assumed (Huntley and Baril 1997; Huntley and Hancock 2001). For fine-grained material, or non-etched grains, the external alpha contribution should be considered and require adequate assessment of the alpha dose and alpha efficiency as well as their associated uncertainties. Also, disequilibrium in decay chains may add to the uncertainty in the final dose rate (e.g., Olley et al. 1997).

Total Dose Rate Uncertainty

For ideal samples, the uncertainty in dose rate is dominated by uncertainties in radionuclide (activity) concentrations (3 %) and conversion factors (3 %). The combined effect of these is around 4 %, which is considered the minimum reasonably attainable uncertainty on dose rate. In many cases, uncertainty will be greater due to uncertainties in burial history and water content. Uncertainties mostly vary between 5 % and 10 % for suitable and less-suitable circumstances, respectively.

The calculation of dose rates and their uncertainties described above make two key assumptions. The first is the “infinite matrix” (IM) assumption, in which the radiation emitted from the sample is equal to that coming in from the surroundings. The second is the “uniform matrix” assumption, in which all parts of the sample are identical. When these assumptions are broken, a correction must be made, implying an increase in the total uncertainty. For example, an object or sedimentary bed within 20 cm of the sample may break the IM assumption (e.g., Wallinga and Bos 2010) as will be the case for deposits that remained at shallow depth for part of their burial history (e.g., Madsen et al. 2005); an irregular sample component, such as shells or pebbles, may break the UM assumption (Cunningham et al. 2011b).

Age Uncertainty

Simple error propagation is usually applied to obtain the uncertainty on the age estimate from uncertainties in equivalent dose and dose rate. Based on the minimal feasible uncertainties presented above, an error of 4–5 % of the age could be obtained (e.g., Ballarini et al. 2003; Roberts and Plater 2007). Smaller uncertainties are not realistic, larger uncertainties are the norm due to limited and/or scattered equivalent dose datasets, and uncertainties in burial history and time-averaged water content.

For larger datasets, uncertainties may be reduced by combining results from a single event layer or by incorporating prior information (e.g., the stratigraphic order) into a Bayesian framework (Rhodes et al. 2003; Cunningham and Wallinga 2012). Care should be taken to differentiate between random and systematic errors. When analyzing the internal consistency of a dataset, only random errors need to be included. However, when luminescence ages are combined or compared with other age information, the systematic errors should also be considered. This issue is discussed in detail by Rhodes et al. (2003).

Age Range

Luminescence dating is a family of methods, using different luminescence signals of natural minerals. Quartz and feldspar minerals are mainly used, and this discussion will concentrate on these minerals.

Lower Dating Limit

Two aspects are important in discussing the lower age limit for luminescence dating:

1. Resetting of the luminescence signal prior to deposition and burial. Incomplete resetting will result in an overestimation of the burial age. Hence, it is advisable to use a luminescence signal that is rapidly reset upon light exposure. This is especially important for young samples, as the remnant age is more likely to be large compared to the burial age of the sample. As the fast-component OSL signal of quartz is most rapidly reset, quartz should be the mineral of choice and appropriate methods should be used to maximize the contribution of the fast component to the net

- signal used for analysis (Cunningham and Wallinga 2010). Madsen and Murray (2009) review the dating of young sediments and show successful application to deposits less than 10 years old.
2. Luminescence sensitivity. The luminescence sensitivity of the quartz or feldspar minerals determines the minimum detection limit of the signal. Usually this is not an important constraint, as results can be improved by measuring more aliquots and averaging results. Ages of around 10 years can be obtained, although the uncertainty tends to be large (c.50 %). In practice, the lower age limit for precise ages is a few decades (see Madsen and Murray 2009).

Upper Dating Limit

The upper age limit of luminescence dating is determined by the saturation of the luminescence signal used. Luminescence dose–response curves can usually be satisfactorily approximated by a saturating exponential Eq. (1):

$$I(D) = I_S \left(1 - \exp^{-\frac{D}{D_0}} \right) \quad (1)$$

where I is the luminescence signal intensity (after background subtraction), I_S is the saturation level, D is the absorbed radiation dose, and D_0 is indicative of the onset of saturation, i.e., it characterizes the shape of the curve. For high doses, the luminescence signal approximates the saturation level and hardly increases with dose and cannot be used to reliably infer the burial dose. Wintle and Murray (2006) suggested that reliable burial dose estimation is limited to the area below $2 \cdot D_0$, and this (arbitrary) criterion is generally applied. In some cases, dose–response curves show an additional saturating exponential component or linear component with continued growth at very high doses. However, the suitability of these components for dating has not been established (Murray et al. 2008), and using this region for dating is therefore not advisable.

Saturation doses for the fast component of the quartz OSL signal vary between samples, with average $2 \cdot D_0$ values around 150 Gy. The resulting age range depends on the dose rate for the sample, but is usually no more than 150,000 years. However, due to sample-to-sample differences in both saturation levels and environmental dose rates, the upper age limit for quartz OSL dating can widely vary and may extend up to 400,000 years (Wallinga et al. 2007).

Extending the luminescence age range is possible by using other luminescence signals, either from quartz or from feldspar. A range of methods have been proposed that use luminescence signals from quartz that saturate at higher doses. Although promising results have been obtained using thermally transferred OSL (reviewed by Duller and Wintle 2012), and violet stimulated luminescence (VSL, Ankjaergaard et al. 2013), these methods are still in development and should be further tested before routine application is feasible.

Feldspar IRSL signals saturate at higher doses than the fast-component OSL signal of quartz, but the application of feldspar dating has long been held back by athermal instability of feldspar luminescence signals (“anomalous fading,” e.g., Wallinga et al. 2007). Recently, these problems have been largely overcome using elevated temperature post-infrared IRSL signal (Thomsen et al. 2008). Post-IR IRSL methods have recently been tested and applied and are now routinely determining ages up to approximately 500,000 years (e.g., Thiel et al. 2011; Buylaert et al. 2012; Kars et al. 2012). Excellent agreement between post-infrared IRSL dating and coupled ESR/ $^{230}\text{Th}/^{234}\text{U}$ dating of tooth enamel at Mala Balanica cave in Serbia (Rink et al. 2013) further supports the use of this method near 500,000 years. Following these encouraging findings, we expect post-infrared IRSL dating methods to be further developed in the near future and be widely

used for dating Quaternary sediments. However, the method is less suitable for younger deposits as the post-infrared IRSL signal is not readily bleachable (Kars et al. 2014), which could potentially result in age overestimation.

[Tsunami deposits](#); [Tsunami sediments](#); [Tsunamiite\(s\)](#)

Definition

Sediments eroded, reworked, transported, and deposited by a tsunami often generate deposits referred to as of tsunamigenic origin, hence tsunamigenic sediments. They are a result of tsunami inundation pending coastal conditions and availability of material. Tsunami deposits contain “exotic” materials of allochthonous provenance when compared to the sediments present at the location the tsunami struck.

Tsunami deposits are considered primary paleoseismic evidence when generated coseismically and can also be defined as off-fault instantaneous stratigraphic expressions of tectonic deformation (McCalpin 2009).

Tsunami is a Japanese word meaning “harbor wave” and was adopted by the scientific community to define long-period waves generated by the sudden vertical displacement of a large volume of water within a water basin (e.g., estuary, lake, sea, ocean).

Geological Signatures

In order to understand the significance of and date any catastrophically produced event, it is important to understand the sedimentological product (Einsele et al. 1996). Despite their potential destructive and erosive power (i.e., creation of geomorphic features), tsunamis can also generate stratigraphic expressions as a result of deposition of tsunamigenic sediments. The magnitude of the tsunami may be determined by the significance of the evidence (i.e., extent, thickness, and geometry of the deposit, type of sediment) and the degree of destruction on land, a reflection of the transport and deposition mechanism. The principal objective of the study of the sediments generated by a tsunami is to identify previous and ancient (paleo) tsunami events. Tsunami interpretation is dependent on the quality of both ancient and modern analogs. Hence, the geological signatures produced by tsunamis provide key evidence that neither the written, instrumental records, nor models alone can supply.

The worldwide abundance of tsunami deposits is considered moderate despite the magnitude of the events themselves. The study and interpretation of the sedimentological record left by a given tsunami is one of the less developed but yet most interesting subfields of paleoseismology, or the

*Email: lopezgi.phd@gmail.com

*Email: lopezgi@sci.haifa.ac.il

study of ancient earthquakes (Shiki 1996; Michetti and Hancock 1997; Shiki et al. 2000). Evidence of tsunami deposits can be found in many forms and diverse locations, both onshore, in subaerial and subaqueous environments, and offshore (submarine environment), provided availability of material to entrain and generate the deposit itself and a successful preservation. The latter applies when the burial process is rapid, and disturbance by external factors (e.g., bio- and geo-turbation, reworking, erosion, tectonic uplift) is minimal or nonexistent.

Tsunamigenic sediments can present a diversity of litho- and biofacies combinations, not always existent contemporaneously. There are a multitude of characteristics inherent to tsunami deposits, from variations in the distribution of facies to particle size range and composition. These characteristics are identifiable using several geological, biological, and chemical methodologies, amid others; however, not a single proxy can be used *solo* without any doubt (Atwater et al. 1995; Chagué-Goff et al. 2011; Goff et al. 2012).

Turbulent onrushing waters may carry mud, sand, gravel, marine organisms, and organic debris far inland, but also the ebb can transport material far offshore. Both tsunami run-up and backwash are responsible for creating different sedimentary facies that may not be present contemporaneously throughout the deposit, hence the impossibility of assigning a single prototype to tsunamigenic sediments and the difficulty in their identification and even recognition (Shiki et al. 2008). They are generally deposited as flow slackens and ebbs, in subaerial environments, and as waters calm and material falls by gravity, in the subaqueous realm. Based on geological evidence recovered from paleo-tsunamis, in addition to observations of modern tsunami deposits, the general characteristics can be described as follows (e.g., Atwater et al. 1995; Dominey-Howes et al. 2006; Chagué-Goff et al. 2011; Goff et al. 2012; López 2012; Ramírez-Herrera et al. 2012):

1. They thin and fine landward and upward in the sequence.
2. They rise landward and away from shore.
3. They may show graded bedding, reflecting both tsunami landward flow and backwash flow.
4. They may show poor sorting if compared to storm deposits.
5. They may show cross-bedding, reflecting landward and seaward currents.
6. The complex backwash deposit may show imbrication of large clasts or shells, evidence of a seaward direction of the flow.
7. The grain size distribution may be bi- or multimodal.
8. Association of multiple coarse/fine couplets is indicative of deposition by successive waves of a tsunami wave train (i.e., periodicity).
9. Microfossil assemblages of foraminifera and diatoms are incorporated, confirming the marine (pelagic and/or benthic species) provenance of the material.
10. Heavy and magnetic minerals are common.
11. The geochemical signature may show higher concentrations of certain elements not common in the embedding sediments.
12. Driftwood and plant detritus are associated with the deposit.
13. Sharp undulating basal contacts, basal load structures, and rip-up or intra-clasts of reworked underlying material (e.g., peat) are indicative of flows with great energy (i.e., turbulent), capable of erosion.
14. The thickness and lithofacies may vary accordingly to the original land surface undulation.
15. Deposits in estuarine and tidal marsh environments are well sorted compared to the chaotic character of the lacustrine ones.

16. A broad range of ages obtained from a single tsunami deposit may suggest a “cannibalistic” behavior during inundation (i.e., reworking, truncation, erosion, and mixing of previously deposited sediments).
17. Stratigraphic position may or may not indicate coseismic subsidence in tectonically emerging coasts, hence origin of the tsunami.

Onshore Deposits

Sedimentary records generated by tsunami inundation onshore subaerially may provide accurate quantitative data that can show precise limits of tsunami inundation and geographical extent for the subsequent generation of tsunami inundation models, provided that correct identification and characterization have been made. Their size and thickness depend upon the size of the tsunami event, its run-up, and the bathymetry/morphology of the locale. Estuaries, fjords, enclosed bays, lagoons, and freshwater lakes along the coast (i.e., subaqueous environments), as well as beaches, coastal flats, marshes, and wetlands (i.e., subaerial environments), can be favorable environments for tsunami wave overwash and related sedimentation.

Besides the characteristics previously described, tsunamigenic sediments are frequently deposited on low-lying coastal subaerial environments as continuous and discontinuous sheets of unconsolidated sediment (from silts to boulders) mixed with organic debris of both terrestrial and marine origin. Normally, these allochthonous tsunami-laid sheets sharply overlay the surface, creating erosional features along its sedimentary contact. They can be of millimeter scale to massively bedded and be poor to well sorted, depending on the sediment availability at the locale. They can be found intercalated by any type of sediment of local origin (e.g., peat, soils, eolian sands, and fluvial or coastal sediments). Intercalation of a series of tsunami and paleo-tsunami deposits and in situ units within the same locale (similar to a layered cake) is a sign of multiple occurrences of modern and ancient tsunami events in the area.

Coastal subaqueous environments may offer an excellent setting for deposition and preservation of tsunami-entrained materials due to the confined nature of the water body, the lacustrine realm being the most favorable one. Distinct sand or coarser material layers can be easily identified intercalated amid low-energy muddy or gyttja layers typical of lakes. The degree of particle size variation determines the hydrodynamic conditions during the event, as well as the multiple-wave incursions into the calm lacustrine basin. Coupling of layers, repetitions, and intercalations are common to tsunami deposits in lakes (e.g., Bondevik et al. 2005; López 2012). Fining-upward sequences of allochthonous materials are a result of particle settling within the water column, during the waning stages of the tsunami. An organic-rich layer may be capping the tsunamigenic sequence due to the different density-settling velocities of siliciclastic particles versus the lighter organic debris (López 2012). Depending on the size of the (semi-) enclosed coastal water body, characteristics typical of submarine tsunami deposits may also be present.

Offshore Deposits

Submarine tsunami deposits are lesser known due to the difficulties related to investigate such realm. Nonetheless, preserved submarine evidence has been found in open bays, continental shelves, and forearc basins, at water depths ranging from 10–20 to about 200 m (e.g., Fujiwara et al. 2000; Bondevik et al. 2005; Shiki et al. 2008). Recent discoveries have also pointed to shallow (3–40 m depths) continental shelves as novel areas with the potential to preserve tsunamigenic sediments (e.g., Van der Bergh et al. 2003; Abrantes et al. 2005; Reinhardt et al. 2006; Smedile et al. 2011). This nearly untapped source for tsunamigenic evidence has proved to be rich and diverse but also intricate due to the hydrodynamics present in the upper continental shelf.

Offshore submarine tsunamigenic sediments may show intercalations of coarser allochthonous sedimentary particles, intermixed with shells and terrestrial plant fragments, embedded within mud layers typical of deep-sea environments (Fujiwara et al. 2000). As a characteristic of the erosive traction force of the tsunami, the bottom contact of the event layer is usually a sharp erosional contact. Textural and structural characteristics may also reveal the underwater conditions of deposition. Cross-stratification, imbrication of larger particles (pebbles and/or shells), and wedge-shaped laminations are typical. Similar to the coastal subaqueous environments, deposition of tsunamigenic materials is characterized by settling from suspension in the water column, hence the fining-upward resulting sequence. Multiple fining-upward sequences or alternating layers of coarser siliciclastic-rich layers and organic-rich caps are evidence of multiple tsunami run-ups and backwash episodes (Fujiwara et al. 2000; Tada et al. 2002; Lawton et al. 2005; Fine et al. 2005).

Dating Tsunamigenic Sediments

The contribution of tsunamis in the sedimentological record depends on the periodicity of the event. The assessment of tsunami risk is strongly dependent on the recurrence cycle of the triggering mechanisms (e.g., earthquake, volcanic eruption, landslide). Constructing a robust chronology of tsunami events and linking them to their potential triggers is one of the most challenging issues in paleo-tsunami research but of vital importance in the quantification of the potential risk to coastal communities. Documenting the tsunami history of a particular location depends on the proper identification of tsunamigenic events in the stratigraphic record. After correct characterization, there are a number of geochronological methods that can be applied to establish the moment of deposition of tsunami-laid sediments.

The periodicity of the tsunami event in a given region may be determined by obtaining an accurate age on a series or succession of preserved tsunami deposits. This is key in determining not only the recurrence interval of past tsunami events in any particular region (e.g., Atwater et al. 1995) but also in elucidating the potential timing of future events and establishment of tsunami hazard prevention plans accordingly.

Historical and modern tsunamigenic sediments can be dated by using historical or witness accounts and historical numerical data (seismic and tidal instrumental records). The latter can only be used for relatively recent events (e.g., since the 1900s). The lack of historical numerical data enhances the value of older written records and aboriginal traditions, archaeological remains, as well as paleoseismic evidence. For prehistoric paleo-tsunami sediments, ages can be obtained by various numerical absolute dating techniques such as radiocarbon, cesium-137, and optically stimulated luminescence (Atwater et al. 1995; Huntley and Clague 1996; Clague et al. 2000; López and Bobrowsky 2001; Donato et al. 2008; Reinhardt et al. 2006; López 2012).

Tsunamigenic sediments are chaotic anomalous layers enriched in a diversity of allochthonous materials of both inorganic and organic origin. Transport, erosion, reworking, and redeposition of organic debris and biological materials (shells) decrease the probabilities of obtaining accurate ages of the sediments. Organic materials (e.g., wood and plant detritus or shells) may have much older ages than that of the tsunamigenic deposit itself, making the age determination difficult. In order to reliably date a tsunami deposit using biological materials, it is important to find them in accordance with the deposition context, i.e., in situ, for example, tree trunks or intact bivalve mollusk shells killed and buried by the tsunami. Archaeological remains, whenever available, may be of more service only when identifiable pieces (e.g., pottery shards, coins) have remained in pristine conditions and in situ (the material has not been moved from its archaeological context). In addition, over

time, cultural material may be reworked, eroded, and incrustated with organisms, losing its identification potential, hence its dating value.

Due to the above, the reliability of using ^{14}C can be at stake when dealing with reworked and redeposited material such as plant detritus and shells within the tsunami deposit. Old carbon (e.g., fossils, coal, older carbon-rich bulk samples) associated with the reservoir effect can contaminate the deposit when introduced by erosion or redeposition. For example, as a global average, marine shells have a mean reservoir age of 400 years. Young carbon (e.g., live roots) can also contaminate tsunami sediments when these are older than the modern surface in which the root in question is growing.

In terms of dating relatively modern and historical tsunami deposits, numerical dating techniques such as ^{210}Pb and ^{137}Cs can be used (e.g., Miller et al. 2013), provided that an age-depth model is constructed. Such methods imply high-resolution sampling down-core or of the exposed outcrop surface with the purpose of building an activity curve showing the nuclide's peak at a particular depth (normally close to the surface) and exponential decay down-core. Both nuclides' activity down-core extrapolation curves are mostly used for sediment accumulation rate assessment but may also reveal the presence of major event layers such as tsunami deposits (rapid deposition or coarser particle size fractions imply no down-core change on the activity profile or depletion of the nuclide). Unfortunately, both dating techniques generally only work in clay- or silt-rich sediments deposited in the last 250 years. Lead-210 is a short-lived nuclide with a half-life of 22.3 years and is a product of the decay of ^{222}Rn in the uranium radioactive chain. It only remains a few days in the atmosphere before falling out on the earth's surface. Successful ^{210}Pb dating of tsunami sands has been achieved for the 1945 Makran tsunami (Arabian Sea; Miller et al. 2013) and the 2004 Indian Ocean tsunami (Thailand; Sakuna et al. 2012). Cesium-137 can only be used for very recent events as it was produced by atmospheric nuclear testing between 1952 and 1972, with peak productions in 1963–1964 (Woodward 1964; Wan et al. 1987; Naidu et al. 1999).

Optically stimulated luminescence (OSL), also known as optical dating (Huntley et al. 1985), was first used by Huntley and Clague (1996) to date tsunami-laid sands on coastal areas of Vancouver Island, Canada, and Puget Sound, Washington, USA. In OSL, due to the fact that the luminescence signal is directly related to light exposure, the exposure of mineral grains to light in a subaqueous environment can be proportionally related to the (hydro-) dynamic processes, i.e., the erosion-reworking-transport-deposition cycle. During this cycle, a mineral grain could be sufficiently exposed to daylight erasing (zeroing) any previously accumulated luminescence signals before its “final” burial. This zeroing process is the backbone of optical dating. More importantly, OSL provides accurate direct dating of the tsunami-laid sediment itself, provided that incomplete zeroing does not mask the luminescence signal of the tsunami event.

OSL dating of beach and underwater littoral sediments has been proven successful in various regions of the world as they can be as effective zeroing environments as the eolian. Several tsunamigenic sediments have been dated with OSL with various degrees of success, for example, the 1755 Lisbon tsunami (Banerjee et al. 2001), historical and paleo-tsunamis on the west coast of the USA (Huntley and Clague 1996; Ollerhead et al. 2001), the ancient 115 A.D. Mediterranean tsunami found in a submerged archaeological site in Israel (Reinhardt et al. 2006), Australia (Switzer and Jones 2008), the Andaman Islands (Kunz et al. 2010), and the 2004 Indian Ocean tsunami sediments in Thailand (Prendergast et al. 2012).

Nonetheless, as recently discovered by Ramírez-Herrera et al. (2012), tsunamigenic sediments can be deposited during nocturnal conditions, obstructing all chances of luminescence signal zeroing. Moreover, due to their distinctive hydrodynamically chaotic behavior, often complicated shallow marine and coastal pathways (Einsele et al. 1996), the level of turbidity of their waters, and their relative short transport time, tsunamis may not allow for sufficient zeroing of the sediments

they entrain, move, and deposit. Hence, dating tsunamigenic sediments by means of OSL can be a challenge, however, possible even in difficult conditions such as in underwater archaeological settings where anthropogenic reworking is most probable (e.g., Reinhardt et al. 2006). In such conditions of chaos and heterogeneity of material, it is always recommended to use multiple dating methods in conjunction with OSL to better constrain the age of the targeted tsunamigenic sediment.

In the event that a tsunamigenic sediment itself cannot be dated using absolute geochronological methods such as ^{14}C , ^{137}Cs , ^{210}Pb , OSL, or historical records, relative dating should be used. This is needed when difficulties arise in finding appropriate datable materials within the tsunami deposit, or even due to their “cannibalistic” character (i.e., intense mixture of multi-provenance materials, hence broad age range). Bracketing the age of a tsunami deposit by dating the immediately underlying and overlying sediment is a viable solution. Chronological techniques such as tephrochronology, biostratigraphy, and dendrochronology have provided excellent bracketing ages for paleo-tsunami deposits (e.g., Atwater et al. 2005; De Martini et al. 2010), as well as correlation with neighboring archaeological artifact materials, so at least a *terminus ante quem* age can be determined.

Summary

The identification and characterization of tsunamigenic sediments are the principal objectives in the corroboration of any tsunami event occurrence. Nonetheless, due to the diverse nature of the deposits, i.e., overwash versus backwash and onshore versus offshore, tsunami sediments are not easily recognizable, let alone identifiable, based on a unique criteria. Multi-proxy approaches pertaining to various fields of research (e.g., geology, biology, archaeology, hydraulics, geochemistry) are to be used combined to better detect these ephemeral, chaotic, yet catastrophic tsunami products.

Tsunamigenic sediments are key to establish geographical correlations of tsunami events and their triggering mechanisms. Without an accurate correlation of events, no real determination of inundation limits, magnitude of the event, danger-prone areas, and extent of the risk can be assessed. Quantification of ancient tsunami events relies on the existence of the geological evidence. Calculation of how often these events occur, hence recurrence intervals, depends on the precise dating of the latter. Without a correct chronological analysis of both historical and paleo-tsunami deposits, the implementation of adequate risk assessment and disaster prevention plans may be at stake.

Chemical dating; CHIME dating; CHIME method; EMP dating; EPMA dating

Definition

The chemical (Th-U-Pb) isochron method (CHIME) involves dating of micrometer-scale monazite, xenotime, zircon, and other minerals by electron probe microanalyzer (EPMA). Ages are obtained through analysis of multiple spots within and between mineral grains in polished thin sections or grain mounts. If the domains analyzed are consistent in age within the precision of measurement and have sufficient variation in Th and/or U content, then the data can be used to construct an “isochron” from which an age can be obtained via linear regression. This method, especially when coupled with data screening by chemical criteria, can produce accurate and moderately precise ages of mineral growth. It has the advantages of being nondestructive, of high spatial resolution, achievable with widely available electron microprobe instruments, and workable on minerals with non-radiogenic (or initial) Pb contents. In addition to spot analysis, electron microprobe dating can be conducted over areas defined by stage stepping, providing maps that discriminate chemically and chronologically distinct domains within monazite as young as 100 Ma.

Introduction

Current age dating methods based on mass spectroscopy (TIMS, SIMS, LA-ICPMS) rely on isotopic analysis to calculate age estimates. The robustness of age estimates can be tested against the criterion of “concordance,” or equivalence of age estimates from independent parent-daughter isotope pairs (e.g., between ^{238}U - ^{206}Pb , ^{235}U - ^{207}Pb , and ^{232}Th - ^{208}Pb). Prior to the widespread availability of such instrumentation, the concept of a “chemical age,” where proportions of total (non-isotopic) U, Th, and Pb were used to calculate age estimates, was applied to the dating of U- and Th-rich rocks and minerals. The chemical age requires assumptions that all Pb present in the sample is radiogenic, a product of the in situ decay of Th and U, and that no Pb has been added or lost from the sample since formation. Such assumptions are problematic, since many minerals include non-radiogenic Pb; in addition, Pb can be mobilized through several geological processes, including heating during metamorphism, hydrothermal activity, and weathering. Some Th- and/or U-bearing minerals, however, incorporate little to no Pb when grown and are relatively robust with respect to Pb isotope systematics under most crustal conditions. The orthophosphate minerals monazite and xenotime, which can incorporate U and Th on the order of several weight percent, typically retain

*Email: suzuki@nendai.nagoya-u.ac.jp

concordant isotope systematics. Zircon is less robust, with an ability to retain radiogenic Pb that strongly depends on the degree of radiation damage accumulated by the mineral; nonetheless, relatively young or low-U zircon does typically retain concordant isotope systematics, either in whole crystals or in micrometer-scale domains within grains that are analyzable by microbeam techniques. These and other U- and Th-bearing minerals are common in most crustal rocks, but typically in accessory amounts only and as grains tens to hundreds of micrometers across. Consequently, they are most suited to microbeam analysis, including chemical dating by EPMA in conjunction with an effective correction for initial Pb. The use of the EPMA for the chemical dating of monazite and zircon was established with the development of CHIME (Suzuki et al. 1991; Suzuki and Adachi 1991a, b), as outlined below. Analytical refinements and variants on the statistical handling of EMPA data to produce age estimates have been developed since (see below, as well as Suzuki and Kato 2008, and references therein). The technique need not be restricted to the electron microprobe; Kusiak and Lekki (2008) utilized a proton microprobe for CHIME dating of monazite, which provides potentially greater peak-to-background sensitivity than EPMA. Age-mapping techniques also have been introduced to reveal the geometry and distribution of growth stages within monazite grains (Williams et al. 1999).

Age Calculation

The amount of Pb that has accumulated in a U-Th-bearing mineral, relative to the amount of U and Th remaining, is given by

$$\begin{aligned} &^{232}\text{Th}, ^{235}\text{U} \text{ and } ^{238}\text{U} : \\ \text{Total Pb} &= \text{Pb}_i + ^{208}\text{Pb} + ^{207}\text{Pb} + ^{206}\text{Pb} \\ &= \text{Pb}_i + ^{232}\text{Th} \{ \exp(\lambda_{232}t) - 1 \} + ^{235}\text{U} \{ \exp(\lambda_{235}t) - 1 \} + ^{238}\text{U} \{ \exp(\lambda_{238}t) - 1 \} \end{aligned} \quad (1)$$

where Pb_i is the initial (non-radiogenic) Pb, t denotes the time after crystallization, and λ_Z are the decay constants $\lambda_{232} = 4.9475 \times 10^{-11} \text{ year}^{-1}$, $\lambda_{235} = 9.8485 \times 10^{-10} \text{ year}^{-1}$, and $\lambda_{238} = 1.55125 \times 10^{-10} \text{ year}^{-1}$ (Steiger and Jäger 1977). Equation (1) is simplified using $^{238}\text{U}/^{235}\text{U} = 137.88$ (Steiger and Jäger 1977) in

$$\begin{aligned} \text{Total Pb} &= \text{Pb}_i + \text{Th} \{ \exp(\lambda_{232}t) - 1 \} \\ &+ \text{U} [\{ \exp(\lambda_{235}t) + 137.88 \exp(\lambda_{238}t) \} / 138.88 - 1] \end{aligned} \quad (2)$$

If Pb_i is assumed to be zero, we can calculate an age from a single set of Th, U, and Pb measurements. This assumption, however, is not self-evident. In the CHIME procedure, we first calculate an apparent age from each set of ThO_2 , UO_2 , and PbO determinations (as wt%) by solving the age equation:

$$\begin{aligned} \text{PbO}/W_{\text{Pb}} &= (\text{ThO}_2/W_{\text{Th}}) \times \{ \exp(\lambda_{232}t) - 1 \} \\ &+ (\text{UO}_2/W_{\text{U}}) \times [\{ \exp(\lambda_{235}t) + 137.88 \exp(\lambda_{238}t) \} / 138.88 - 1] \end{aligned} \quad (3)$$

where W symbolizes the gram-molecular weight of each oxide: $W_{\text{Th}} = 264$ ($232 + 32$), $W_{\text{U}} = 270$ ($238 + 32$), $W_{\text{Pb}} = 224$ ($208 + 16$) for Th-dominant minerals and $W_{\text{Pb}} = 222$ ($206 + 16$) for U-dominant minerals. Taking the apparent age, we convert the sum of measured ThO_2 and UO_2 into ThO_2^* (for Th-dominant minerals) or UO_2^* (U-dominant minerals) as follows:

Fig. 1 Plot of PbO versus ThO₂* for monazite grains in a granite sample from the Hida metamorphic belt, central Japan (Suzuki and Adachi 1991b). Error bars in the figure represent 1σ analytical uncertainty, and errors referred for the age and Pb_i (intercept) are 2σ

$$\text{ThO}_2^* = \text{ThO}_2 + \text{UO}_2(W_{\text{Th}}/W_{\text{U}}) \times [\{\exp(\lambda_{235}t) + 137.88 \exp(\lambda_{238}t)\} / 138.88 - 1] / \{\exp(\lambda_{232}t) - 1\} \quad (4a)$$

$$\text{UO}_2^* = \text{UO}_2 + \text{ThO}_2(W_{\text{U}}/W_{\text{Th}}) \times \{\exp(\lambda_{232}t) - 1\} / [\{\exp(\lambda_{235}t) + 137.88 \exp(\lambda_{238}t)\} / 138.88 - 1] \quad (4b)$$

Minerals such as monazite or zircon that grew during a single geological event can vary significantly in Th and U content, both between and within grains. If these have consistent amounts of Pb_i and have remained closed to Pb loss or gain, all analytical data will form a linear array (Fig. 1), with the slope (m) and intercept (b):

$$\text{PbO} = m \times \text{ThO}_2^* + b \text{ (Th-mineral)} \quad (5a)$$

$$\text{PbO} = m \times \text{UO}_2^* + b \text{ (U-mineral)} \quad (5b)$$

We determine the best-fitting regression line through the procedure proposed by York (1966), taking account of uncertainties in the microprobe analyses, and calculate the first estimation of age (T) from the slope (m) of equations:

$$T = \ln \{m (W_{\text{Th}}/W_{\text{Pb}}) + 1\} / \lambda_{232} \text{ (Th-mineral)} \quad (6a)$$

$$m (W_{\text{U}}/W_{\text{Pb}}) = \{\exp(\lambda_{235}T) + 137.88 \exp(\lambda_{238}T)\} / 138.88 - 1 \text{ (U-mineral)} \quad (6b)$$

Then, we can obtain an improved estimate by replacing the apparent ages (t) in Eq. (4) with the first age estimate (T) and iterate to the desired tolerance. The y-intercept of the line represents an average Pb_i for all data points. A significant amount of Pb_i, if present, would deviate the line from the origin; inconsistent Pb_i, Pb disturbance, or the presence of multiple age domains would result in scattering of data away from a linear array.

Variations in the mathematical treatment have been proposed by several authors. Montel et al. (1996) proposed the calculation of an age from Eq. (2) by assuming no Pb_i and estimation of a probable age from several determinations after propagating uncertainties with representation by a bell-shaped probability curve. Rhede et al. (1996) represented the age equation (2) for monazite by an equation of a plane in three-dimensional ThO_2 - UO_2 - PbO space:

$$PbO = aThO_2 + b + cUO_2 \quad (7)$$

where $a = (1/W_{Th}) \times [\exp(\lambda_{232}t) - 1]$, $b = \text{average } Pb_i$ and $c = (1/W_U) \times [\{\exp(\lambda_{235}t) + 138 \exp(\lambda_{238}t)\}/139 - 1]$. Cocherie and Albarede (2000) ignored parameter b and proposed a new $Th/Pb = f(U/Pb)$ graphical representation.

EPMA Analysis of Th, U, and Pb in Minerals

Target minerals for chemical dating include monazite, zircon, xenotime, polycrase, thorite, huttonite, uraninite, and allanite. Analysis does not differ fundamentally from the conventional method on a wavelength-dispersive-type EPMA. However, certain difficulties that are normally unimportant in major element analyses become acute in the accurate determination of Th, U, and Pb concentrations. Critical factors that affect determinations include X-ray peak interferences, background estimations, type of detector gas, collimator slit, accelerating voltages, probe currents, and count rates (Suzuki and Adachi 1991a,b; Jercinovic and Williams 2005; Suzuki and Kato 2008). Adopting 400 s integration times for a 150 nA probe current, the detection limit of PbO at a 95% confidence level is around 100 ppm. Monazite with 10 wt% ThO_2 generates around 420 ppm PbO, and zircon with 2 wt% UO_2 generates around 260 ppm PbO in 100 Ma. Thus EPMA dating can provide monazite and zircon ages younger than the Cretaceous period. Imayama and Suzuki (2011) successfully dated Miocene monazite by adopting a 3,200 s integration of counting at peak and background positions.

Chemical Criteria for Screening of EPMA Data

Monazite $((Ce, La, Nd, Y) PO_4)$ commonly contains significant brabantite $((Th, U)Ca(PO_4)_2)$, huttonite $((Th, U)SiO_4)$, and $CaSO_4$ substitutions. Excluding minor substitution by halogens and Sr, atomic $(Ca + Si)/(Th + U + Pb + S) = 1$, and significant deviations from this value are normally encountered only in analysis of altered or metamict portions. The $(Ca + Si)/(Th + U + Pb + S)$ value therefore provides a criterion for probable discordance in Th-U-Pb isotope systematics (Suzuki and Kato 2008). The value may also deviate from unity if X-ray excitation overlaps with mineral grains adjacent to the target mineral; nonstructural elements, such as potassium, may also be detected. Screening of monazite analyses with these chemical criteria commonly reduces scatter in an analytical dataset. In the case of zircon, secondary alteration of radiation-damaged domains, which causes loss of radiogenic Pb and contamination by non-radiogenic Pb, is often associated with enrichment in Ca (Geisler and Schleicher 2000), so that high Ca (>0.05 wt%) zircon typically yields unreliable ages (Suzuki and Kato 2008). Thus Ca content, along with S and K, can be used as chemical criteria for the screening of zircon analyses.

Fig. 2 Compositional and age maps of a monazite grain in migmatite from the high-temperature/low-pressure Ryoke metamorphic belt, central Japan (Kawakami and Suzuki 2011). Attached photomicrograph shows apparent ages calculated from spot analyses. Numbers in italics represent analyses rejected by chemical criteria of $0.95 < (\text{Ca} + \text{Si})/(\text{Th} + \text{U} + \text{Pb} + \text{S}) < 1.05$ and $\text{K}_2\text{O} < 0.05$ wt%

Age Mapping

The age-mapping technique highlights the geometry and distribution of age domains on the micrometer scale within individual grains (Williams et al. 1999). Depending on the intrinsic response of the EPMA detector, a dwell time of 0.5–1 s may be sufficient for monazites with 1.0 wt% PbO under 15 keV and 150 nA beam conditions. However, the dwell time required for young monazites with 300–600 ppm PbO ranges from 50 to 100 s. To shorten the mapping time, multiple spectrometers for Pb measurement can be adopted (Suzuki and Kato 2008).

The raw intensity data are corrected for background and interferences and converted into concentrations in the same way as spot-by-spot analysis (Suzuki and Kato 2008) or by calibration against standard intensities (Williams et al. 1999). The background for each pixel is obtained from the relationships between ThMα + UMβ line counts and counts at fixed offsets from spectral lines, which are determined before the measurement of Th, U, Pb, and Y intensities. Then the age of each pixel is calculated from the concentration through Eq. (2) by assuming $\text{Pb}_i = 0$, and the resulting age value is stored in the corresponding pixel of a new map. Figure 2 exemplifies age and composition maps of a young monazite grain that shows an 83.5 ± 2.4 Ma high-Y rim on a 96 Ma core (Kawakami and Suzuki 2011).

Fig. 3 BSE and WDS elemental images of garnet (grt G) and inclusions of monazite in a garnet-cordierite migmatite from the Higo metamorphic terrane of western Kyushu, Japan (From Dunkley et al. 2008)

Applications

The dating of accessory minerals by EPMA readily provides age estimates for geological events. There is, however, widespread recognition of the difficulty of assigning age data to specific events, especially in terranes which have experienced multiple episodes of high-temperature metamorphism. Grains of accessory minerals such as monazite and zircon commonly preserve reliable age data from multiple stages of growth, which need to be understood in the context of paragenetic mineral assemblages. The clearest interpretation of an age estimate requires the fewest assumptions and the support of petrographic evidence for textural and compositional equilibration. Thus, the technique is best done on datable minerals in situ, in polished thin sections where mineral assemblages are preserved.

An example of petrographically constrained CHIME dating is provided by Dunkley et al. (2008), on the Higo metamorphic terrane of western Kyushu, Japan, which underwent high-grade metamorphism during a tectonic event considered by previous investigations to have occurred in either the Permo-Triassic or mid-Cretaceous period. In this study, monazite grains were dated that occur in textural equilibrium with the peak metamorphic assemblage spinel + sillimanite + garnet + plagioclase + biotite, and aligned with a mineral foliation and gneissosity developed during peak metamorphism. Monazite grains were also found as inclusions within garnet porphyroblasts (Fig. 3), where they would be shielded from hydrothermal fluids that potentially could have disturbed Pb in monazite. The dating of monazite both in inclusions and the foliated matrix thus constrains the timing of metamorphic mineral growth. In both cases, CHIME ages of around 115 Ma were obtained.

Partitioning of Y between coexisting monazite, xenotime, and garnet allows correlation of monazite growth with garnet growth and/or consumption (Pyle et al. 2001). Figure 4 shows Y and

Fig. 4 Yttrium and age maps of monazite grains and MnKα and YLα maps of porphyroblastic garnet in a quartzofeldspathic granulite from the Gyeonggi massif, Korea (Suzuki 2009)

age maps of monazite and Mn and Y maps of garnet in a quartzofeldspathic granulite from the Gyeonggi massif in the Korean Peninsula (Suzuki 2009). The sample shows little evidence of a retrograde overprint beyond minor growth of biotite along garnet grain boundaries. The garnet grain decreases in Y from core to rim with peripheral Y enrichment and shows a core-to-rim increase in Mn, which can be attributed to a retrogressive modification along with biotite formation. Zoning patterns of Y differ among the monazite grains. The monazite grain enclosed in garnet shows a core-to-rim decrease in Y, and those in the matrix show a peripheral enrichment of Y on low-Y interiors. Due to the compatibility of Y in garnet, an increase in garnet growth during prograde and peak metamorphism decreases the availability of Y in the effective bulk rock. The marginal Y decrease in monazite within garnet is synchronous with an increase in garnet growth during prograde granulite-facies metamorphism. The Y-poor domains in matrix monazite have grown along with garnet, and Y-rich margins on matrix monazite grains are attributed to retrograde replacement of garnet by biotite. Age maps show no age variation between three chemical domains on individual grains, which together yield a CHIME age of $1868 \pm 24 \text{ Ma}$. The age map combined with compositional maps is a powerful tool to reveal stages of a metamorphic history within a single event.

Uranium–Lead, Igneous Rocks

Donald W. Davis*

Department of Earth Sciences, Earth Sciences Centre, University of Toronto, Toronto, Ontario, Canada

Definition

The measurement of magma crystallization ages for volcanic and plutonic rocks using the uranium–lead radioactive decay system.

Introduction

The crust is dominated by igneous rocks, which record ancient geologic processes. Precise dating is one of the most powerful tools for understanding crust formation and is the widest application of radiometric geochronology. The ages of igneous rocks are measured by dating minerals that contain radiogenic daughter elements.

The U–Pb system is considered the most robust and useful geochronometer for igneous rocks largely because of the mineral zircon (ZrSiO_4 , Fig. 1, and Cross-Reference ► [Uranium–Lead, Zircon](#)), which contains high trace levels of U and strongly rejects Pb during crystallization. Therefore, present-day Pb within it is dominantly radiogenic. Initial Pb in a newly crystallized mineral, called common Pb, can be distinguished because it has a different isotopic composition from the radiogenic Pb. Zircon is a common and easily recoverable trace mineral in siliceous igneous rocks such as granitoid plutons and felsic volcanics that are widespread in continental and arc environments. Partial melting of older rocks buried deep in the crust may not completely destroy their zircon, which is often preserved as older cores in younger rocks that crystallize from the melt. This zircon is overgrown by a phase giving the age of the melt, while the cores preserve the age of the original rock or protolith. The presence of older zircon in a younger population is called inheritance. It can be a significant problem in age interpretation but is also a source of information on the provenance of the magma.

Other minerals favorable for U–Pb geochronology include baddeleyite (ZrO_2 , Fig. 2) and monazite (CePO_4). Baddeleyite is common in mafic rocks, such as gabbro and diabase dykes, which normally do not contain zircon. Like zircon, baddeleyite contains several hundred ppm of U and essentially no common Pb. Unlike zircon, it is resistant to Pb loss and gives accurate ages on very tiny grains. Monazite is low in common Pb, normally contains high U concentrations ($>1,000$ ppm), and is relatively resistant to Pb loss. It is however much rarer than zircon, occurring mostly in highly evolved crustal rocks such as granites produced from the melting of sediments. Titanite, rutile, apatite, perovskite, and columbite-tantalite can also be suitable for U–Pb dating but contain relatively high common Pb concentrations. The first three are common trace minerals but may be susceptible to metamorphic growth and resetting. The last two are relatively rare.

Methods

The most precise method of U–Pb dating is by isotope dilution (ID). This involves dissolving a mineral grain, chemically separating the U and Pb, and determining the amount of the isotopes by mixing them with a known quantity of an enriched isotope, called the spike, and measuring the isotopic composition. Isotopes are usually measured by thermal ionization mass spectrometry (TIMS) or multi-collector inductively coupled plasma mass spectrometry (MC-ICPMS). Methods of sample treatment were introduced for avoiding altered, disturbed zircon domains to achieve accurate results (Krogh 1982; Mattinson 2005). The secondary ion mass spectrometer (SIMS) was developed to measure ages of individual domains within polished zircon crystals at the scale of tens of microns. The earliest model is known as the SHRIMP (Compston 1999) and has continued to be developed along with other models (e.g., Rollinson and Whitehouse 2011). Laser ablation inductively coupled plasma mass spectrometers (LA-ICPMS) were developed more recently and have similar capabilities (e.g., Alves et al. 2013) although they still require more sample than SIMS and produce a deeper ablation spot (tens of microns compared to 1–2 microns for SIMS). Although spot zircon ages generally have less precision than ID analyses, they are much faster to obtain and they allow older cores and younger overgrowths to be readily dated within complex zircon grains. Currently, U–Pb ages can be routinely determined to a 95 % confidence level of about ± 0.05 % or better from single zircon grains by ID and ± 0.5 % by SIMS and LA-ICPMS from 20 to 30 micron diameter spots on polished zircon.

Applications

Precambrian Greenstone Belts

The Precambrian makes up about 80 % of geologic time but contains few fossils. It comprises the continental shields where many of the rocks are deformed into linear structures known as greenstone belts. One of the first successful applications of high-precision U–Pb dating was to unravel the chronology of Archean greenstone belts so as to understand the development of the early crust. The necessity of eliminating secondary Pb loss from zircon and achieving the age accuracy required to resolve timing of eruptions within an average greenstone belt (about ± 1 Ma) was a major incentive for developing the air abrasion method for achieving accurate results on zircon (Krogh 1982) and for improving chemical separation methods so that single grains could be dated. Much of this early work was carried out in the Superior Province (e.g., Corfu et al. 1989; Davis et al. 1989). It provided evidence for a north to south progression of late plutonism and deformation, suggesting that the craton formed by accretion of oceanic arc and micro-continental terranes through plate tectonic processes broadly similar to those operating today.

Geologic Time Scale

The geologic time scale was historically based on relative dating of sedimentary rocks using fossils that can be correlated from units in different areas and ranked in relative age using superposition of stratigraphically higher (younger) over lower (older) units. Arthur Holmes promoted the early development and application of U–Pb dating and was able to publish surprisingly accurate ages for the principal geologic periods in his booklet “Age of the Earth” (1927). At this time, before precise mass spectrometry, it was necessary to use chemical methods to measure U and Pb in rare highly radioactive minerals found in granites and pegmatites. Determining time intervals and rates of geologic processes requires the most precise ages, and a great deal of recent work is directed toward dating important fossil-based marker units, such as mass extinction boundaries. Possible correlations with large igneous and meteorite impact events can be tested using precise geochronology in order to understand the driving forces of evolution. This work requires precisely dated zircon from thin volcanic ash layers within sedimentary rocks. Early work on the Paleozoic time scale was carried out by Tucker et al. (1990) using ID-TIMS and Compston and Williams (1992) using SIMS. This led to much debate over discrepancies that were later traced to problems, now resolved, with the SIMS standard zircon.

The largest known mass extinction occurred at the end of the Permian period just before the beginning of the Triassic. Well-preserved stratigraphic sections in China contain numerous volcanic ash beds in latest Permian strata that have been a focus of recent work in precise zircon dating. They have allowed the extinction event to be dated at 252.28 ± 0.08 (Shen et al. 2011). Volcanic and plutonic rocks associated with the early stages of the Siberian flood basalts, the largest known volcanic province, have given similar ages (Kamo et al. 2003). This coincidence suggests that the extinction was caused by a rapid increase in atmospheric CO₂ level at the beginning of volcanism and therefore that major igneous events can cause mass extinctions. A similar correlation has been found between the Triassic-Jurassic extinction at 201.3 ± 0.2 Ma and eruption of the Central Atlantic magmatic province at 201.38 ± 0.02 Ma (Schoene et al. 2010). The necessity of achieving the highest possible levels of precision for dating such samples was a major driving force for developing the chemical abrasion method to isolate pristine zircon (Mattinson 2005).

Plutonism

The proportional error of U–Pb ages is approximately independent of the absolute age, so that the absolute error is smaller in younger rocks. While age errors not much better than ± 1 Ma can be routinely achieved for Archean rocks, errors of ± 0.1 to ± 0.01 Ma can be achieved for ages of 100 Ma or younger. This has allowed detailed study of the construction of young composite felsic intrusions such as in Leuthold et al. (2012), Schoene et al. (2012), and Matzel et al. (2006) where the age range for batholith emplacement was determined by dating individual plutonic phases with errors of 10–50 Ka. A similar study successfully resolved emplacement of components of the 56 Ma Skaergaard layered mafic intrusion over a time scale of 100 Ka (Wotslaw et al. 2012). Such studies reveal details that were masked by the limited precision of earlier dating. Emplacement and crystallization of large plutons can no longer be considered instantaneous but are seen to proceed over a time span of tens of thousands of years during which different generations of zircon crystallize (autocrysts from extended crystallization within a magma chamber and antecrysts from earlier batches of magma), in addition to much older zircon incorporated from host rock (xenocrysts).

Ages of Ophiolites and Ocean Crust Accretion

Basalt is the most common rock type on Earth's surface, but most of it is found in the oceanic crust, which is continually being produced at mid-ocean ridges and recycled into the mantle at subduction zones. Consequently, the oldest parts of actively spreading ocean crust are only about 200 Ma, far younger than ages preserved on unsubductable continental crust. However, fragments of ancient oceanic crust have in the past been thrust onto continents and preserved from subduction. Such fragments are called "ophiolites." Most are thought to have originated in small ocean basins that formed in extensional environments between oceanic arcs and continental margins. They were thrust (obducted) onto the adjacent continent in continental collision zones. Some ophiolites provide an exposed section through ocean crust, which is otherwise inaccessible to observation except through ocean drilling. Therefore, they have been a key source of information on the structure and formation of the ocean basins. They are also useful as indicators of the position of previous ocean basins in ancient collision zones, such as the Paleozoic (ca. 500–350 Ma) Caledonian–Appalachian orogen in Newfoundland. Although the major product of mid-ocean ridges is basalt and gabbro, mafic magma in large chambers can sometimes differentiate into plagiogranite or tonalite, which contains abundant zircon. Such samples were used by Dunning and Krogh (1985) to date ophiolites associated with the pre-Atlantic Iapetus Ocean. A more recent study by Rioux et al. (2012a) dated zircon from gabbro in the Oman–United Arab Emirates ophiolite at the level of ± 20 Ka and showed that magmatism lasted over the interval ca. 96.4–95.5 Ma, providing constraints on spreading rate. Zircon from gabbro dredged at actively spreading ocean crust in the East Pacific Rise was dated over the range 142–127 Ka with errors of ± 6 to ± 80 Ka (Rioux et al. 2012b), and in the Mid-Atlantic Ridge over the range 290–90 Ka with similar errors (Lissenburg et al. 2012). At this level of precision, the age spread within samples probably reflects the time scale of crystallization of the gabbro plutons.

Large Igneous Provinces and Continental Reconstruction

Although differentiated gabbros and gabbro pegmatite can contain zircon, the realization that baddeleyite (ZrO_2) is a widespread trace mineral in mafic intrusive rocks (Heaman and Lecheminant 1993) allowed more general application of U–Pb geochronology to mafic igneous rock. Application of baddeleyite dating continued to be relatively rare until Soderlund and Johansson (2002) developed an improved method for recovering tiny baddeleyite crystals on the Wilfley table (a shaking table routinely used to concentrate heavy minerals such as zircon from

rock powders). One of the earliest applications of baddeleyite geochronology is Krogh et al. (1987). Davis and Sutcliffe (1985) dated early mafic plutonism associated with the 1,100 Ma Midcontinent Rift (MCR) using both zircon and baddeleyite, which both occur in the same mafic sill.

Mafic rocks in the continental crust tend to be concentrated in Large Igneous Provinces (LIPs) that are thought to have been caused by rapid massive basaltic eruptions due to decompression melting of the mantle during the ascent of mantle plumes. In many cases these events led to continental breakup and the formation of new ocean basins. Continental flood basalts associated with such events in the Precambrian are often eroded away but leave the source channels through which the magma ascended exposed as giant radiating dyke swarms. Evidence suggests that emplacement of these swarms was rapid (1 Ma or less, Lecheminant and Heaman 1989), so they form markers whose paleomagnetic directions can be used to define a polar wander path for the drifting continents, provided that their ages are precisely known. The latest work is focused on using ages to identify fragments of the same dyke swarms on different continents that drifted apart sometime after emplacement of the swarms. Their orientation can be used as a “bar code” to help fit the continental fragments together into their pre-rift configuration (e.g., French and Heaman 2010; Nilsson et al. 2010; Soderlund et al. 2010).

Conclusions

The 60-year history of modern U–Pb geochronology of igneous rocks has produced an enormous amount of age data without which much of the progress in understanding ancient geological processes would not have been possible. Different methods of U–Pb dating (ID-TIMS, SIMS, LA-ICPMS) have been developed, but it is generally recognized that they have complementary strengths and weaknesses, so the best approach is to use them where they are most effective. Accuracy and sensitivity continue to improve with better instrumentation and understanding. It can be expected that sub-million-year age resolution will become available throughout the time scale, providing new insights into planetary development.

Uranium-Lead, Ore Deposits

Rolf L. Romer*

Inorganic and Isotope Geochemistry, GFZ German Research Centre for Geosciences, Potsdam, Germany

Definition

Metamictization. Gradual to complete transformation of an originally crystalline mineral into the amorphous state by exposure of the crystal lattice to alpha particles emitted from U and Th.

$\mu. {}^{238}\text{U}/{}^{204}\text{Pb}$, atomic ratio.

Ore deposit. Natural occurrence of mineral(s) that can be worked at an economic profit, generally used for metallic minerals. The broader term *mineral deposit* also includes nonmetallic minerals.

Introduction

The first age determinations based on the radioactive decay of U were made on ore minerals, using the U-He method (1904) and the U-Pb chemical method (1907; see “► [Uranium-Lead, Chemical Isochron U-Pb Method \(CHIME\)](#)”). The first U-Pb isotopic ages and ${}^{207}\text{Pb}/{}^{206}\text{Pb}$ ages also were determined on ore minerals (see “► [Historical Development \(of Dating Methods\)](#)” and “► [Uranium-Lead Dating](#)”). This early interest in (uranium and uranium-rich) ore minerals for dating mainly was due to the large amounts of U, He, and Pb, respectively, needed to determine their contents – and, thus, He/U and Pb/U ratios – reliably. Nonetheless, these early age determinations were not precise. Furthermore, it became increasingly apparent that some of these ages also were inaccurate due to open-system behavior of the U-He and U-Pb systems in high U minerals. With the development of the K-Ar, Rb-Sr, and the ${}^{40}\text{Ar}$ - ${}^{39}\text{Ar}$ methods and later the Re-Os method (see “Ar-Ar and K-Ar Dating,” “Rb-Sr Dating,” and “Re-Os Dating”), direct dating of ore minerals by the U-Pb method was increasingly substituted. An exception to this trend represents the dating of U deposits, where U-Pb dating continued to be the method of choice. At the same time as the role of the U-Pb method lost importance in the dating of ore deposits, the U-Pb dating of – in particular – zircon, monazite, and xenotime evolved to become the most precise and accurate dating method for magmatic and metamorphic rocks (see “► [Uranium-Lead, Zircon](#)”).

The dating of gangue minerals (by K-Ar, Rb-Sr, and the ${}^{40}\text{Ar}$ - ${}^{39}\text{Ar}$ methods) or sulfides (Re-Os method) avoids some of the problems inherent to the dating of U-rich minerals by the U-Pb method (e.g., open-system behavior due to metamictization), but results in a series of other problems: (i) the dated gangue mineral and the ore minerals may be not cogenetic; (ii) the geochronologic system of some gangue minerals may be easily reset during later overprint (i.e., deformation, fluid flow, metamorphism), resulting in a system in which the dated mineral may be texturally related to the ore formation, but its age, however, corresponds to the overprint; (iii) the paragenetic redistribution

*Email: romer@gfz-potsdam.de

of ore elements into secondary minerals may occur much later than the deposit formation and may not be related to the formation of dateable gangue minerals.

In the 1990s, U-Pb ID-TIMS dating of ore minerals regained importance, especially the dating of Nb-Ta minerals of the columbite-tantalite-tapiolite series and to a lesser extent Sn and W minerals (cassiterite, ferberite-hübnerite). Furthermore, the development of the laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) U-Pb dating method provided a rapid and relatively cheap dating tool increasingly used to date ore minerals. Dating of ore minerals, as for instance columbite-tantalite or cassiterite, allows not only the dating of ore deposits and the linking of the ore deposits to a broader geological context but also the use the age of detrital grains from heavy mineral concentrates as a guide for exploration/prospection for the primary deposit and for the provenance certification of ore concentrates to suppress ore trading from areas of armed conflicts, e.g., COLTAN (http://www.bgr.bund.de/EN/Themen/Min_rohstoffe/CTC/Home/CTC_node_en.html).

With the development of microanalytical tools, such as high-resolution ion probes and LA-ICP-MS (see “► [Laser Ablation Inductively Coupled Mass Spectrometer \(LA ICP-MS\)](#)”), minerals typically used for the dating of magmatic and metamorphic rocks by conventional isotope-dilution thermal ionization mass spectrometry (ID-TIMS), i.e., zircon, monazite, and xenotime, became increasingly used for the dating of ore deposits, in particular for hydrothermal ore deposits.

Direct Dating of Ore Deposits

Dating of ore minerals provides the most straightforward approach to date an ore deposit and to give insight into different stages of metal redistribution. Basically, any mineral can be dated by the U-Pb method if it fulfills the following constraints: (i) its composition allows for the substitution of U into the crystal lattice (e.g., U may substitute for Fe and Mn), (ii) the crystal lattice has no places for the substitution of Pb (Pb readily substitutes for K or Ca), and (iii) the mineral is chemically stable and is not easily altered. For U-Pb dating, it is not a high U content that is important, but a high $^{238}\text{U}/^{204}\text{Pb}$ ($= \mu$) ratio. Actually, minerals with high U contents tend to become metamict and, thus, open systems. In contrast, minerals with relatively low U content that effectively exclude the incorporation of Pb during their formation have high μ ratios, will not turn metamict, and eventually develop very radiogenic Pb isotopic composition. These minerals are suitable for U-Pb dating. It should be noted that minerals that can be dated by the U-Pb methods commonly are not major phases in the ore deposit (exception are U minerals in U deposits): if the available U is distributed among the major phases, none of them has a particularly high μ , which would make it unattractive for U-Pb dating.

A wide range of primary and secondary U minerals has been dated by the U-Pb method, yielding precise and accurate ages. Nonetheless, dating of U minerals is not trivial, and there is a plethora of processes (five are listed here) that may disturb the U-Pb systematics and result in both imprecise and inaccurate ages:

1. High U minerals produce with time significant amounts of Pb that may not be accommodated in the crystal lattice and form separate Pb phases (e.g., galena) with anomalously radiogenic Pb isotopic compositions. This results in a variable reduction of the apparent Pb/U ages of the U mineral.
2. Metamictization may lead to open-system behavior (see below).

3. Fine-grained U minerals may experience significant amount of intermediate daughter loss (see below).
4. Many U minerals are rather chemically reactive, and U (as U^{6+}) may be redistributed by oxidizing fluids. This redistribution commonly results in $^{238}U/^{234}U$ and $^{238}U/^{230}Th$ activity disequilibria, which for geologically young secondary minerals affect the U-Pb ages.
5. If secondary U minerals do not exclude Pb completely, they may incorporate highly radiogenic Pb from the precursor mineral.

Zircon, xenotime, and monazite from pegmatites, high-level granites, and greisen typically are very U or Th rich and commonly have variably disturbed U-Pb systems that do not allow for precise and accurate U-Pb dating of these rocks. Columbite-tantalite represents an alternative for dating these rocks (e.g., Romer and Smeds 1996). Although columbite-tantalite also may have high U contents, metamict sections can be removed by selective dissolution, which eventually yields concordant U-Pb data. Incomplete dissolution of metamict parts of the crystal commonly yields variably reverse discordant data and a negative lower intercept. Columbite-tantalite also has been successfully dated by LA-ICP-MS. In addition, cassiterite has been successfully dated by the U-Pb ID-TIMS method, but it has thus far not been used widely, possibly due to dissolution problems (Gulson and Jones 1992).

Carbonatites and related alkaline rocks have been successfully dated by U-Pb dating of perovskite and baddeleyite (see “► [Uranium-Lead, Rubidium-Strontium, Kimberlite](#)”). In contrast, zircon in carbonatites and related alkaline rocks may have been introduced during explosive emplacement to a significant extent from the wall rocks. Other minerals in these rocks that may be accessible to U-Pb dating include apatite and columbite-tantalite, whereas other Nb-Ta-rich minerals like euxenite, pyrochlore, and microlite commonly have higher U and/or Th contents and therefore become metamict over time, making them effectively unsuitable for U-Pb dating.

Indirect Dating of Ore Deposits

For many ore deposits, direct dating is not possible, either because the ore minerals cannot be dated (low U contents and high Pb contents) or because the datable minerals are rather easily altered or have such high U contents that they turn metamict and, thus, represent open systems for U-Pb dating. Indirect approaches to date ore deposits include (i) dating of non-ore minerals that are part of the same mineral assemblage as the ore minerals and (ii) dating of contact metamorphic minerals or selvages.

In Ca-silicate minerals, Pb generally substitutes to a significant amount for Ca, which results in low μ values for these minerals and significantly reduces their suitability for U-Pb dating. In skarn mineral assemblages, however, Pb typically is largely sequestered in calcite or epidote, leaving little Pb to be incorporated in other Ca-silicates. Therefore, skarn deposits have been successfully dated by the U-Pb method using a wide range of Ca-silicates, including garnet, vesuvianite, and titanite. In these minerals, U substitutes for Fe and may reach contents of a few ten to a few hundred ppm. As skarn minerals used for U-Pb dating may have relatively unradiogenic measured Pb isotopic compositions, the appropriate correction of initial Pb is very important, but not trivial as skarn minerals may contain initial Pb that is derived from both the intrusion and wall rocks and their relative contribution varied during the development of the skarn mineralization.

Magmatic iron ores have been successfully dated using titanite and apatite (Romer et al. 1994). Titanite intergrown with magnetite yields the emplacement age, whereas titanite in cavities yields

a minimum age for the emplacement of the iron ore. Apatite is considerably more readily disturbed than titanite and, therefore, should not be the mineral of choice for the dating of magmatic iron ores that have been thermally overprinted. Apatite may recrystallize at relatively low temperatures – in particular if a fluid is present – thereby losing some of its Pb, eventually yielding apparent ages that correspond to any point between the times of formation and disturbance. Furthermore, the rare earth elements (REE) in apatite may exsolve to form monazite (and less commonly xenotime), which also redistributes U, Th, and Pb between the host apatite and the secondary REE phosphates and, thus, disturbs the U-Pb system of apatite.

A wide range of minerals (e.g., apatite, zircon, titanite, monazite, xenotime, hübnerite) have been successfully used to U-Pb date hydrothermal vein deposits (Parrish 1990; Nesbitt et al. 1999; see also “► [Rubidium-Strontium, Hydrothermal Events](#)”). Especially if these minerals grow into open vugs, it is important to bear in mind that later fluid flow may result in partial resetting of their U-Pb system. Mineral growth from a fluid may result in strong fractionation of U and Pb, scavenging or incorporating U and leaving Pb in the fluid. Such minerals eventually develop highly radiogenic Pb isotopic compositions and may define precise ages. Calcite is a mineral that in rare occasions may be dated by the U-Pb method. Fe-Mn microparticles may scavenge U and develop radiogenic Pb isotopic compositions. The successful dating of such particles, however, depends on the presence of a container mineral that prevents intermediate daughter loss.

Magmatic and hydrothermal mineral deposits may develop marked contact metamorphic zones and selvages, respectively, that are accessible for isotopic dating. Thus, if there are no datable minerals in the magmatic or hydrothermal ore, such contact mineral assemblages may represent a last resort to constrain the age of the mineralization, as they commonly yield the maximum age for the mineralization.

Effects of Crystal Size and Metamictization

The decay of uranium (and thorium) to lead proceeds over a series of variably short-lived daughter isotopes. Each alpha decay results in the recoil of the daughter nucleus (see “► [Radiation Defect](#)”). This displacement leads to an open U-Pb (Th-U) geochronologic system on the nanoscale. As the U-Pb system of each small volume loses and gains daughter nuclei, this open-system behavior would become apparent at the nanoscale only if the distribution of U is heterogeneous. Otherwise, loss and gain are balanced. On the microscale, all recoil-related open-system processes effectively represent system internal redistributions of the daughter nuclei that do not affect the behavior of the bulk system; the U-Pb system appears as a closed system. In very small particles (10 μm or less), however, a significant portion of the recoiled nuclei is displaced to crystal surfaces and to linear and planar defects that favor the loss of intermediate daughter nuclei from the mineral. Among the intermediate daughter nuclei of the various U and Th decay series, ^{222}Rn and ^{226}Ra , which are intermediate daughters of the ^{238}U decay series, are especially likely to be lost. Radon is a gas and Ra is a water-soluble alkaline earth element that may substitute for Ba in silicates and sulfates. As ^{222}Rn and ^{226}Ra are longer lived than Rn and Ra isotopes of the ^{235}U and ^{232}Th decay series, it is only the ^{238}U - ^{206}Pb system of microcrystalline material that behaves as a notoriously open system. Although this open-system behavior affects all microcrystalline material, it becomes isotopically obvious especially in low-temperature U-rich rocks and ores, such as black shales, collapse-breccia pipes, and roll front-type uranium deposits that all may contain colloform and fine-dispersed uraninite. Consequences of the loss of intermediate daughter isotopes of the ^{238}U decay series are too-young apparent $^{206}\text{Pb}/^{238}\text{U}$ ages and too-old $^{207}\text{Pb}/^{206}\text{Pb}$ ages. Nonetheless, in the

$^{235}\text{U}/^{207}\text{Pb}$ - $^{206}\text{Pb}/^{207}\text{Pb}$ diagram, the formation age may be derived for systems that had experienced combined Pb and Ra+Rn loss (Ludwig and Simmons 1991). Microcrystalline uraninite, however, may appear to have a closed U-Pb decay system if uraninite occurs as inclusions in another mineral that acts as container. Dating of the inclusion together with its surrounding container results in a closed U-Pb system that yields concordant data in the $^{206}\text{Pb}^*/^{238}\text{U}$ - $^{207}\text{Pb}^*/^{235}\text{U}$ diagram.

Alpha-recoil of the daughter nucleus results in lattice damage in the crystal. The tracks of the alpha particle and the daughter nucleus and – in particular – their stopping environments are volumes with broken crystal bonds. Although broken crystal bonds facilitate the migration of the daughter nucleus, each of these damaged zones is surrounded by crystalline material, effectively preventing migration and open-system behavior. It is the superposition of many of these damaged regions that results in increasingly larger volumes of damaged crystal lattice and longer transport distances. The damaged volumes eventually may intersect with linear (e.g., fission tracks) or planar (twin, deformation, and displacement planes) defects in the crystal or with crystal surfaces, allowing for open-system behavior of the U-Pb decay system (Romer 2003). The accumulation of defects, which results in the metamictization of the crystal lattice, depends on the uranium content of the mineral and time: the higher the uranium content, the sooner a mineral becomes metamict. The progressive metamictization of U-rich minerals is the reason why early dating attempts of ore minerals using the U-Pb system were not successful and why the U-Pb dating of old and/or U-rich minerals in general is problematic.

Effect of Multiple Metal Redistribution on U-Pb Dating

The structures that control the formation of ore deposits may be reactivated during later changes in the regional stress field, whereby metals of the existing ore deposit are redistributed. Similarly, metals of surface-near deposits may be redistributed by meteoric water. In both cases, this later redistribution may be the process that results in the concentration of the metal content to a level that makes it an economically interesting deposit. For these deposits, the age of formation of the primary deposit may be of less relevance than the age of enrichment. Metal redistributions are unlikely to be dated successfully by indirect methods. Direct dating using the U-Pb method may encounter two types of problems:

1. Secondary minerals that do not exclude Pb completely may inherit Pb from their precursor minerals. If the primary mineral had a high μ value, it would have developed a radiogenic Pb isotopic composition. Thus, such initial Pb would give the impression of the presence of an inherited component. In the concordia diagram, the U-Pb systematic of these secondary minerals would define a discordia line between the age of the secondary mineral and the age of its precursor mineral. If both primary and secondary deposits are relatively young, inheritance may not result in marked discordance and, instead, the data would define a data range of apparently concordant data.
2. In very young secondary minerals (a few 10^5 years) that can be dated by the U-Pb method, e.g., U-micas, the redistribution of U may be associated with an uncoupling of Th and U and thus in an initial disequilibrium in the ^{238}U - ^{206}Pb decay series (actually a deficit in ^{230}Th) that eventually results in a deficit in ^{206}Pb . Furthermore, there may have been an initial $^{238}\text{U}/^{234}\text{U}$ activity disequilibrium. Both of these disturbances can be accounted for.

Conclusions and Outlook

There is no fundamental difference between dating magmatic and metamorphic rocks and ore deposits by the U-Pb method. There are, however, a few problems that may be associated with the U-Pb dating of ore deposits that typically can be avoided for magmatic and metamorphic rocks. These include (1) open-system behavior due to metamictization (caused by high U contents), (2) intermediate daughter loss because of small crystal size, (3) multiple metal redistribution due to chemical reactivity of dated mineral (e.g., U minerals), and (4) unknown behavior of the dated mineral during thermal overprint and exposure to fluids. Some of these problems can be avoided by dating gangue minerals rather than the ore minerals.

The development of microanalytical in situ methods, in particular U-Pb dating by LA-ICP-MS, has significantly changed the possibilities in the dating of ore deposits. Most importantly, the ease and speed with which U-Pb LA-ICP-MS can be done allows a trial and error approach in minerals that have not yet been demonstrated to be reliable U-Pb chronometers. As positive as this extension of U-Pb dating to include uncommon ore minerals may appear, it is important to remember that all processes that lead to analytical problems in U-Pb dating by ID-TIMS, i.e., Pb-loss, metamictization, size-related loss of intermediate daughter isotopes, inheritance of radiogenic Pb from precursor minerals, and for very young minerals isotopic disequilibrium in the ^{238}U decay series, do not disappear only because U-Pb dating is done using a different analytical method. While these disturbances are readily apparent in precise and accurate ID-TIMS data – in particular minor Pb-loss and intermediate daughter loss – they may be analytically not resolvable in low-precision U-Pb data obtained by LA-ICP-MS or microprobe. The lack of resolution, however, does not a priori imply that these disturbances are not there. Furthermore, multiple events relatively close in time, which are analytically resolvable by U-Pb ID-TIMS, may yield overlapping U-Pb LA-ICP-MS data and thus, interpreted as a single event, result in apparently precise ages that are not accurate. Interpretation of such inaccurate data may lead to disturbed time scales for the development of ore deposits or to “processes” and “events” that actually do not exist.

Uranium–Lead, Extraterrestrial, Early Solar System

Yuri Amelin*

Research School of Earth Sciences, The Australian National University, Canberra, Australia

Synonyms

[Uranium–lead cosmochronology](#)

Definition

The science of relating events that transformed a cloud of interstellar gas to our solar system to time, by means of using decay of uranium isotopes ^{238}U and ^{235}U to lead isotopes ^{206}Pb and ^{207}Pb .

Introduction

Stars and their planetary systems form by gravitational collapse of dense parts in large interstellar molecular clouds. It is thought that, about 4.57 billion years ago, our solar system formed by a similar process. The early history of our solar system cannot be observed directly, but it is recorded in the very early minerals and rocks that were removed from the ongoing process of accretion before formation of the planets, and thus escaped geological reworking. These primitive rocks are preserved in several non-planetary environments – in asteroids that experienced only moderate heating, in comets – and as interplanetary dust particles floating in space. The asteroids that were extensively melted are thought to be the sources of igneous meteorites. Collisions between asteroids excavate rocks from their surfaces and interiors and, in some cases, send fragments (called meteoroids) to the Earth-crossing orbits. When meteoroids collide with the Earth's atmosphere, they get heated and produce glowing objects known as meteors (or shooting stars, or fireballs if larger than average size). Partial melting and ablation of the surface during atmosphere passage reduces the size of meteoroids and destroys many of them completely, but in many cases, their interior parts survive and fall on Earth. These remnants of meteoroids, known as meteorites, are our main source of knowledge about the chronology and evolution of our solar system.

Meteorites and Planetary Materials

The U–Pb-isotopic chronometer measures the timing of the last significant fractionation between U and Pb. Minerals and rocks that contain U, but did not incorporate any Pb during their formation, or lost all Pb in some secondary process, are most suitable for U–Pb dating and can produce the

*Email: yuri.amelin@anu.edu.au

most accurate and model-independent ages. In terrestrial rocks and minerals, Pb is effectively excluded during crystallization of the minerals such as zircon from the magma. Along with high U concentrations about 10–1,000 ppm or higher, the absence of initially present Pb makes zircon, baddeleyite, and monazite the best geochronometer minerals. Magmatism in the Moon and Mars also produced zircon and baddeleyite, although not as ubiquitous as on the Earth due to the absence of abundant liquid water. These minerals are providing the most accurate U–Pb-isotopic dates for lunar (Nemchin et al. 2009; Grange et al. 2013) and Martian (Zhou et al. 2013) rocks. In contrast, chondrites (meteorites from asteroids that never melted) did not experience large-scale melting. Zircon in chondrites is very rare, small, and low U and has an uncertain, possibly metamorphic, origin. Its usefulness for U–Pb dating has been, so far, very limited. Almost all existing data on chondrite U–Pb chronology were obtained by analysis of two types of objects. The first is mm-sized (rarely cm-sized) compact aggregates of various shapes composed of Ca, Al, Ti-rich oxide, and silicate minerals such as spinel, hibonite, Ca, Ti-rich pyroxene, melilite, and anorthite called Ca, Al-rich inclusions, or CAIs. The second is mm-sized or smaller spherical aggregates composed mainly of ferromagnesian olivine and pyroxene with some feldspathic glassy or microcrystalline material (known as mesostasis) and less abundant Ca-rich pyroxene, Fe, Ni metal, and sulfides called chondrules. It is thought that chondrules formed through local flash heating of the nebular dust, with possible addition of earlier asteroidal melts in some cases. Most CAIs and chondrules experienced partial or complete melting, but because of their small size and rapid cooling, the melt differentiation did not do far enough to produce datable zircon and baddeleyite. However, small size of chondrules and CAIs, and relatively low pressure in the nebula where they formed, caused efficient Pb removal through evaporation. This fractionation, driven by the large difference in volatility between U and Pb (Lodders 2003), is the main geochemical mechanism that makes dating of the chondrite components possible. Achondrites occupy an intermediate position between chondrites and planetary materials. Their parent bodies have experienced both evaporation and magmatic differentiation. In some cases, one or both of these processes efficiently fractionated U and Pb, and such achondrites (e.g., angrites) are key materials in constructing the early solar system timescale.

The Early Days of Cosmochronology

The U–Pb cosmochronology was born in 1942–1946, when E. K. Gerling, A. Holmes, and F. G. Houtermans estimated the age of the Earth at 3.0–3.9 Ga on the basis of A. Nier's Pb-isotopic analyses of lead and uranium ores (see review by Mattinson 2013). In the mid-1950s, the U–Pb dating method was actively developed and applied to common geological problems by dating minerals such as zircon (Tilton et al. 1955). Cosmochronology was established as a quantitative scientific discipline as a part of that development and the desire to apply the improved dating methods to the most challenging problems. It is marked by the papers by Patterson (1955, 1956), where the ages of meteorites now known as equilibrated ordinary chondrites, eucrites, and iron meteorites were determined with the Pb–Pb method. The meteorite ages reported in these papers are often cited as examples of remarkable consistency with the current best estimate of the age of the solar system. Existence of short-lived radionuclides in the early solar system was discovered shortly after by Jeffery and Reynolds (1961), but for the following 30–40 years, the studies of the decay products of short-lived (now extinct) isotopes in meteorites were mainly concerned with nucleocosmochronology, understanding the history of stellar nucleosynthesis and the age of the elements (Podosek and Swindle 1988), while dating of solar system formation was based on the

same long-lived radionuclide systems that were used in terrestrial geochronology: U–Th–Pb, ^{40}K – ^{40}Ar , ^{87}Rb – ^{87}Sr , and ^{147}Sm – ^{143}Nd (Tilton 1988).

Modern U–Pb Among Other Meteorite Dating Methods

In the late 1980s and 1990s, it was realized that the duration of solar system formation was only of the order of 10 Ma and precision of about 1 Ma or better is required to resolve events. The short-lived chronometers can provide such precision, whereas the long-lived systems, with the exception of $^{207}\text{Pb}/^{206}\text{Pb}$, cannot. As a result, modern chronology of the earliest solids relies entirely of extinct radionuclides with half-lives shorter than ~ 20 Ma, coupled with the U–Pb system. The most popular extinct radionuclide chronometers, which are also most commonly used together with U–Pb, are ^{26}Al – ^{26}Mg (half-life 0.7 Ma), ^{53}Mn – ^{53}Cr (half-life 3.7 Ma), and ^{182}Hf – ^{182}W (half-life 8.9 Ma). While the other long-lived (extant) radionuclide pairs – ^{40}K – ^{40}Ar , ^{87}Rb – ^{87}Sr , ^{187}Re – ^{187}Os , ^{176}Lu – ^{176}Hf , ^{147}Sm – ^{143}Nd , and ^{146}Sm – ^{142}Nd – are very important as terrestrial and planetary chronometers, and isotopic tracers for both terrestrial and extraterrestrial rocks, their role in dating pre-planetary rocks is limited (Kleine and Rudge 2011; Amelin and Ireland 2013).

Methodology and Techniques of U–Pb Dating Meteorites

All U–Pb dates of meteorites with precision of better than 1–2 Ma, sufficient to resolve the timing of the stages of accretion, are obtained by analyses of either whole rocks or minerals such as clinopyroxene or Ca phosphates apatite and merrillite, after removal of the surface contamination containing non-radiogenic Pb by acid leaching. Both thermal ionization mass spectrometry (TIMS) and multicollector plasma ionization mass spectrometry (MC-ICPMS) are capable of producing very precise dates. Isotope dilution using ^{202}Pb – ^{205}Pb double spike for Pb and ^{233}U – ^{236}U double spike for U is becoming increasingly popular and is used with both TIMS and MC-ICPMS. Using double spikes is recognized as the most capable way for accurate determination of concentrations and isotopic compositions of Pb and U with simultaneous fractionation correction. Other techniques – standard-sample bracketing and fractionation correction relative to $^{203}\text{Tl}/^{205}\text{Tl}$ – can be used to precisely measure Pb-isotopic composition by MC-ICPMS, but they unfortunately cannot precisely measure U–Pb ratios in the same fraction. Since the discovery of significant $^{238}\text{U}/^{235}\text{U}$ isotopic variations in the CAIs (Brennecka et al. 2010), measurement of U isotopic composition is considered a mandatory part of every age determination of CAIs. Whether the same requirement applies to the studies of other meteorite components is currently unclear. Recent studies suggest that $^{238}\text{U}/^{235}\text{U}$ variations among chondrules, bulk chondrites, and achondrites are much smaller than in CAIs (Amelin et al. 2010; Brennecka and Wadhwa 2012; Connelly et al. 2012), even if they are slightly outside of the estimated analytical uncertainties. Using an average $^{238}\text{U}/^{235}\text{U} = 137.79 \pm 0.02$ in U–Pb dating of chondrules and achondrite is an acceptable temporary solution, but direct U isotopic analysis of every sample is a better approach.

Ages of CAIs

CAIs are present in most types of carbonaceous and ordinary chondrites, but only in CV (Vigarano type) carbonaceous chondrites, they are large enough to be extracted and dated individually

Fig. 1 Pb-isotopic ages of CAIs

(pooling several CAIs together to get more material is not acceptable because they are diverse in mineralogy and composition, even in a single meteorite). Ever since CAIs were recognized as the oldest macroscopic objects that formed in the solar protoplanetary disk, they attract attention of geochronologists and serve as the reference points in many timescales of the solar system formation. U–Pb ages of CAIs, from the first studies by Chen and Tilton (1976) and Tatsumoto et al. (1976), served as a time marker for the beginning of accretion in our solar system. Published Pb-isotopic ages of CAIs from CV chondrites, summarized by Tilton (1988), Allègre et al. (1995), Amelin et al. (2009), and recently by Amelin and Ireland (2013), are compiled in Fig. 1.

All CAIs studied between 1976 and 2002 were extracted from a single, very large, CV chondrite – Allende. Now precise Pb-isotopic ages are determined on the CAIs from four CV chondrites that differ in the degree of alteration in the parent body, shock, and terrestrial weathering. Despite this diversity in secondary processes, all recent age determinations of CAIs from Allende (Amelin et al. 2010), Efremovka (Connelly et al. 2012), and NWA 4502 (Amelin et al. 2013) are in excellent agreement, with a total range for the ages of about 0.2 million years – from 4567.18 ± 0.50 to 4567.40 ± 0.27 Ma. All these studies include analyses of the $^{238}\text{U}/^{235}\text{U}$ ratios. An attempt to calculate an age correction based on an empirical $^{238}\text{U}/^{235}\text{U}$ versus Th/U correlation for other CAIs produced a discrepant age for a CAI from CV chondrite NWA 2364 (Bouvier and Wadhwa 2010). This result further emphasizes that the $^{238}\text{U}/^{235}\text{U}$ must be determined in any chronological study of CAIs.

Ages of Chondrules

In Pb-isotopic dating of chondrules, it is more difficult to achieve high precision than in dating CAIs, because of lower U content (usually about 10–20 ppb), higher content of non-radiogenic Pb, and smaller size than CV chondrite CAIs. Like in dating CAIs, pooling several chondrules for analysis is undesirable, because ^{26}Al – ^{26}Mg ion microprobe dating of individual chondrules has revealed age variations between chondrules in most chondrites. Modern Pb-isotopic dates obtained on individual large chondrules from CR (Amelin et al. 2002) and LL3 (Connelly et al. 2012)

chondrites indicate that chondrule formation probably started simultaneously with CAI formation and continued for up to 3–4 million years. Several studies of chondrules from Allende, mostly using multi-chondrule fractions and/or older, less efficient leaching techniques, yielded similar although less precise ages. CB chondrites contain the youngest chondrules that postdate the CAIs by 4–5 million years (Krot et al. 2005). It was proposed that these chondrules, and metal grains – another main component of CB chondrites – formed from a vapor–melt plume produced by a giant impact between planetary embryos after dust in the protoplanetary disk had largely dissipated.

Ages of Achondrites

Eucrites – the most common stony igneous meteorites composed mainly of low-Ca orthopyroxene, plagioclase, and pigeonite, were among the first meteorites studied for U–Pb systematics. The eucrite Nuevo Laredo was analyzed by Patterson (1956) and provided the most radiogenic data point that largely controls the slope of the isochron he used to estimate the age of the solar system and the Earth. Eucrites remained popular in the studies of the early solar system chronology until the 1990s and helped to establish the main benchmarks of early solar system evolution. However, eventually it became clear that their complex geological history prevented accurate and straightforward age determination. Meteorites of other classes, such as angrites (basaltic achondrites composed of Al–Ca–Ti-rich clinopyroxene, Ca-rich plagioclase, and Ca-rich olivine), anomalous eucrite-like meteorites (coming from asteroids other than Vesta, which is thought to be the parent body of eucrites), and some unclassified basaltic achondrites, although rare, are better suited for high-resolution dating of the stages of nebular condensation and accretion. The oldest known achondrite is eucrite-like meteorite Asuka 881394 which is only 1–2 million years younger than CAIs (Wadhwa et al. 2009) and is approximately coeval with chondrules. Quenched angrites such as D’Orbigny, a subgroup of angrites with the texture indicating rapid cooling, postdate CAIs by 4 million years (Amelin 2008; Brennecka and Wadhwa 2012). Several anomalous achondrites with diverse mineralogy and chemical and oxygen isotope composition, indicating their origin from different asteroids, are 1–2 million years younger than quenched angrites (e.g., Bouvier et al. 2011). Plutonic angrites (a slowly cooled variety of angrites with similar mineralogy and oxygen isotopic composition as quenched angrites, and probably originating from the same asteroid) are 5–7 million years younger than quenched angrites. Eucrite-like achondrite Ibitira and primitive achondrite Acapulco (a rock with approximately chondritic composition but igneous texture, indicating melting of a chondritic source material with no igneous differentiation) have the same age as the youngest plutonic angrites, or about 10 million years younger than CAIs. These data indicate that many asteroids accreted and melted within 5–10 million years after the beginning of accretion marked by formation of CAIs and remained undisturbed since then. The 5–10-million-year time estimate is consistent with the estimated life spans of protoplanetary disks around young protostars based on astronomical observations.

Cooling History of Asteroids

Cooling paths of asteroids can be established by Pb-isotopic dating of two or more minerals from the same meteorite with different closure temperatures for diffusion of Pb (diffusion of U in the minerals used in U–Pb geochronology is much slower, so the closure of the isotopic system is

controlled by Pb diffusion). The cooling path deduced this way could be used to constrain the timing and duration of formation of the meteorite parent body and to interpret its structure. Some meteorites such as equilibrated (i.e., metamorphosed) ordinary chondrites and plutonic angrites contain U-bearing silicates and Ca phosphates apatite and merrillite that can be dated independently, and their ages interpreted as the timing of cessation of Pb diffusion in these minerals. Using experimental data on the rates of Pb diffusion in pyroxene and apatite of Cherniak et al. (1991) and Cherniak (2001) and Pb–Pb isochron dates of chondrules and apatite separates, Amelin et al. (2005) estimated the average cooling rate of the parent body of the Richardton ordinary chondrite (H5) at 26 ± 13 K/million years over the period of 4,563–4,551 million years. More precise Pb-isotopic dating of pyroxene and silicic apatite in the plutonic angrite NWA 4590 yielded the age difference of 0.55 ± 0.29 million years and a much faster cooling rate of 540 ± 290 K/million years, implying either a small size or a late breakup of the angrite parent asteroid.

Building Coherent Timescale of the Early Solar System with Integrated U–Pb and Extinct Radionuclide Dates

Although U–Pb is a versatile chronometer of meteorites, it can only date rocks and minerals that contain uranium, and events that fractionate uranium from lead. If a meteorite can be dated with one or more short-lived radionuclide chronometer, and it can be shown that these dates and the U–Pb date refer to the same event, then the extinct radionuclide chronometers can be linked to absolute time and a timescale of solar system formation can be constructed using multiple chronometers (see, e.g., Amelin and Ireland 2013 for details). This approach allows us to use minerals that concentrate short-lived radionuclides, such as plagioclase containing ^{26}Al , and olivine containing ^{53}Mn , as geochronometers, and date events that cannot be dated with the U–Pb method. A classical example is the timescale of the early solar system constructed by Lugmair and Shukolyukov (1998) using a set of ^{53}Mn – ^{53}Cr dates and the Pb-isotopic age of the angrite Lewis Cliff 86010 (Lugmair and Galer 1992) as an anchor to the absolute time. Angrites are especially well suited as reference samples for intercalibration of isotopic chronometers. Their rich and diverse mineralogy and good preservation of angrites enables their precise and accurate dating with many long-lived ($^{235,238}\text{U}$ – ^{232}Th – $^{206,207,208}\text{Pb}$, ^{176}Lu – ^{176}Hf , $^{146,147}\text{Sm}$ – $^{142,143}\text{Nd}$, initial Sr) and short-lived (^{53}Mn – ^{53}Cr , ^{26}Al – ^{26}Mg , ^{60}Fe – ^{60}Ni , ^{182}Hf – ^{182}W) isotopic chronometers. With multi-chronometer dates for several angrites and other well-preserved achondrites, as well as chondrules and CAIs, we can also verify initial abundances of short-lived radionuclides in the early solar system and find out whether they were homogeneously distributed. This information provides constraints on the environment in which our solar system formed, for example, it can tell us whether it was influenced by nearby massive stars during accretion.

Summary

The U–Pb system is a powerful and versatile chronometer of the early solar system materials and processes. Pb-isotopic dates show that CAIs formed 4567.2–4567.4 million years ago, chondrules formed during the following 3–4 million years, and differentiated asteroids formed between 1–2 and 10 million years after CAIs. This age distribution is consistent with an astronomical evidence on the rates of evolution of protoplanetary disks and suggests that, during accretion, our solar system comprised an assembly of hot and cold domains, pristine dust, and partially molten

planetesimals that coexisted and interacted for less than 10 million years. Subsequent metamorphic events and cooling of asteroids can be studied by Pb-isotopic dating of silicate and phosphate minerals from the same meteorite. Combining U–Pb with short-lived radionuclide chronometers helps to construct a timescale with higher resolution, tests it for internal consistency, and gives us hints to the environment of the solar system formation.

Apatite

W. Jack Rink*

School of Geography and Earth Sciences, McMaster University, West Hamilton, Ontario, Canada

Synonyms

Chlorapatite (chlorine-rich variety); Dahllite (carbonate-bearing hydroxyapatite); Fluorapatite (fluorine-rich variety); Francolite (carbonate-rich variety); Hydroxyapatite (hydroxyl-rich variety)

Apatite is described herein and as a biomineral (biological apatite). The mineral apatite has the formula $\text{Ca}_5(\text{PO}_4)_3(\text{F}, \text{Cl}, \text{OH})$ and is characterized (Fig. 1) by phosphorus tetrahedrons which share oxygen with nine-coordinated calcium sites and singly charged anion lattice sites hosting F, Cl, or OH that are surrounded by a planar arrangement of three calcium atoms (Beever and McIntyre 1946). It occurs widely as an accessory mineral in all classes of rocks: igneous, metamorphic, and sedimentary (Klein and Hurlbut 1999). It is also found in pegmatites and other veins, probably of hydrothermal origin. The source of its datability is the radioactive trace element uranium that substitutes for calcium.

It is most commonly used as a dating material in thermochronology of large-scale earth processes via three different dating methods: (U-Th)/He, $^3\text{He}/^4\text{He}$, and fission track, recently covering topics such as exhumation studies of mountain ranges (Cecil et al. 2006), transient erosion of orogens (Rahl et al. 2007), glacial erosion (Ehlers et al. 2006; Shuster et al. 2005), and erosion of foreland basins (Cederbom et al. 2011) or exotic applications like the age and temperature of shock metamorphism

*Email: rinkwj@mcmaster.ca

of meteorites (Min et al. 2004). Apatite's versatility as a dating material is attested through the wide array of other dating methods that have been applied. Thomson et al. (2012) have reported the successful application U-Pb dating in apatite using laser ablation multicollector inductively coupled plasma mass spectrometry. In addition, cosmogenic nuclide dating of apatite using ^3He (Farley et al. 2006), uranium-series dating of phosphorites (Jarvis et al. 1994), and Lu-Hf and Pb step-leaching geochronology in metamorphic apatites have also been reported.

Feldspar, Infrared-Stimulated Luminescence

Mayank Jain*

Center for Nuclear Technologies, Technical University of Denmark, DTU Risø Campus, Roskilde, Denmark

Definition

This entry primarily concerns the characteristics and the origins of infrared-stimulated luminescence in feldspars.

Introduction

Feldspar is a dominant (~60 %) rock-forming mineral group in the Earth's crust. Plagioclase feldspars ($\text{NaAlSi}_3\text{O}_8$ – $\text{CaAl}_2\text{Si}_2\text{O}_8$) are also commonly observed in meteorite samples and are a major mineral constituent on the surface of other extraterrestrial bodies such as the Moon and Mars. In luminescence dating, K-feldspar (KAlSi_3O_8) is the most commonly used dosimeter after quartz.

Feldspars have a direct band gap (with parabolic conduction/valence band) which varies with mineralogical composition: 7.86, 7.70, and 7.62 eV in $\text{NaAlSi}_3\text{O}_8$, KAlSi_3O_8 , and $\text{CaAl}_2\text{Si}_2\text{O}_8$, respectively (Malins et al. 2004; Poolton et al. 2006). Additionally, feldspars have low-mobility band-tail states which may extend up to >1 eV in individual samples (Poolton et al. 2006, 2009). Both structural and atomic defects states occupy the band gap, which give feldspars their dosimetric (geochronometric) characteristics. Exposure to ionizing radiation creates free charge (electrons and holes) that can be trapped at these defects and be subsequently excited either thermally or optically in the UV–vis–NIR (ultraviolet–visible–near infrared) range. This entry concerns the near-infrared (NIR, henceforth IR) resonance feature observed between 750 and 1,000 nm during optical stimulation of these trapped charges and its dosimetric characteristics.

The main interest in the IR resonance in feldspars follows from the fact that IR-stimulated luminescence (IRSL) signal grows to typically more than 1 kGy with ionizing dose, thus giving the potential for increasing the upper end of the optically stimulated luminescence (OSL) dating range by a factor of about 5–10. Moreover, feldspar IRSL is typically the only preferable dating signal either in samples that lack quartz (e.g., basic volcanic provinces, Moon, Mars, meteorites, etc.) or in samples that have insensitive quartz. Being mineral specific, there is also a significant methodological value in using IR resonance for targeting, identifying, or cleaning signals from feldspar phases in untreated polymineral samples (e.g., fine silt or clay-sized sediments, or field dating samples).

Historical Development

To the author's knowledge, the first published study demonstrating the phenomenon of OSL was based on IR stimulation of prior excited strontium sulfide and strontium selenide (rare earth element doped) phosphors (Ellickson 1946). Ellickson demonstrated that there is a relationship between the IRSL signal and the thermoluminescence (TL) traps in these materials and that the shape of the IRSL signal decay is dependent on the IR intensity and it followed second-order kinetics. However, it took several decades to realize the potential of OSL or IRSL in dosimetry and dating. IRSL was independently discovered by Hutt et al. (1988) while measuring excitation spectra of previously irradiated K-feldspar samples. These authors observed strong multiple, overlapping peaks in the region of 1.2–1.6 eV (~750–1,000 nm) and proposed that the IR resonance in feldspars arises by a two-step process: IR photon absorption by a trapped electron (photoionization energy of ~2.5 eV) causing transition to its excited state, followed by a thermally assisted transition to the conduction band. This study kick-started widespread use of feldspar IRSL for luminescence dating because of cheap availability IR light-emitting diodes (Poolton and Bailiff 1989) that could be easily implemented in a TL/OSL reader (Bøtter-Jensen et al. 1991). Subsequent studies established that IRSL was thermally stable and bleached easily with daylight, although somewhat less rapidly compared to the OSL of quartz (see Murray et al. 2012), making it a suitable signal for dating. However, unfortunately, IRSL signal suffered from a special type of instability popularly known as “anomalous fading” (loss of thermally stable charge at room temperature; Wintle 1973). In the last two decades or so, the single biggest issue in IRSL dating has been tackling the anomalous fading problem. For example, there has been focus on defining the mechanisms of fading (Spooner 1994; Visocekas et al. 1994; Huntley 2006; Larsen et al. 2009), fading correction methods (Huntley and Lamothe 2001; Kars et al. 2008), and a hunt for more stable IRSL signals (Fattahi and Stokes 2004; Tsukamoto et al. 2006; Thomsen et al. 2008; Buylaert et al. 2009, 2012; Jain and Ankjærgaard 2011). There has also been a significant thrust, both experimentally and theoretically, to understand the basic physical mechanisms involved in IRSL production with the ultimate objective of obtaining a better insight into the fading problem (e.g., Poolton et al. 1994, 1995a, b, 2002a, b, 2006; Jain and Ankjærgaard 2011; Andersen et al. 2012; Jain et al. 2012; Kitis and Pagonis 2013). See Duller (1997) for an extensive review on the subject.

Characteristics of the IRSL

The IRSL emission occurs in several different bands centered at ~1.7, 2.2, 3.1, 3.7, and 4.1 eV (see review by Krbetschek et al. 1997 and the later extensive survey by Baril and Huntley 2003a). Baril and Huntley observed for preheated samples that the 2.2 eV band was dominant in plagioclase feldspars, while the 3.1 eV band was dominant in alkali feldspars. They also observed a band at 1.7 eV that was primarily present in the samples that did not receive any preheating after irradiation. The 3.1 eV band is probably due to the native lattice defects, while 2.2 and 1.7 eV emissions are considered to arise from Mn^{2+} and Fe^{3+} transition metal ion impurities, respectively (see Poolton et al. 2001; Krbetschek et al. 1997). The 3.1 eV band is commonly used in IRSL dating, and it suffers from anomalous fading, which is now widely accepted to be caused by tunneling of electrons from the ground state of the dosimetric trap to the holes trapped at luminescence centers (Spooner 1994). It has been proposed that the orange-red emission in IRSL is more stable in terms of anomalous fading (Fattahi and Stokes 2004).

The UV band shows a strong thermal dependence at high temperatures (0.15 eV activation energy) and a small or no thermal dependence at low temperatures (0.05 eV–0.0005 eV activation energy) in both K- and Na-feldspar samples (Rieser et al. 1997; Poolton et al. 2009). It has also been shown that IRSL involves higher thermal activation energy at the end of the IRSL decay curve than at the beginning (Li 2010). The peak energy of the IR resonance is quite stable with temperature (Andersen et al. 2012); the main effect of temperature is an apparent broadening of the resonance structure. The IRSL decay rate generally increases with temperature (see McKeever et al. 1997); however, the extent of this change can vary significantly from sample to sample. An intriguing thermal characteristic of feldspar IRSL is that the net signal intensity as well as the net depletion of the trapped charge increases with stimulation temperature. Jain and Singhvi (2001) found that the dosimetric trap giving rise to OSL and IRSL in K-feldspar can be gradually emptied by high-temperature IR stimulations, suggesting a strong thermal dependence on trap emptying in the IRSL process. They attributed this effect to existence of a light sensitive trap deeper than the IRSL trap and speculated that this trap may not show anomalous fading because of expected greater localization. This thermal characteristic, general to all feldspars, implies that the IRSL signal can be regenerated thermally after IR bleaching at a lower temperature. For example, it is possible to do an IRSL measurement at room temperature followed by another measurement at a higher temperature (Thomsen et al. 2008) or by a sequence of systematically increasing temperatures (Li and Li 2011a); these signals are often known as elevated temperature “post-IR-IRSL” (pIR-IRSL) signals. The general characteristic of these high-temperature signals is that they show less anomalous fading compared to the first IRSL signal measured at room temperature (Thomsen et al. 2008; Li and Li 2011a; Buylaert et al. 2012).

Mechanism: IR Resonance and Luminescence Generation

The resonance feature observed in the excitation spectra of prior irradiated feldspar rock mineral or sediment samples has been widely studied by various workers (e.g., Bøtter-Jensen et al. 1994; Baril and Huntley 2003b; Poolton et al. 1995a, 1997, 2009; Barnett and Bailiff 1997; Andersen et al. 2012). The broad resonance spectrum consists of 1–3 overlapping peaks superimposed on a monotonously rising continuum. Spectral analysis suggests that there are two resonance peaks in the region ~1.42–1.56 eV, which are generally characteristic of most feldspar samples, and an occasional peak at about 1.25 or 1.34 eV.

The dominant resonance in the region of ~1.44 eV is widely accepted to arise due to ground-to-excited state transition in a deep dosimetric electron trap upon direct absorption of an IR photon and subsequent recombination. The exact peak energy of the resonance has been found to change with the feldspar composition. Poolton et al. (1995a) modeled this peak shift assuming a hydrogenic donor center (1s-2p transition) and an effective electron mass of $0.757 m_e$ to obtain peak energies of 1.44, 1.42, and 1.27 eV in K, Na, and Ca end-members, respectively. The effective electron mass was later confirmed to be $0.79 m_e$ using optically detected cyclotron resonance in a sample of Na-feldspar (Poolton et al. 2001).

Despite a general agreement on the origin of the resonant energy, there has been a considerable debate on the luminescence generating mechanism subsequent to resonant excitation. The Hütt model (Hütt et al. 1988) assumes recombination via the conduction band after a thermally activated transition from the excited state; however, the thermal barrier of about 0.8 eV for such a process is rather high and is not likely to be overcome on the measurement time scales (few tens of seconds) at or below room temperature. Studies using exo-electron emission have confirmed that the

conduction band does not participate in the IRSL process at room temperature (Ankjærgaard et al. 2006). The most widely accepted model today is the “band-tail state” model proposed by Poolton et al. (1994). These authors investigated the relationship between crystal structure and the OSL properties of feldspar and suggested existence of low-mobility band-tail states arising due to high density of atomic or structural perturbations (impurity atoms, variations in bonding angles, lattice distortions, etc.). The band-tail state model is based on a donor–acceptor recombination, where an excited state electron undergoes tunneling or phonon-assisted band-tail hopping in order to recombine with a trapped hole. This model also explains the broad continuum underlying the resonance peak (Poolton et al. 2002a, b).

The proof for the existence of the band-tail states and their role in charge transport by thermal hopping or tunneling comes in more recent studies (Poolton et al. 2009; Jain and Ankjærgaard 2011). Jain and Ankjærgaard (2011) developed a comprehensive phenomenological model based on a single dosimetric trap. They proposed that two dominant recombination routes in the band-tail states (0.05 eV phonon-assisted diffusion and quantum mechanical tunneling) together with energy-dependent, localized or delocalized recombinations give rise to a range of observable luminescence phenomena (both thermal and optical) in feldspars. This model is able to qualitatively relate all observable luminescence behavior of feldspar to a single dosimetric trap and the known available energy levels such as the excited state (~1.44 eV) of the trap and the band-tail states.

The IRSL Trap

There has also been a significant debate in literature on whether the IRSL signal originates from a single or multiple electron traps. The multiple trap hypothesis is generally based on examination of thermal characteristics of the IRSL signals; these include a systematic depletion in the TL signal with the duration of IR exposure (e.g., Duller 1995) and an increasing depletion in the IR intensity with preheat (anneal) temperature (the so-called “pulse-anneal” curves; Duller 1994). A gradual systematic decrease in such data, either as a function of exposure time or preheat temperature, suggests that IRSL arises from multiple discrete or a continuum of traps in feldspars. However, based on a systematic study of sample ages with preheat temperatures, Murray et al. (2009) concluded that decrease in the intensities of the low-temperature TL peaks due to IR exposure reflects reduction in the hole population rather than the trapped electron population. They identified the source of IRSL to be the trap responsible for the TL peak at ~400 °C. There has also been a significant discussion on the origin of the high-temperature or PIR-IRSL signals. Jain and Singhvi (2001) attributed that high-temperature IR stimulation accesses a deeper (type B in their terminology) trap compared to the IR at room temperature. They also speculated that the deeper trap may be more stable in terms of anomalous fading. The same hypothesis has been advocated also in later works to explain the pulse-anneal behavior of the PIR-IRSL signals (Li and Li 2011b). However, a consideration of localized recombination through the excited state in feldspars suggests that pulse-anneal curves can be explained by both single and multiple trap hypothesis and such data are, therefore, inconclusive for determining the types of trapping states (Thomsen et al. 2011). Jain and Ankjærgaard (2011) demonstrate that it is phenomenologically possible to explain all thermal and optical behavior of feldspars in terms of a single dosimetric electron trap with different recombination routes/mechanisms.

A more direct examination of the single vs. multiple trap issue is acquired through excitation spectroscopy. For a wide range of excitation energies (visible to IR), the luminescence output has

been observed to be consistent with a single trap model (Baril and Huntley 2003b; Andersen et al. 2012; Kars et al. 2013). Similarly, the resonance peak does not vary with stimulation temperature up to 290 °C apart from the expected thermal broadening effect suggesting that the same trap is sampled even at very high temperatures (Andersen et al. 2012). There has been observed a minor blue shift in the excitation spectra measured after a prior IR bleach (i.e., pIR-IRSL resonance) of about 10–20 meV; this shift is compatible with the measured phonon assistance required for electron transport in the band-tail states (Jain and Ankjærgaard 2011) confirming that IRSL and the PIR-IRSL signals arise from the same dosimetric trap (Andersen et al. 2012).

There have been several attempts to estimate thermal trap depth using the first-order analysis of the pulse-anneal data; these give a range of values: 1.7 eV (Murray et al. 2009), 1.66 eV (Li and Tso 1997), and 1.8 eV (Li and Li 2011b). The values for PIR-IRSL range from 2.2 to 2.4 eV or 1.9 to 2.1 eV depending on whether the continuum of states in the band tails is considered or not (Li and Li 2011b, 2013). It is, however, questionable whether the first-order analysis is valid for feldspars in view of the complex energy structure and different recombination routes (Jain and Ankjærgaard 2011). Jain et al. (2012) have developed a new numerical model for analysis of such systems, which seems to be able to explain the shape of the TL and IRSL decay curve using a single dosimetric trap (Kitis and Pagonis 2013). Further tests of the model to predict luminescence behavior of feldspars is necessary.

The presence of the band-tail states makes it difficult to measure the trap depth directly by optical methods. Some estimates of optical trap depth in literature are 2.5 eV (Clark and Sanderson 1994), >2.5 eV (Baril and Huntley 2003b), and >2.4 eV (Short 2005; Jain and Ankjærgaard 2011). In a recent extensive study, Kars et al. (2013) have given tentative estimates of optical trap depth to be ~2.1 for Na-feldspar and ~2.5 eV for K-feldspar.

Dating Methods Using IRSL

Use of IRSL in dating requires detection and, if necessary, correction for anomalous fading. Today the most commonly used dose measurement method is SAR (single-aliquot regenerative dose), which is based on sensitivity monitoring using a test dose (Murray and Wintle 2000; Wallinga et al. 2000). Estimation of precise fading rate for age correction has been an issue. Auclair et al. (2003) adapted the SAR method to measurement of fading rates, which are subsequently used to correct ages using a simple integration of charge depletion (t^{-1} dependence) and trapping over the geological time scales (Huntley and Lamothe 2001) or a more complex model using distance distributions (Kars et al. 2008). Age corrections are typically 20–40 % and the correction models are highly extrapolative. In the past 5 years, several new dating methods, based on very low or nonfading IRSL signals, have been proposed. Of these, the method based on the pIR-IRSL signals is becoming increasingly routine in dating applications; this method relies on preferential selection of electrons that are distant enough from any holes so as not to undergo ground-state tunneling in nature (Thomsen et al. 2008; Buylaert et al. 2012).

Ancient Inks: A Forensic Art Historical Perspective

Howell G. M. Edwards*

Chemical and Forensic Sciences, School of Life Sciences, University of Bradford, Bradford, UK

Definition

Ink: A colored, usually liquid, material used for writing which is applied with a brush, stylus or pen to a variety of surfaces such as paper, papyrus, parchment, vellum or fabrics.

Inks have been used to record events and data in documentation and for the decorative arts since 2700 BCE; a description of the different types of ink used historically for nearly 5,000 years will be followed by a survey of analytical information available based on their chemical composition which can provide a chronological assessment. In conclusion, analytical case studies are presented briefly of two important historical manuscripts, namely, the *Vinland Map*, which purportedly was drawn in the early fifteenth century and shows the northeastern coast of North America some 60 years before the voyage of Columbus, and the Voynich Manuscript, a mysterious historiated fifteenth-century herbal which has thus far defied translation and which has been termed the most enigmatic ancient manuscript in existence.

Introduction

The earliest form of writing, cuneiform, involved the inscribing of characters into wet clay which was then fired to produce ceramic tablets; the adoption of cut reed pens and fluid inks applied to paper was perfected in China around 2700 BCE and attributed to the Chinese philosopher Tien-Lcheu. Hence, ink has existed for over 4,700 years of human history – its name derives from the Latin *incaustum* and the early French *encre*; a major problem in the dating of inked artifacts is the rather limited range of experimental compositions of historical inks, which can reliably be described as being either early carbon-based or later iron gallotannate inks (Thompson 1996; Cradock 2009; Brunelli and Crawford 2003).

The earliest ink, formulated in China from carbon black suspended in an aqueous solution of water and gum arabic, is now known as *India ink* because the best carbon supplies at that time for this purpose were sourced in India; the carbon was synthesized by burning wood such as pine, in which the partially combusted resin helped to bind the sooty deposits, in a limited amount of air under an upturned iron or ceramic dish. Other carbons were sourced from the calcination of animal bone and ivory, which produced a deeper black color – these contained residues of calcium phosphate derived from the hydroxyapatite component and provide an analytical signature of *bone black* or *ivory black*.

The discovery of natural mineral oils and petroleums afforded another opportunity for the production of a deep black sooty residue upon combustion in a limited supply of oxygen. A hierarchical basis for recipes for the production of carbonaceous soot existed in which certain botanical materials were highly prized for combustion to form the blackest inks, such as peach stones, almond shells, and vine twigs. There was much empiricism in the formulation of early inks

*Email: h.g.m.edwards@bradford.ac.uk

as evidenced by the universal adoption of gum arabic as a binding agent; in addition to assisting the suspension of the insoluble carbon particles in the aqueous ink medium, the water-soluble gum arabic modified the viscosity of the ink, assisting in the writing flow when applied with reed pens, quills, and brushes and also improving the adhesion of the ink to the substrate. However, the addition of too much *gum arabic* resulted in a brittleness of the dried ink applied and a tendency for the writing to flake off – hence, the debris found between the leaves of ancient manuscripts frequently contains particles of ink from the associated script which can provide a rich source of analytical information without involving the destruction of the manuscript text. Different names have been recorded for carbon black inks through the ages, dependent upon formulation or source, such as *bistre* (Seaver 2004), an extract from sooty fires which possessed a warm brown color, and *sepia*, a dark, semitransparent ink from cuttlefish much used by the Romans.

Despite prior historical usage for a period of some 3,800 years, from about 1130 ACE *iron gall* ink replaced *carbon black* ink as the favored medium of writing; *iron gall* ink, more correctly described as an iron gallotannate, was the first water-based ink to be made from a chemical reaction between aqueous solutions of iron (II) sulfate and extracts of oak galls with the addition of gum arabic. Oak galls are spherical nutlike protuberances resulting from the egg laying of wasps on oak trees – the best galls were those fully developed from which the emerging wasp larvae had hatched. As encountered with the carbon-based inks, there are many recipes in existence for the manufacture of iron gall inks; indeed, the chronology for the first appearance of iron gall inks must predate the mediaeval since Pliny in the first century ACE describes in detail the preparation of aqueous gall solutions which blacken in the presence of *copperas*, an iron sulfate ore, which can be used for writing. An example of the complexity of an iron gall ink composition is provided by the following recipe for an ink “of the highest quality” in the sixteenth century: 8 oz powdered Aleppo galls, 4 oz logwood chips, 4 oz iron sulfate, 3 oz powdered gum arabic, 1 oz copper sulfate or verdigris (basic copper acetate), and 1 oz sugar – all heated and triturated in 12 lb of water followed by filtration and the addition of alum, ammonia, beer, lemon juice, oil of cloves, ground walnuts, lavender, wine, boiled oil, and extract of amber or shellac in brandy to minimize the growth of mould.

Iron gallotannate inks quickly became the medium of choice for mediaeval scribes because, unlike the carbon-based inks, they interacted chemically with cellulose substrates, conferring better adhesion and permanence on the script (Thompson 1956). However, this improvement in the better writing permanence of iron gall inks caused severe corrosion problems for paper manuscripts in particular. In some cases, this process resulted in the formation of holes in the manuscript (*lacunae*) in place of the writing (Fig. 1); many manuscripts have suffered irreversibly in this way and pose problems for conservation and the preservation of their integrity (Reissland and de Groot 1999; Reissland 2002). It has been found that arresting the decay can be achieved by the application of calcium bicarbonate, lime, magnesite, and calcium phytate, but generally irreparable damage has resulted for the original script and text (Rouchon-Quillet et al. 2004; Barrow 1972; Delage et al. 1990).

The corrosive effect of iron gallotannate inks upon cellulosic substrates can be related to the iron-catalyzed breakdown of cellulose in an acidic environment (Proost et al. 2004); in this process the Fe^{2+} react with acidic decomposition products of the cellulose to form hydroxyl and oxygenyl radicals, from which the subsequent creation of hydrogen peroxide destroys the cellulose substrate and oxidizes the iron to Fe^{3+} (Bulska and Wagner 2004). Hence, it has been suggested (Proost et al. 2004) that measurement of the $\text{Fe}^{2+}/\text{Fe}^{3+}$ ratio in an ancient iron gall ink could provide a means of assessing its age, although clearly the actual rate of degradation of the ink would be dependent upon several environmental factors, not the least of which would be the recipe and formulation of the original ink. The elemental migration of iron atoms into the substrate also can

Fig. 1 A historical manuscript showing evidence of serious corrosive deterioration from iron gall ink on paper

provide a measure of the age of the script, as determined from Auger spectroscopy, but pitfalls can be encountered in the form of hair follicles in vellum substrates (de Pas and Flieder 1976).

The next development in ink manufacture occurred in the mid-nineteenth century, when a new range of organic dye-based colored inks became available following upon Perkin's synthesis of mauveine; at the London Society of Arts in 1858, the advent of this new range of brightly colored dyestuffs was advocated for ink manufacture with the additional adoption of graphite in place of soot for carbon-based inks.

Other Ancient Inks

It is true that most ancient manuscript texts and writing have been accomplished using black ink, but other colors have been identified, although these are strictly limited; examples include red inks (*cinnabar*, *dragon's blood*, *Brazilwood* extracts), purple (*folium*, *caput mortuum*, *purpurum* extracts) and gold. The major problem that was identified early on with the use of alternatives to carbon black or iron gall-based inks is that unless the pigment was a mineral, such as *cinnabar* or in some rarer cases *hematite*, the extracts from botanical or marine sources were dyestuffs, which were badly affected by light and handling – such was the case for *folium* (also known as *turnsole*) and *purpurum*. The ancient scribes and artists termed these dyes “fugitive” and thereby recognized their impermanence (Lee 2007; Ball 2001).

The problem that faces analytical scientists and art historians is the dating of inked manuscripts; unlike historiated manuscripts such as *Books of Hours* and the *Lindisfarne Gospels*, ancient texts and maps often do not have any coloring pigments associated with them, so the identification of the chemical composition of the ink was an important analytical source of information. Radiocarbon dating procedures are usually not practicable for the dating of ancient inks because of the quantities of specimen required in the destructive analysis, although of course some useful ancillary information can result from the radiocarbon dating of the manuscript substrates.

Dating of Ancient Inks

Traditional methods of characterization of ancient inks (de Pas and Flieder 1976; Cradock 2009) involve the application of techniques such as proton-induced X-ray emission (PIXE) spectroscopy, thin layer chromatography, ultraviolet–visible spectroscopy, infrared spectroscopy, Raman microscopy, micro-X-ray fluorescence spectroscopy, capillary electrophoresis, Rutherford back-scattering spectroscopy, scanning electron microscopy, scanning Auger spectroscopy, and mass spectrometry (La Porte and Stephens 2012; Senvaitiene et al. 2005). The major problems facing the analysts arise from variation of ink composition over the centuries. The central analytical discrimination for the differentiation between iron gall inks and carbon-based inks is the recognition of elemental carbon signals versus those of metallic iron. Secondary issues relate to the analytical identification of potential additives such as gum arabic, shellac, and copper; in this respect, infrared spectroscopy and mass spectrometry provide valuable molecular information that other techniques do not. Thin layer chromatography has been found to be not particularly useful for the compositional discrimination of ancient inks (Senvaitiene et al. 2005). In contrast, the identification of elemental iron by SEM/EDAXS, micro-XRF, and PIXE techniques is often used to indicate the presence of an iron gall ink in preference to a carbon-based ink. Iron gall inks possess an ultraviolet absorption with a sharp, strong band at 215 nm and a shoulder at 269 nm, characteristic of an iron gallotannate complex, compared with corresponding bands at 218 and 274 nm for the uncomplexed gallotannic acid.

Raman spectroscopy can be used to detect amorphous and graphitic carbon and has been applied to the analysis of ancient carbons and inks: a typical Raman spectrum of an ancient carbon derived from a botanical source gives two features, a broad band at $1,320\text{ cm}^{-1}$ ascribed to sp^3 hybridized carbon atoms (the D band) and a sharper band at $1,580\text{ cm}^{-1}$ attributed to sp^2 hybridized carbon atoms (the G band).

As an illustration of the information that can be deduced from the ink analysis of ancient manuscripts, two important manuscripts purporting to be from the fifteenth century will be described in more detail here – one of these, the *Vinland Map*, possesses only black ink on two sheets of vellum (Skelton et al. 1965; Seaver 2004), whereas the other, the *Voynich Manuscript*, is polychrome and comprises 240 sheets of vellum, but with again only black ink script (Kennedy and Churchill 2004; D’Imperio 2012). Both manuscripts were discovered in the early to mid-twentieth century with limited historical provenances and have since been the subject of some intense analytical eschatological and historical research.

Case Study 1: The Vinland Map

The *Vinland Map* is a vellum map of the Old World, measuring approximately $28 \times 40\text{ cm}$, that identifies an area in the Western Atlantic, *Vinlanda Insula*, the so-called Vinland of Scandinavian Viking folklore, showing an area to the northeast of North America, described thereon as “a new and fertile land to the west.” It first appeared in 1957 bound together with a manuscript known as the *Tartar Relation* (the *Historia Tartarorum*), which had an unusual composition of vellum and paper and two leaves of vellum alternating with six of paper, the latter exhibiting bulls’ head watermarks which were identifiable with the Basle Council of the 1430s. The cartographic importance of the *Vinland Map* centered upon its predating the voyage of Christopher Columbus and his epic discovery of the New World in 1492 by approximately 60 years and fed the rumor that

Columbus could actually have used such a map based on earlier Viking seafaring exploits, notably those of Leif Ericson (Seaver 1998).

In 1957, the *Vinland Map* and *Tartar Relation* were examined by British Museum experts in ancient maps and incunabula (Skelton et al. 1965). The philanthropist Paul Mellon donated them to the Beinecke Rare Book and Manuscript Library in Yale University, and in 1972 the Yale University Library commissioned an analysis of the *Vinland Map*, thereby starting a controversy which has raged for over 40 years and is still ongoing! The scientific analysis of the *Vinland Map* opened with a detailed polarized microscopic and X-ray diffraction (XRD) analysis of the inked areas (McCrone and McCrone 1974) from which it was concluded that the presence of anatase, a polymorphic form of titanium (II) oxide, in the ink dated the map firmly to the twentieth century (Gettens and Stout 1942) and indicating the *Vinland Map* to be a fake (Baynes-Cope 1974). Further analyses using scanning electron microscopy and energy-dispersive X-ray (EDX) (McCrone 1988; McCrone 1999) determined that the ink was not an iron gallotannate as found on the associated *Tartar Relation* but was carbon black. The ink and parchment of the *Vinland Map* were reanalyzed (Cahill et al. 1987) using proton-induced X-ray emission (PIXE) spectroscopy and challenged the McCrone conclusion (Delage et al. 1990). Radiocarbon dating of the vellum (Donahue et al. 2002) gave a date of 1432 $\pm$ 11 ACE, which agreed to within one standard deviation with the watermarked date on the associated paper in the *Tartar Relation*.

In 2002, a definitive Raman microspectroscopic study of the *Vinland Map* was undertaken (Brown and Clark 2002) with 632.8 nm laser excitation. The inked areas were apparently composed of two parts: a yellow line which was strongly adherent to the parchment substrate and an overlaid black line which showed evidence of severe loss in parts due to the black pigment “flaking off.” The analysis of the black ink gave the characteristic D and G bands for amorphous carbon at 1,325 and 1,580 cm^{-1} , respectively. The presence of anatase was evident, with characteristic bands at 142 and 398 cm^{-1} and seems to be indicative of a clever forgery; however, care must be taken as anatase has actually been identified in genuine archaeological artifacts significantly predating its established synthesis in the twentieth century (Edwards et al. 2006).

Case Study 2: The Voynich Manuscript

In 1912, Wilfrid Voynich revealed the discovery of his eponymous manuscript, which apparently dates to the early fifteenth century: the 240 vellum pages with black script and historiated polychrome figures, now labelled the “world’s most mysterious manuscript,” resemble a herbal compilation of botanical medicine and alchemy. Believed to be written either in a secret code or in a lost language, the major problem with this manuscript is that it has thus far defied all attempts at translation. The historical provenance of the *Voynich Manuscript*, like that of the *Vinland Map*, is steeped in international intrigue (Kennedy and Churchill 2004; D’Imperio 2012). A recent comprehensive and elegant analysis of the iron gall ink on the Voynich Manuscript has been undertaken (Barabe 2009) using polarized light microscopy, SEM/EDAX spectrometry, micro-XRD, and IR spectroscopy.

Unlike the *Vinland Map*, the *Voynich Manuscript* is historiated and has the advantage of supporting analytical information resulting from the interrogation of the associated pigments to assist in the chronology (Birren 1965; Feller 1966; Roy 1993; Fitzhugh 1997; Berrie 2007; Eastaugh et al. 2004; Harley 1982), which seems to be well established in the mediaeval period.

Conclusion

The identification of and analytical discrimination between ancient inks and the recognition of the corrosive nature of iron gallotannate inks are well documented, but the dating of specimen manuscripts is generally not feasible solely by examination of the ink composition alone; the consideration of associated information from radiocarbon dating of the manuscript substrates, eschatology, lexicography, and chronological placement of historiated pigments materially assists in the verification of the antiquity of a manuscript.

Volcanic Rocks, Ar/Ar

Ajoy K. Baksi*

Department of Geology & Geophysics, Louisiana State University, Baton Rouge, LA, USA

Feasibility

The cooling rate for extrusive material (lava flows and ash beds) is rapid; even for lavas that are ~20 m thick, the central portions cool to <100 °C, in ~10 years following extrusion. Therefore, the time of emplacement is a geological instant as seen from the viewpoint of $^{40}\text{Ar}/^{39}\text{Ar}$ dating. It is critical that the material should remain “undisturbed” thereafter; the material should not be reheated to (say) >100 °C or suffer tectonic deformation. This is generally the case; exceptions are to be found in a series of lava flows (e.g., flood basalts) where reheating close to the contact with the overlying flow is to be expected. In collecting material for dating in such cases, samples must be taken from near the center of each flow, especially if the overlying flow is quite thick (> 10 m). In principle, any material containing measurable quantities of K should be datable; over 50 years of research has shown that the best materials for dating are the minerals sanidine, biotite, hornblende, plagioclase, as well as whole-rock material; for the latter, basaltic (mafic) material appears to be the best, though andesite and rhyolite have been dated successfully in whole-rock form.

Background

The $^{40}\text{Ar}/^{39}\text{Ar}$ method is the most widely used geochronological tool for volcanic rocks, capable of dating a wide variety of materials and covering the age span of ~2 ka to ~4.5 Ga (Renne et al. 1997; Renne 2000). It is particularly useful for dating of relatively young material (< 10 Ma) and yields high-precision ages. For older material where age comparison with other techniques (e.g., U-Pb dating) can be made, $^{40}\text{Ar}/^{39}\text{Ar}$ ages are very precise but commonly are ~1 % younger than U-Pb ages. Since the argon dating techniques are the only ones that utilize a gaseous substance as the daughter product, the possibility of partial resetting of the argon clock remains of concern. In $^{40}\text{Ar}/^{39}\text{Ar}$ stepheating, examination of the results on age spectrum/isochron plots was thought to overcome these problems. All plateau/isochron ages must pass the requisite statistical test for reliability (see Baksi 2005; Sharp and Clague 2006; Baksi 2010a). Further, the samples should be deemed to be unaltered as evaluated by the alteration index (AI) technique (Baksi 2007a), which looks to the level of $^{36}\text{Ar}_\text{I}$ in the phases that are being dated. This is critical, as numerous examples are seen in the literature in which statistically reliable plateau ages are known to underestimate the time of crystallization (Baksi 2010a, b, 2012a, 2014). The AI method works best for whole-rock mafic material as well as plagioclase (see Baksi 2010a, Fig. 2, and Baksi 2014, Fig. 8). Total gas or total fusion ages should not be unequivocally treated as accurate estimates of the time of crystallization (see Baksi 2012a, 2013).

*Email: akbaksi@yahoo.com

Mafic/Intermediate Lava Flows

These are normally dated using crushed whole-rock material and/or plagioclase separates. In both instances, the material used for dating must be as unaltered as possible. This necessitates handpicking of grains under binocular microscope, followed by acid leaching to remove altered phases. For whole-rock material, leaching with dilute nitric acid or hydrochloric acid is followed by washing with distilled/deionized water and dried. For plagioclase separates, leaching with dilute hydrofluoric acid, followed by careful rinsing and drying as above, is the best procedure. Whole-rock material often contains an order of magnitude more K than plagioclase and is easier to date from the analytical point of view, entailing use of smaller subsamples. However, the resulting age spectra commonly show the effects of ^{39}Ar recoil loss/redistribution, from fine-grained phases. Interpretation of such age spectra can be complicated, but with care, useful results can be recovered relating to the time of crystallization. Firstly, step age errors must be calculated carefully using methods set out in Dalrymple et al. (1981). In general, steps extracted at laboratory temperatures of $\sim 700\text{--}1,000\text{ }^{\circ}\text{C}$ may serve to define plateau sections; the highest-temperature steps (with high Ca/K ratios) are dominated by gas extracted from plagioclase (and less so from pyroxene) within the rock. Thus, a small(er) number of steps, each of quite high internal precision, may yield a plateau age. For plagioclase samples, recoil problems are generally absent; the purity and homogeneity of the subsample can be investigated by noting the $^{37}\text{Ar}_{\text{Ca}}/^{39}\text{Ar}_{\text{K}}$ (and hence the Ca/K) of each step in the age spectrum. Published age spectra for both whole-rock material and plagioclase should show the Ca/K ratio of each step. For unaltered plagioclase samples, it may be possible to obtain a plateau from (a larger number of) steps covering a wide range of temperatures ($\sim 600\text{--}1,400\text{ }^{\circ}\text{C}$), each of somewhat lower internal precision. The results should also be carefully examined on an isochron plot (preferably the inverse mode, $^{39}\text{Ar}_{\text{K}}/^{40}\text{Ar}$ versus $^{36}\text{Ar}_{\text{I}}/^{40}\text{Ar}$). If the resulting initial $^{40}\text{Ar}/^{36}\text{Ar}$ ratio (IR) is statistically different from the atmospheric argon value (295.5), the plateau age should not be utilized. If the IR is >295.5 , the specimen displays the presence of excess ^{40}Ar , and the isochron age should be henceforward used. However, if the IR is <295.5 , the sample is disturbed (generally caused by alteration), and both the resulting isochron and plateau ages should not be used as accurate estimates of the time of crystallization.

Some important events dated by the $^{40}\text{Ar}/^{39}\text{Ar}$ technique involve the rapid extrusion of large amounts of mafic rocks in flood basalt provinces. One example is the Parana flood basalts (South America) involving $\sim 1.5 \times 10^6\text{ km}^3$ of material erupted in $<1\text{ Ma}$ at $\sim 134\text{ Ma}$ (Renne et al. 1992). For younger flood basalt provinces, such as the Columbia River basalts in the USA, high-precision $^{40}\text{Ar}/^{39}\text{Ar}$ ages together with their magnetostratigraphy can be combined with the GPTS at $\sim 17\text{--}15\text{ Ma}$, to arrive at a more detailed history of eruption rates for this smaller ($\sim 1.4 \times 10^5\text{ km}^3$) flood basalt province (Jarboe et al. 2010; Baksi 2013).

Acidic Lavas and Ash Beds

These are best dated using sanidine separates. This high-K (8–14 %) mineral should be pure and unaltered. The latter involves binocular examination and picking, followed by washing with dilute HF as outlined above for plagioclase. Since sanidine is difficult to degas, a laser or double-walled vacuum apparatus (Staudacher furnace) should be used. Relatively small subsamples can be used and often show essentially flat age spectra, yielding high-precision plateau ages. Correction for $^{36}\text{Ar}_{\text{Ca}}$ is generally very small; care should be exercised in dealing with steps where the analytical data suggest that the $^{40}\text{Ar}^*$ content is $>100\text{ }\%$. In such instances, the step age should be corrected to

denote 100.0 % of $^{40}\text{Ar}^*$ (Baksi 2012b). If this procedure is not followed, the resulting (plateau) age is biased to the high (too old) side by an amount that may exceed the (2σ) internal error of the plateau age. The data should also be examined on isochron plots as outlined above. In many instances, the data points will fall close to the $^{39}\text{Ar}_K/^{40}\text{Ar}$ axis and the resulting isochrons will yield IR with large errors. Unless these values are statistically different from the atmospheric argon value, the plateau age and error should be used henceforward. In a limited number of cases, the IR will prove to be >295.5 , showing that excess argon is present. In this situation, the isochron age and error are to be used; an important case illustrating this is the work of Renne et al. (1997) in dating material from 79 AD eruption of Mt. Vesuvius.

Other materials from volcanic rocks that may be dated are micas (notably biotite) and amphibole (hornblende). In principle, biotite can yield high-precision results, but may be affected by three different sets of problems: (1) ^{39}Ar recoil loss from very fine-grained material, (2) the presence of excess argon, and (3) the purity of the material dated. The first of these would be indicated by total gas and/or plateau ages that are too old on stratigraphic grounds or compared to other dating methods; a check with the K-Ar date on the material can be useful. The presence of excess argon is often difficult to detect and correct, even for quite old material. This is best illustrated by the careful work of Renne (1995) in looking at material related to the formation of the Siberian Traps, USSR. This involved painstaking work on a number of biotite subsamples and comparison of the results with that obtained on coexisting hornblende; this source of error is evidently more serious for intrusive rocks, but may affect volcanic material also. The purity of the material dated can be checked by careful attention to the Ca/K ratio of each step. If these show values of >0.05 , the subsample may be chloritized to a degree that negates the use of resulting plateau/isochron ages. The use of amphibole separates to obtain accurate ages for volcanic material is relatively uncommon; due to the relatively low precision of ages (low K content) and seeming heterogeneity of “pure” separates, its utility will not be considered herein.

The melting of surface rocks by bolide impacts can be successfully dated by the $^{40}\text{Ar}/^{39}\text{Ar}$ technique, as evidenced by the work of Swisher et al. (1992) on the Chicxulub Crater (Mexico) thought to have been genetically linked to the global faunal extinction event noted at the Cretaceous-Paleogene boundary at ~ 65 Ma. In the age range of a few ka to few Ma, the $^{40}\text{Ar}/^{39}\text{Ar}$ step heating technique appears to yield good results.

Important Events Dated by the $^{40}\text{Ar}/^{39}\text{Ar}$ Method

This method is the only parent-daughter geochronological system that yields high-precision results for young (< 10 Ma) rocks. For older material, the U-Pb methods when applicable yield ages that are more precise, are tied to absolute calibration of spikes, and are more “robust.” Two important (sets of) events of geological importance dated by the argon techniques are (1) the calibration of the geomagnetic polarity time scale (GPTS) for ~ 0 – 10 Ma and (2) the ages of rocks from the Hawaiian-Emperor Chain in the Pacific Ocean and the timing of the bend in the chain (HEB).

(1) The K-Ar-derived GPTS for 0 – 10 Ma, used to calculate seafloor spreading rates for many decades, was shown to have systematic errors, with “ages” that were ~ 5 – 7 % too young (Baksi 1995). Use of $^{40}\text{Ar}/^{39}\text{Ar}$ ages helped to illustrate that seafloor spreading rates calculated for the past ~ 3 Ma by geochronology, astrochronology (based on Milankovitch cyclicities), and space geodesy agreed to within ± 1 % (Baksi 1994). The errors in the K-Ar dates were caused by incomplete degassing of sanidine samples and/or alteration of whole-rock basalts, leading to lowered ages. In effect, alteration (chemical weathering) is ubiquitous and is best detected by noting the amount of

^{36}Ar released in each step of $^{40}\text{Ar}/^{39}\text{Ar}$ incremental heating studies (Baksi 2007a). (2) Since alteration is primarily caused by the interaction of silicate phases in rocks with water, submarine samples are commonly altered (Baksi 2007b). This is also verified by the work of Sharp and Clague (2006) who showed that the age of the HEB is 50 Ma – not the ~43 Ma previously used for three decades; critical examination (Baksi 2010b) reveals that the younger age (~43 Ma) is based on the dating of altered samples.

$^{40}\text{Ar}/^{39}\text{Ar}$ dating of young rocks/events is liable to be affected by the presence of small amounts of excess ^{40}Ar ; if uncorrected for, this can result in “ages” that are up to ~10 % too old. The dating of volcanic events took a leap forward through the work of Renne et al. (1997), who obtained the correct age for samples erupted during the 79 AD eruption of Mt. Vesuvius. This calibration into the “historic realm” was achieved on sanidine which contained traces of excess ^{40}Ar . Careful examination of such data sets by the isochron technique (York 1969) is a critical component. Very young (< 300 ka) andesitic rocks from South America have been successfully dated in whole-rock form (Singer et al. 2008) and contain low level of $^{36}\text{Ar}_\text{I}$ (Baksi 2010b).

Problems Requiring Attention

For older material (> 50 Ma), $^{40}\text{Ar}/^{39}\text{Ar}$ ages tend to be ~1 % younger than (more robust) U-Pb ages (see Min et al. 2000; Baksi 2014). This systematic difference is thought to be caused by (a) incorrect choice (use) of the decay constants of ^{40}K and/or (b) incorrect (K-Ar) ages used for the monitors/standards utilized in $^{40}\text{Ar}/^{39}\text{Ar}$ dating work (see Renne et al. 2010). Making the necessary corrections to bring U-Pb and $^{40}\text{Ar}/^{39}\text{Ar}$ ages into concordance for events >50 Ma (see Renne et al. 2010) results in systematic discordance in the ages for the GPTS (0–10 Ma) obtained by the $^{40}\text{Ar}/^{39}\text{Ar}$ method versus astrochronology (Baksi 2013). A careful *absolute* $^{40}\text{Ar}^*$ calibration of a commonly used mineral (standard) should have high priority. Currently, for the widely used Fish Canyon sanidine, the age is tied to the absolute age of GA-1550 biotite (see Renne et al. 1998). However, the argon calibration of GA-1550 biotite (McDougall and Wellman 2011) was achieved with atmospheric (air) argon that was not *dry*.

A final note of caution is made regarding the fact that radiometric ages for volcanic units must always fall in stratigraphic order, i.e., obey the principle of superposition. Numerous cases in the recent literature highlight problems that may occur in this regard (e.g., Barry et al. 2010, 2013; Baksi 2012a, 2013).

Chert

L. Paul Knauth*

School of Earth and Space Exploration, Arizona State University, Tempe, AZ, USA

Cherts are nodular masses and beds of microcrystalline quartz that replace carbonate sediment or opaline biologic oozes of diatoms or radiolarians during burial. The replacement can occur during early to deep burial, so chert is younger than the time of host sediment deposition by variable amounts not easily determined. The quartz itself contains no radionuclides that can be used for age-dating the time of crystallization. Detrital impurity grains may contain datable material, but the age is that of the source area and not of the sediment. The value of cherts in age-dating relates to the unsurpassed preservation that silicification affords fossils.

Silicification involves a slow micron-by-micron replacement process. Silicified fossils better survive the alteration effects of subsequent burial, uplift, and weathering. Acid dissolution of carbonate frees isolated examples, and these probably represent the majority of invertebrate fossils used to establish the paleontological record and to age-date sedimentary rocks. Ages established from the fossils relate to the time of original deposition even though silicification is secondary. Organic remains in nodular cherts can be preserved down even to the cellular level. Microfossils in such cherts provide much of the record of the Precambrian life, but their evolutionary history is still insufficiently established to be widely useful for age-dating.

In Cenozoic and Paleozoic bedded cherts, microquartz in the tiny volumes originally occupied by radiolarian tests resist dissolution in HF and NaOH relative to the matrix microquartz. Gentle etching reveals the radiolarian morphology so well that biostratigraphic ages can be established with surprising precision. Radiolarian age-dating of bedded chert sequences was a breakthrough in unraveling the structural geology and history of the great folded mountain sequences in the Alps and Western United States (e.g., De Wever et al. 2001). Tertiary diatomaceous oozes are abundant and incompletely transformed into microquartz. Fossil ages can be determined from these usually without acid etching.

The $^{18}\text{O}/^{16}\text{O}$ ratio of cherts is highly variable but generally decreases in progressively older cherts (Knauth 2005). The explanation remains controversial but is likely due to past higher climatic temperatures. The highest values for Archean examples are lower than the lowest values for younger examples, so the $^{18}\text{O}/^{16}\text{O}$ ratio is a crude age indicator of cherts older than 2.5 billion years.

Dissolved argon in the silicifying fluid can be trapped within tiny fluid inclusions in the microquartz that precipitates from it. Since the isotopic composition of atmospheric Ar evolves with time, appropriate samples might yield approximate age dates. Analyses of 3.5 billion-year-old hydrothermal quartz have now better constrained atmospheric Ar isotopic evolution, so this method holds considerable promise (Pujol et al. 2013).

While the geochemical and radiometric age-dating of cherts remains limited, biostratigraphic ages of the enclosed fossils remain among the most accurate achieved for the Phanerozoic

*Email: Knauth@asu.edu

sedimentary rocks. The exquisite microfossil record in older cherts, the “amber of the Precambrian,” offers hope for similar utility extending back in time to the earliest sediments.

Hominid Evolution Timescale

Antoine Balzeau*

Department of Prehistory, UMR 7194, CNRS and Muséum national d'Histoire naturelle, Paris, France

The hominid evolution timescale has been established thanks to primate genomic sequencing (Schrager and Voloch 2013). It is now generally accepted that the divergence between our closest relatives, bonobos and chimpanzees (*Pan lineage*), and modern humans dates back to at least 7.0 Ma (Fig. 1) based on genetic data from extant primate species. However, discoveries of fossil hominins have also been crucial to the debate on the theoretical aspects and for the acceptance of the timing of the appearance of the hominin lineage. These fossils are still debated, but *Sahelanthropus tchadensis*, ca. 7 Ma, and *Orrorin tugenensis*, ca. 6 Ma, may represent one of the earliest evidences of the hominin lineage. Unfortunately, contemporary evidence of early specimens of the *Pan* lineage is not yet documented. The oldest fossils attributed to *Pan* are only 500 Ka and the divergence between bonobos (*Pan paniscus*) and chimpanzees (*Pan troglodytes*) would have occurred around 2 Ma based on genetic evidence. A discussion exists on the use of the terms hominid and hominin, but the general agreement, now, is to use the term hominin to refer to all the member of the human clade, i.e., to specimens that are bipedal and that share anatomical specificities related to this mode of locomotion. Between 6 Ma and 1.8 Ma, more fossil hominins are known. They belong to at least three genera (*Ardipithecus*, *Australopithecus*, and *Paranthropus* and maybe *Kenyanthropus*) and 13 species and were mostly unearthed in South and East Africa but also in Central Africa (Chad for *Sahelanthropus tchadensis* and *Australopithecus bahrelghazali*). Another major event on the hominid timeline was the appearance of the genus *Homo* around 2.5–2 Ma that coincides with the first hominin migration out of Africa. However, the definition of the genus *Homo* is controversial or at least problematic, as its ranges of anatomical and behavioral variations have been widely expanded and encompass those now known for other hominins. An important event of divergence between several species (*Homo heidelbergensis* and possibly *Homo rhodesiensis* emerging from *Homo erectus sensu lato* and then evolving into *Homo neanderthalensis* and *sapiens*) has occurred in Africa and possibly in Eurasia around 500 ka. That led in particular to the appearance of the *Homo sapiens* species 200 ka years ago. *Homo neanderthalensis* is important for cultural and historical reasons (first discovery of fossil hominin in Europe, questions on a possible other humanity, etc.), but also because it is the species with the largest fossil record in relation to their early use of burials. Finally, our species has cohabited with several other species (at least *Homo erectus*, *Homo neanderthalensis*, and *Homo floresiensis*) until very recent times, only several ka compared to 7 Ma of hominid evolution. Recent developments in paleogenetics (e.g., Meyer et al. 2012) have offered new information about the recent history of the human lineage, but these data need to be integrated in the wider range of existing paleoanthropological data (Henke and Tattersall 2007) to be interpreted.

Lucy

William H. Kimbel*

Institute of Human origins, School of Human Evolution and Social Change, Arizona State University, Tempe, AZ, USA

Lucy is the colloquial name given to a presumed female partial skeleton of the Pliocene hominin species *Australopithecus afarensis*. The specimen, cataloged as Afar Locality (A.L.) 288–1, was found by Donald Johanson in November 1974, at the Hadar site, in the west-central part of the Afar Rift Valley, Ethiopia. Pyroclastic sediments in the Hadar Formation at the Hadar site have been dated by K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods to between 3.4 Ma and 3.0 Ma, which brackets the younger half of the known temporal range of *A. afarensis* (Kimbel and Delezene 2009). More than 375 specimens of *A. afarensis* have been recovered from fluviolacustrine sediments at Hadar through 2012. The species is also definitively represented in similar-age deposits of several other Afar basin sites (including Dikika, Ledi-Geraru, Woranzo-Mille, and Maka) and in the Koobi Fora Formation, at Koobi Fora, Kenya. The oldest known fossils of the species, including the type specimen (a mandible, LH-4), occur in the Upper Laetolil Beds (3.5–3.8 Ma), at Laetoli, northern Tanzania.

Lucy and other specimens of *A. afarensis* epitomize the mosaic emergence of human anatomy during the early evolution of our lineage (Kimbel and Delezene 2009). The cranium and jaws retain many features from the common ancestor we shared with chimpanzees, including a small brain (350–550 cc) and projecting snout, but the relatively low-crowned canine teeth wore down from their tips as in modern humans. While *Lucy*'s hip, knee, and foot were adapted to a balanced two-legged stride, with fully extended knee and powerful push-off at the great toe, she had long, powerful arms and curved fingers, reminiscent of the tree-climbing anatomy of the great apes. These anatomical contrasts have been fodder for intense scholarly debate regarding the adaptations of our early ancestors (Ward 2002).

Paleosol

Gary E. Stinchcomb*

Department of Geosciences, Pennsylvania State University, University Park, PA, USA

Paleosol is defined as a soil that formed on a landscape of the past (Yaalon et al. 1971; Retallack 2001). The definition of paleosol is not straightforward as it can vary by geologic discipline. Quaternary geologists often define paleosols as having been buried, exhumed, and/or at the surface as relict soils. In this case, a paleosol must contain evidence of a nonextant soil-forming environment, e.g., glacial climate (Birkeland 1999). Geologists who primarily work in the pre-Quaternary often define paleosols as lithified, fossil soils that document a past landscape (Retallack 2001).

Like modern soils, paleosols record evidence of the physical, chemical, or biological alteration of a preexisting material to a more stable form, i.e., weathering. These weathering features formed partly as a result of five primary environmental factors: (i) climate, (ii) organisms, (iii) relief, and (iv) parent material operating through (v) time (Jenny 1941). Paleosols are therefore valued for their record of paleoenvironment(s) and paleoclimate(s) in both Quaternary and pre-Quaternary records. Because paleosols record past landscape conditions through an interval of time, they are often subject to a variety of dating methods. Generally speaking, dating methods applied to soils and paleosols are used to assess the duration of soil formation and/or provide a numerical age estimate during which the soil formed.

The duration of formation may be assessed qualitatively, e.g., “young” or “old” soil, or quantitatively, e.g., a soil formed for 2,000 years. Soil geomorphologists study how modern soils vary as a function of time when all other properties are held constant, i.e., a soil chronosequence (Jenny 1941; Birkeland 1999; Holliday 2004 – see Table 7.2). A number of profile properties have been shown to vary as a function of duration of soil formation, young to old. Age-related properties derived from chronosequences have been used in geomorphic and geoarchaeological research of paleosols; however, there are a number of potential pitfalls and caution should be exercised when trying to obtain a numerical age estimate using this approach (Holliday 2004).

Absolute dating methods are applied to paleosols and buried soils to derive numerical estimates. Common approaches include radiocarbon (^{14}C), U-series, luminescence techniques, and cosmogenic-nuclide exposure dating (Holliday 2004; Balco and Rovey 2008). Radiocarbon is perhaps the most frequently method used to derive a numerical age estimate for late Quaternary paleosols (Holliday 2004). Radiocarbon of soil organic matter from a buried surface horizon can be dated to derive an apparent mean residence time (Holliday 2004 and references therein). Both radiocarbon and luminescence dating have been applied to eolian and alluvial parent materials on which the paleosol formed to derive a maximum numerical estimate (age-maxima) of soil formation (Holliday 2004).

U-series dating has been applied to pedogenic carbonates to assess the age of a paleosol or buried soil (Holliday 2004). Recent advances in cosmogenic-nuclide exposure dating have refined the burial-age estimates for paleosols using an isochron approach (Balco and Rovey 2008). The slope

*Email: ges130@psu.edu

of ^{10}Be and ^{26}Al from concentration profiles in paleosols has been used to derive a numerical estimate of burial age.

Thermochronology, Detrital Zircon

J. I. Garver*

Department of Geology, Union College, Schenectady, NY, USA

Definition

Detrital zircon thermochronology is the study of thermal histories of rocks revealed through cooling ages obtained from detrital zircon. Most studies focus on fission-track or helium dating of suites of single grains to reveal the thermal evolution of a source region.

Introduction

Detrital zircon thermochronology is focused on the evaluation of ages of detrital zircon grains to reconstruct the thermal evolution of source rocks that supplied sediment to a basin. Zircon (ZrSiO_4) is an accessory mineral that crystallizes primarily in silica-rich igneous rocks, but after erosion and deposition it occurs widely in sedimentary rocks and their metamorphic equivalents (Bernet and Garver 2005). Because zircon is very durable in typical sedimentary environments on Earth, it typically survives sedimentary transport and in fact can be concentrated in heavy mineral assemblages where mineralogical fractionation occurs naturally by sedimentary processes. Zircon is also resistant to chemical attack and thus can also survive interaction with basin fluids that may affect host strata during burial and diagenesis. Because of this durability, zircon can be polycyclic and survive multiple sedimentary cycles (Poldervaart 1955).

Zircons contain trace amounts of non-formula elements of which uranium and thorium are most important because these elements decay through natural radioactive disintegration (Hancher and Hoskin 2003). A typical detrital zircon will contain between 100 and 1,000 ppm uranium, and the U:Th ratio is generally between about 2:1 to 1:1 (Garver and Kamp 2002), although metamorphic zircons are known to have very high thorium concentrations (Rubatto 2002). Because of the relative abundance of uranium and the difference in decay rates, uranium is of primary importance in detrital zircon studies.

Radioactive Decay in Zircon

Uranium decays through two modes. The primary mechanism of decay is α -decay in which uranium decays to lead (Pb) through a series of intermediate daughter elements and the ejection of α -particles (^4He) (Reiners 2005). During the decay of ^{238}U , the most common isotope of uranium, radioactivity in this decay chain results in the release of eight α -particles (see ► [U-Th:He Dating](#)). Uranium can also disintegrate through spontaneous fission, but this process is much less common (by a factor of about 2×10^6) (Tagami 2005). Spontaneous fission results in two subequal energetic fragments of the original uranium atom that recoil away from one another through the crystal lattice, and in the process, they produce an amorphous zone of disorder that is <10 nm wide and about 10,000 nm long

*Email: garverj@union.edu

(10 μm) (Wagner and van den Haute 1992). This zone of disorder is called a fission track (see ► [Fission-Track Dating and Thermochronology](#)). Single detrital zircon grains are routinely dated using helium dating or fission-track dating to understand the thermal evolution of the source rocks. Most published studies of zircon thermochronology use the fission-track method (see Garver et al. 1999; Bernet and Garver 2005; Reiners and Brandon 2006).

Closure Temperatures

Effective closure of the isotopic system is a key aspect of analysis in detrital thermochronology (Reiners and Brandon 2006). For zircon helium dating (ZHe), closure occurs at about 180 °C, and in zircon fission-track (ZFT) dating, effective closure occurs in a window between about 250 °C and 340 °C (see discussion Reiners and Brandon 2006; Tagami 2005; Bernet 2009). In both cases, closure or annealing appears to be partly governed by total radiation damage and rate of cooling. Thus, in detrital thermochronology, zircons provide information about the low-temperature cooling history (180–340 °C) of the source region (Garver et al. 2005). Note that this is fundamentally different from information provided by U/Pb dating of single zircon grains (see ► [Uranium-Lead, Detrital Zircon](#)), because the former technique provides information on the cooling history of the source terrane and the latter provides the crystallization age. Because zircon can be polycyclic, some detrital zircon U/Pb ages may provide age information on what was ultimately the original source rock, but these rocks may be unrelated to the orogenic cycle that produced a sediment source (see discussion in Bernet and Garver 2005). With ZHe or ZFT dating, the thermal signature of the sediment-source terrane is evaluated. In most cases, this is directly related to orogenesis and tectonic processes related to uplift and exhumation in orogenic belts (Garver et al. 1999). Thus, detrital thermochronology is the preferred approach if the goal is to understand the direct relationship between source terrain evolution and basin sedimentation (as in Fig. 1; see Garver et al. 1999; Carter and Bristow 2000).

Exhumation and Erosion

Detrital zircon grains provide a rich record of the cooling history of source terrains that eroded to supply sediment to adjacent sedimentary basins (Fig. 1; see Bernet et al. 2004). Rocks in a source terrain are exhumed by tectonic or erosional processes, meaning that they are brought from lower levels in the crust to the surface. The process of exhumation allows for rocks to move upward in the crustal column to the surface. In this setting, rocks pass through the closure temperature (T_c) for a particular dating system as they transit to the surface. Exhumation rates of the orogenic belt can be determined provided a number of key variables can be reasonably constrained: these include the closure temperature (T_c), the geothermal gradient, and time required to erode and transport detritus to an adjacent sedimentary basin (in Fig. 1, $t_c - t_d$). Together, the transit time past the closure isotherm and the time required to transfer detritus to a sedimentary basin are referred to as the *lag time* (in Fig 1, this is $t_c - t_d$; see Brandon and Vance 1992; Garver and Brandon 1994; Garver et al. 1999). In virtually all orogenic settings, there is a lag between closure and deposition, which is primarily a function of exhumation rates (Garver et al. 1999; Bernet and Garver 2005; Reiners and Brandon 2006). Thus, detrital zircon thermochronology has been extensively used to better understand exhumation rates of rocks in orogenic belts (for examples, see Brandon and Vance 1992; Bernet et al. 2004; Spiegel et al. 2004; Ruiz et al. 2004; Enkelmann et al. 2009; Whitchurch et al. 2011).

Fig. 1 Schematic diagram showing the relationship between exhumation and erosion in the source region and deposition of eroded material in a flanking basin. In detrital thermochronology, zircons eroded from the source terrain are deposited in sequential layers in a basin. Zircons in rocks are exhumed from depth and in the process pass through an effective closure isotherm during transit to the surface. To relate closure temperature to depth of exhumation, some assumptions need to be made about the temperature of closure and the geothermal gradient (Modified from Garver et al. 1999)

Zircon Thermochronology Studies

Many traditional studies have focused on Mesozoic and early Cenozoic basin settings (Brandon and Vance 1992; Bernet et al. 2001; Ruiz et al. 2004; Spiegel et al. 2004; Whitchurch et al. 2011). A number of recent studies have used modern detritus from active orogenic belts to understand exhumation, and many of these have been focused on fast-exhuming orogenic belts where sedimentary storage between erosion and deposition is negligible. In very-fast-exhuming mountains, the cooling ages can be less than 5 Myr and in some cases less than 1 Myr. Detrital grains that are this young provide a few analytical challenges because the small number of daughter products (helium or a fission track) generated during this period can be difficult to detect. An additional challenge in these settings is the significant advection of the isotherms in the source terrain and the requirement for modeling how isotherms may have changed during orogenic evolution (Reiners and Brandon 2006). In the Chugach-St. Elias orogen (Alaska), ZFT cooling ages from modern rivers and glaciers indicate a local area of intense erosional exhumation where grain ages are less than 3 Ma. This result illuminates the relationship between surface processes (glacial erosion) and tectonics processes at the junction of a tectonic boundary (Enkelmann et al. 2009).

While there is no theoretical limit to how old a zircon can be to provide useful thermochronological information, there are some practical and analytical considerations that make analysis of exhumation rates of Precambrian terrains difficult. Part of the analytical challenge is that the high density of fission tracks and the amount of radiation damage in ancient grains can hinder analysis and systematic behavior of zircons (Montario and Garver 2009). To study Precambrian thermochronology, it is important to understand the thermal history of the strata because many sedimentary sequences have been heated to temperatures sufficient to anneal fission tracks or to allow the loss of helium ($>180\text{--}200\text{ }^{\circ}\text{C}$). Detrital zircon in Cambrian strata that sit uncomfortably above the Grenville basement rocks (Mesoproterozoic, c. 1,000–1,250 Ma) in New York State (USA) were dated using high-resolution ZFT dating using a scanning electron microscope (SEM) to

Fig. 2 Example of a detrital zircon study from Eocene strata of the Orca Group in southern Alaska (Modified from Carlson 2012). In this study, 100 detrital zircons were dated using zircon fission track, and then the crystallization age of each grain was determined by LA-ICP-MS. This double dating allows for a detailed understanding of how arc volcanics and the metaplutonic basement have clear and distinct thermal histories that are recorded in detrital zircon grains

image and count fission tracks (Montario and Garver 2009). In the case of the exhumation of the Grenville basement, post-Grenville exhumation was recorded at ~780 Ma, followed by basement heating related to the rifting of Rodinia at ~540 Ma – both events occurring during the Neoproterozoic (Montario and Garver 2009). In this study, apparent single-grain cooling ages as old 2.0 Ga were obtained.

In many detrital zircon thermochronologic studies along convergent margins, there can be a significant number of quickly cooled zircon grains that represent near-surface volcanic or plutonic activity. In these cases, the cooling age may represent volcanic activity and may be unrelated to exhumation of rocks in a source terrain (Garver et al. 2000). It can be difficult to determine if a single-grain age is the result of a volcanic eruption that cooled at the surface or the result of intrusion followed by rapid exhumation from greater depth. One approach used to address this situation is to double-date single grains using both low-temperature methods (i.e., fission track) and U/Pb methods (i.e., high temperature; see Fig. 2). Those grains with concordant low- and high-temperature ages are inferred to have a volcanic origin.

Analytical methods have improved in recent years, and dating of single crystals by two or more methods is possible, but not yet routine. Because FT dating of zircon is not destructive, a zircon can be dated after ZFT by either LA-ICP-MS or ZHe approaches (both of which are destructive). This approach allows for an incredibly informative data set where single crystals reveal details about when rocks were formed and when they were cooled (Carter and Bristow 2000; Rahl et al. 2003; Reiners et al. 2005; Carlson 2012). An example from the Eocene Orca Group in the accretionary complex of southern Alaska (Fig. 2) shows ZFT and U/Pb double dating that reveals the relatively simple thermal evolution of the volcanic arc complex in the Cretaceous and the more protracted

formation of a lower Mesozoic basement complex that was exhumed in the Early Cretaceous. This data set contains some detrital zircons that are volcanic (rapidly cooled) because the ZFT and U/Pb ages are concordant within error (see Carlson [2012](#)).

For detrital zircon in basin strata to retain provenance information, the host strata must have remained below the annealing temperature for its entire history; otherwise, the zircon may have its thermal record reset or partially reset (Bernet and Garver [2005](#)). For the FT system, this means that basin strata must remain below temperatures of about 200 °C; otherwise, resetting or partial resetting can compromise provenance information. Nevertheless, data from those settings may be useful to better understand postdepositional heating of the basin (Garver et al. [2005](#)).

Summary

Detrital zircon thermochronology is the study of the thermal histories of source terrains that shed sediment into flanking basins. The primary aim of most studies is to use cooling ages in sedimentary detritus to reconstruct the temporal framework of exhumation in orogenic highlands that supply sediments to basins. Most published studies use fission-track dating on single zircon grains, but there is an emerging literature where helium dating is used (Reiners and Brandon [2006](#)). Cooling ages of single zircon grains can be related to exhumation of crustal rocks in an orogenic belt or high-level volcanic activity. In young rapidly exhumed orogenic belts, populations of cooling ages may be 1 Myr or less than crystallization ages. In old terrains, Precambrian cooling ages have been determined and used to understand source evolution. If basin strata have been heated to temperatures of 180–200 °C, the original thermal record of the source rock may be compromised (annealed or partly annealed); however, the reset grains may then provide information about postdepositional thermal events.

Thermochronology, Meteorites

Kyoungwon Min*

Department of Geological Sciences, University of Florida, Gainesville, FL, USA

Definition

A field of research constraining thermal histories of meteorites (rocks produced in extraterrestrial environment and delivered to Earth) and interpreting the results in the context of Earth and planetary science.

Introduction

Since the formation of our solar system at 4,568.2 Ma (Bouvier and Wadhwa 2010), individual solid objects in the solar system experienced a range of planetary processes associated with temperature changes. Accretion, impact, breakup, metamorphism, and alteration are some of these planetary processes, which provide valuable information into the early evolution of the solar system. In addition, peak temperature conditions and cooling paths are crucial in understanding various physical properties (e.g., dimensions, internal structures) of solid bodies. The field of research known as “thermochronology” provides a means of investigating the thermal histories of meteorites (or their parental rock bodies) and interpreting the resulting data.

Methods

Thermal histories of meteorites can be constrained from multiple independent approaches. Peak temperature conditions of meteorites, particularly during thermal metamorphism or shock events, are commonly estimated based on phase equilibria, microscopic textures, refractive indices, and natural remanent magnetization data. Cooling rates of meteorites are constrained using metallographic textures, elemental diffusion in minerals, and ^{244}Pu fission tracks. Absolute ages and corresponding temperature conditions are investigated through radioisotopic thermochronometers. Radioactive decay is a natural process where an unstable parent isotope releases energy as it transforms to one or more daughter isotopes (“► [Radiation and Radioactivity](#)”). Because the rate of decay for a given radioactive isotope is nearly constant regardless of the physical conditions or types of hosting materials, the age can be determined by measuring the abundances of parent and daughter isotopes. Each element has unique diffusion properties in the host materials, allowing ages determined for various geochronological systems to be associated with a range of temperature conditions experienced by the host material. Therefore, a time-temperature path can be deduced by studying one or more radioisotopic systems. U-Th-Pb (“► [Uranium-Lead, Extraterrestrial, Early Solar System](#)”; Bouvier et al. 2007), $^{40}\text{Ar}/^{39}\text{Ar}$ (“► [Extraterrestrial Materials \(K-Ar/Ar-Ar\)](#)”; Turner et al. 1978; Bogard 2011), and (U-Th)/He (“► [U-Th:He Dating](#)”; Min 2005) thermochronometers are most commonly used for meteorites.

Case Studies

H Ordinary Chondrites

H chondrites comprise the most distinctive group among officially identified meteorites. They are by far more abundant than other types of ordinary chondrites and provide one of the most complete descriptions of their parent asteroid. Thermal histories of H chondrites were extensively investigated using nearly all the available thermochronologic methods in order to understand accretion process, metamorphism, internal structure, physical dimension, and shock impact history of the parent body.

After the accretion of the H parent body, it experienced thermal metamorphism during its early history primarily due to the radioactive decay of ^{26}Al . Early investigations of U/Pb systematics revealed that many H5–H6 chondrites cooled through the closure temperatures of phosphates during the first ~60 Myr after formation of Ca–Al-rich inclusions (CAIs) (Göpel et al. 1994). Based on U/Pb systematics of the Richardton meteorite (type H5 ordinary chondrite), it was suggested that the accretion of the H parent body was initiated at 1.7 Ma after the formation of CAIs and continued for 3.5 Ma (Amelin et al. 2005). Similar conclusions were derived using Hf/W systematics, which suggested that the accretion was started no earlier than ~1.7 Ma after the formation of CAI, was almost completed by ~6 Ma, and was followed by peak metamorphism until ~10 Ma (Kleine et al. 2008).

A layered internal structure was suggested for the H parent body. This “onion shell model” posits that H meteorites are derived from different depths in a hypothetical parent body where the highly metamorphosed meteorites (H6) from the inner part of the parent body were surrounded by successive shells of lower-grade rock (H5–H3) (Wood 1967; Hutchison et al. 1980; Pellas and Storzer 1981). This model predicted an inverse correlation between peak metamorphic temperatures and cooling rates. However, cooling rates determined from the metallographic methods were not consistent with the suggested inverse correlations. Consequently, the “metamorphosed-planetesimal model” was proposed (Scott and Rajan 1981), which proposed that the maximum metamorphism occurred in small planetesimals, followed by accretion that formed the chondritic parent body. A slightly revised model was suggested: collision-driven fragmentation of an onion shell body during the peak metamorphism followed by a rapid reassembly (Grimm 1985; Taylor et al. 1987). Subsequent thermochronologic studies on Hf/W (Kleine et al. 2008), U/Pb (Göpel et al. 1994; Blinova et al. 2007), $^{40}\text{Ar}/^{39}\text{Ar}$, and ^{244}Pu fission tracks (Trieloff et al. 2003) revealed the inverse relationship for a large number of H chondrites for both high- and low-temperature regimes, supporting the onion shell model (Harrison and Grimm 2010). Simulations of the thermal histories based on the onion shell model (Miyamoto et al. 1981; McSween et al. 2002) imply a relatively small parent body (radius = ~50–100 km). However, thermal histories of some H chondrites cannot be explained by a simple monotonic cooling predicted by the onion shell model (Kessel et al. 2007). Data for those rocks require modifications of the simple model that include fragmentation and reassembly of the onion shell parent body (Ganguly et al. 2013).

Shock impact is one of the major planetary processes which generate a significant amount of heat, thus resetting many isotopic chronometers, particularly K/Ar and (U–Th)/He. Three major impact periods were identified for H chondrites primarily through $^{40}\text{Ar}/^{39}\text{Ar}$ thermochronometer: at >4.45 Ga (planetary accretion phase), at 4.1–3.5 Ga (lunar cataclysm), and at <1 Ga (Bogard 1995; Swindle et al. 2009, 2013).

L and LL Ordinary Chondrites

Cooling histories of LL chondrites were investigated using I/Xe (Bernatowicz et al. 1988), U/Pb (Göpel et al. 1994; Bouvier et al. 2007), $^{40}\text{Ar}/^{39}\text{Ar}$ (Hohenberg et al. 1981), (U–Th)/He (Min

et al. 2013), and ^{244}Pu fission tracks (Pellas and Storzer 1977, 1981). Their post-metamorphic cooling rate is generally lower than H chondrites, suggesting that the LL asteroid had a larger dimension than the H parent body (Pellas and Storzer 1981; McSween et al. 2002; Bouvier et al. 2007).

L chondrites with clear evidence of shock are more common than H and LL chondrites. $^{40}\text{Ar}/^{39}\text{Ar}$ and (U-Th)/He ages of L chondrites are significantly younger than H and LL chondrites, most likely caused by impact-related heating in their parent body (Heymann 1967; Bogard et al. 1976, 1995; McConville et al. 1988; Wasson and Wang 1991; Korochantseva et al. 2007). The ages are highly clustered in a range of ~400–500 Ma, which is commonly suggested as the timing of catastrophic breakup of their parent body. A large number of fragments of L chondrites were discovered within mid-Ordovician (~470 Ma) sedimentary layers, thereby supporting the hypothesis that the parent body of L chondrites was rapidly delivered to Earth after the catastrophic disruption of the parent asteroid (Schmitz et al. 2001, 2003; Heck et al. 2004, 2008).

Acapulco Meteorite

Based on petrographic observations (McCoy et al. 1996), Ca zoning patterns in olivine (Zipfel et al. 1995), and Fe-Mg ordering in orthopyroxene (Zema et al. 1996), the primitive achondrite Acapulco is thought to have cooled rapidly from ~1,100 °C to ~350 °C. These constraints, combined with absolute ages from Hf/W (Touboul et al. 2009) and $^{207}\text{Pb}/^{206}\text{Pb}$ systematics (Göpel and Manhès 2010), suggest a more detailed thermal history with a cooling rate that peaked at ~4,556 Ma, which was interpreted to be the timing of a breakup of the parent body. The cooling path below ~350 °C is controversial. $^{40}\text{Ar}/^{39}\text{Ar}$ and ^{244}Pu fission track data suggest a significant reduction of cooling rate below ~350 °C (Pellas et al. 1997), which can be related to the reassembly of the broken pieces immediately after the breakup. However, the suggested cooling rate change at ~350 °C was questioned based on the revised decay constant of ^{40}K (Kwon et al. 2002) combined with new $^{40}\text{Ar}/^{39}\text{Ar}$ data (Renne 2000). (U-Th)/He ages obtained from single phosphate grains are identical to the age of the solar system within their uncertainties and are significantly older than expected from ^{244}Pu fission track data, suggesting the possibility of a rapid cooling down to ~100 °C (Min et al. 2003).

ALH84001 Martian Meteorite

ALH84001 is one of the most important Martian meteorites because of its exceptionally old crystallization ages (Sm/Nd age = 4.41–4.57 Ga, Rb/Sr age = 3.84–4.55 Ga) and its long residence in the Martian crust. $^{40}\text{Ar}/^{39}\text{Ar}$ ages of ~3.8–4.2 Ga are commonly attributed to an intense period of impacting of the Martian surface (Ash et al. 1996; Turner et al. 1997; Bogard and Garrison 1999). A number of young and scattered (U-Th)/He ages on phosphate grains (0.1–1.5 Ga; Min and Reiners 2007) and whole-rock Ar diffusion kinetics (Cassata et al. 2010) suggest the existence of one or more high-temperature shock events after the primary impact at ~4.0 Ga. Based on the Ar diffusion modeling, the temperature of the Martian surface was estimated to be cold (<~22 °C) for most of the past ~4.0 Ga (Shuster and Weiss 2005; Cassata et al. 2010).

Summary and Conclusions

To investigate thermal histories of meteorites, a wide range of thermochronologic tools are used. Some constrain cooling rates or relative temperature changes over age differences, whereas others yield absolute timings of when the meteorites cooled down to certain temperatures. The current

understanding of the thermal histories of meteorites provides crucial information of various planetary processes, internal structures and physical dimensions of the parent bodies, as well as the surface temperature evolution of the Martian crust.

Environmental Releases

Robert Morrison*
Hawi, HI, USA

Definition

Environmental Forensics. The systematic and scientific evaluation of physical, chemical, and historical information for the purpose of developing defensible scientific and legal conclusions regarding the source or age of a contaminant release into the environment (Morrison and Murphy 2013).

Introduction

The study of contaminant releases into the environment is termed *environmental forensics*. Forensic techniques used to date and identify the origin of a contaminant release include dendroecology, aerial photogrammetry, compound-specific isotopic analysis (CSIA), congener analysis, contaminant transport modeling (liquid and colloidal), molar ratio analysis, biological, isotopic, and chemical pattern recognition, corrosion modeling, lipid and associated biological techniques, scanning electron microscopy (SEM), and advanced multicomponent analysis of chemical data. The following text describes selected techniques used to identify the source and age of a contaminant release into the environment.

Source Identification

Forensic techniques for identifying a contaminant source are often similar to environmental investigations designed to define the areal extent of a contaminant release for remediation purposes. Environmental forensics transcends traditional investigative techniques, however, by employing scientific techniques in combination to identify and discriminate between sources of a contaminant release. Three approaches used to identify contaminant sources include (1) association of a diagnostic chemical with a particular use and/or time frame; (2) chemical, biological, and isotopic techniques; and (3) congener analysis.

Diagnostic Chemicals Used for Source Identification

Examples of diagnostic chemicals indicative of a discrete production time frame for source identification and release dating in the United States (USA) include (USEPA 1978; Kaplan et al. 1997; ATSDR, 2002a, b; Morrison and Murphy 2006):

- 1,4-dioxane with methyl chloroform indicative of a post-1951 release
- Monsanto Aroclor 1016 (produced between 1971 and 1974)
- Aroclor 1260 as the predominant Aroclor used in electrical transformers prior to 1971

*Email: RobertForensics@aol.com

- Cessation of DDT production in 1972, aldrin/dieldrin in 1974, and mirex in 1962 to 1978
- The gasoline oxygenate methyl tertiary butyl ether (MTBE) as indicative of a post early-1980s release

Diagnostic chemicals in a formulation specific to a particular application offer the potential to link a chemical with a particular temporal activity; an example is the presence of the stabilizer thymol with trichloroethylene (TCE) as indicative of pharmaceutical grade TCE used prior to 1984 (Totonidis 2005). The presence of octene, nonene, and *n*-pyrrole with tetrachloroethylene (PCE) in an environmental sample is indicative of its use as a dielectric fluid in electrical transformers, likely in the 1980s (Morrison and Murphy 2013). A substantial body of peer-reviewed literature is available that describes using diagnostic chemicals for source identification and/or dating of contaminant releases (Morrison 1999, 2013; Murphy and Morrison 2002, 2007, 2014; Morrison and Murphy 2006; Peters et al. 2007; Morrison and O'Sullivan 2010, 2012, 2014).

Chemical, Biological, and Isotopic Techniques

Chemical techniques for source identification include molar ratio analysis and degradation relationships, including the chlorinated solvent PCE degradation series ($\text{PCE} \rightarrow \text{TCE} \rightarrow 1,2\text{-DCE} \rightarrow \text{vinyl chloride}$) for which common plots include $[\text{TCE}/\text{PCE}]$, $[\text{DCE}/\text{TCE}]$, $[\text{DCE}]/[\text{PCE} + \text{TCE}]$, $[\text{cis} + \text{trans } 1,2 \text{ DCE} + \text{VC}]/[\text{PCE} + \text{TCE}]$, $[\text{VC}]/[\text{PCE} + \text{TCE}]$, $[\text{cis} + \text{trans- } 1,2\text{DCE}]/[\text{PCE} + \text{TCE}]$, and $[\text{VC}]/[\text{cis} + \text{trans-}1,2 \text{ DCE}]$ as a means to identify and discriminate between multiple sources of PCE. Techniques used to distinguish sources for crude petroleum hydrocarbons include diagnostic biomarker ratios, including acyclic isoprenoids (e.g., (pristine)/(phytane), (pristine)/(*n*-C₁₇) and (phytane)/(*n*-C₁₈), terpanes (e.g., (C₂₁)/(C₂₃ tricyclic terpane) and (C₂₈bisnorhopane)/(C₃₀αβ hopane)) and steranes (e.g., (C₂₇αββ/C₂₉αββ steranes at *m/z* 218) and (C₂₈αββ)/(C₂₇αββ + C₂₈αββ + C₂₉αββ) at *m/z* 218) (Morrison and Murphy 2006). The normalized distribution, ratios and cross-plots of polyaromatic hydrocarbon (PAHs) sources are similarly available for source identification (Fig. 1), some of which are used to distinguish between petrogenic and anthropogenic sources (e.g., (fluoranthene + pyrene)/(C₂+C₃+C₄ phenanthrenes) and (phenanthrene/anthracene) versus (fluoranthene/pyrene)) (Fig. 2) (Morrison and Murphy 2006; Wang and Stout 2007; Wenning and Martello 2014).

Fig. 1 Normalized cross-plots of polyaromatic hydrocarbons used to distinguish between petrogenic and anthropogenic sources of petroleum hydrocarbon releases

Fig. 2 Normalized histogram using the relative abundance of various polycyclic aromatic hydrocarbons (PAHs) listed along the x-axis to distinguish between creosote and Bunker C fuel

For distinguishing a release from a sanitary sewer from other sources, detergent metabolites including 4-*n*-octylphenol, 4-*tert*-octylphenol, diethoxynonylphenol, NPEO-2, OPEO-2, ethoxynonylphenol NPOE-1, ethoxyoctylphenol OPEO-1, and 4-nonylphenol are available. Other indicators include pharmaceutical indicators, trihalomethanes, and human fecal bacteria such as *Bacteroidales* and viruses (i.e., hepatitis A, adenovirus, and enterovirus). Other biological markers include sterols (i.e., cholesterol, β -sitosterol, 3 β -coprostanol, and stigmastanol, β - and α -cholestanone, campesterol, stigmastanol, and epicoprostanol) as indicators of fecal contamination. The fecal sterol 3 β -coprostanol is produced in the gut of some mammals, including humans, pigs and cats, by the microbially mediated reduction of cholesterol under anaerobic conditions. Sterols and stanols can be combined to distinguish between the release of feces containing swine and cow waste. The specificity of steroids as a means to differentiate cow feces from pig slurries is available by considering fecal stanol diagnostic compounds, including coprostanol, epicoprostanol, campenstanol, sitostanol, 24-ethylcoprostanol and 24-ethylepicoprostanol and/or their ratios. Another forensic opportunity is the detection of nanoparticles (1–100 nm), such as nanosilver (*n*-Ag) and nano-titanium oxide (*n*-TiO₂) that are associated with fabric and exterior paints, respectively, in environmental samples as surrogates for the releases of contaminants from these potential sources (Benn and Westerhoff 2008).

Bulk and compound-specific isotopic analysis (CSIA) can be used to identify and discriminate between different sources of contamination. Examples of the use of CSIA and bulk isotope analysis include whether methane gas is biogenic or anthropogenic (¹H/²H); the origin of sulfur from naturally occurring hydrothermal sulfate or from the oxidation of reduced sulfur in pyrite-rich ore materials using four stable isotopes (³²S, ³³S, ³⁴S, ³⁶S); discrimination between sources of crude oil releases (¹³C/¹²C); characterization of the biochemical evolution of dissolved organic carbon; examination of biodegradation of RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine) using δ^{15} N and

$\delta^{18}\text{O}$ enrichment; MTBE (methyl tertiary butyl ether) source identification using ($^{13}\text{C}/^{12}\text{C}$); the origin (naturally occurring or anthropogenic) of perchlorate using $^{18}\text{O}/^{16}\text{O}$, $^{35}\text{Cl}/^{37}\text{Cl}$, and $^{17}\text{O}/^{16}\text{O}$ ratios; the kinetics of natural attenuation/degradation of contaminants; the origin of PCBs, pesticides, and lead; the identification of sulfur sources using stable sulfur isotope signatures; and the origin of PCE and TCE using differences in carbon, chlorine, and/or hydrogen isotope ratios. In hydrology investigations, isotopes are used to estimate ages of groundwater based on $^{18}\text{O}/^{16}\text{O}$ and assumptions about past temperatures and recharge compositions. In environmental forensic investigations, the primary isotopes and ratios include hydrogen ($^2\text{H}/^1\text{H}$), carbon ($^{13}\text{C}/^{12}\text{C}$), nitrogen ($^{15}\text{N}/^{14}\text{N}$), oxygen ($^{18}\text{O}/^{16}\text{O}$), sulfur ($^{34}\text{S}/^{32}\text{S}$), and for chlorinated solvents, chlorine ($^{37}\text{Cl}/^{35}\text{Cl}$).

CSIA is also used to distinguish between naturally occurring and anthropogenic sources of chloroform in soil gas and groundwater. In one study, $\delta^{13}\text{C}$ values of chloroform (-22.8 to -26.2 ‰) in soil gas collected in a forested area were within the same range as values from the soil organic matter (-22.6 to -28.2 ‰) but were more enriched in ^{13}C compared to industrial chloroform ($\delta^{13}\text{C}$ values of -43.2 to -63.6 ‰ (Hunkeler et al., 2012)).

Congener Analysis

The term congener refers to individual compounds, regardless of their homologue class. PCBs, dioxins, and furans are conducive to congener analysis for source discrimination. Figure 3 is a normalized histogram for virgin PCE solvent and sludge residue from a distillation still at a facility in Japan (Fukai and Nakata 2001). Many of the chlorinated dibenzodioxins (CDDs) and chlorinated dibenzofurans (CDFs) in the new PCE solvent in Fig. 3 are OCDD and HpCDD enriched in the distillation sludge, thereby providing a potential means to (a) develop a working hypothesis regarding the source of the PCE and CDD/CDF compounds found with a particular PCE/dioxin/furan profile and (b) whether the PCE originated from new or spent PCE.

Fig. 3 Normalized histogram of TCDD and PCDD congeners in new PCE solvent and in distillation sludge from a dry cleaning facility using PCE

Dating a Contaminant Release

Forensic techniques used for source identification can often bracket the time when a release occurred. Another approach is contaminant transport modeling of atmospheric, surface, and sub-surface releases of contaminants. Forensic contaminant transport models include simulations to identify the age of contaminant releases in the atmosphere, liquid releases on a paved/unpaved surface, liquid transport through the unsaturated zone, vapor transport, and intrusion models in soil and groundwater models. Groundwater models used to date a contaminant release include (a) measuring the leading edge of a contaminant plume, (b) hydrolysis modeling of methyl chloroform, and (c) inverse modeling.

Leading Edge of a Contaminant Plume in Groundwater

The term L is the length of the contaminant plume. Some portion of L , ΔL , is due to longitudinal dispersion. If the groundwater seepage velocity is u and the retardation factor for the contaminant in question is R , so that the contaminant transport velocity is u/R , then the release date, t , is estimated as

$$t = (L - \Delta L) \frac{R}{u}. \quad (1)$$

The longitudinal dispersion can be estimated as

$$\Delta L = 2\sqrt{\frac{Dt}{R}} = 2\sqrt{\frac{\alpha_L ut}{R}} = 2\sqrt{\alpha_L(L - \Delta L)} \cong 2\sqrt{\alpha_L L} \quad (2)$$

where D is the coefficient of hydrodynamic dispersion, α_L is the longitudinal dispersivity, and molecular dispersion is neglected. The factor of two is included because this appears as part of the characteristic length scale in two- and three-dimensional analytical solutions. The approximate solution for ΔL , for large L , is

$$\Delta L \cong 2\sqrt{\alpha_L L} - 2\alpha \cong 2\sqrt{\alpha_L L} \quad (3)$$

and

$$t = \left(\frac{R}{u}\right)(L - 2\sqrt{\alpha_L L}) \quad (4)$$

which illustrates the importance of correcting for longitudinal dispersion as it decreases with the length of the plume. The groundwater seepage velocity and retardation is expressed as:

$$u = \frac{KI}{\theta_c} \quad (5)$$

and

$$R = 1 + \frac{\rho_b K_d}{\theta_c} \quad (6)$$

where K and I is the hydraulic conductivity and gradient over the plume length, respectively, θ_e is the effective porosity or interconnected pore space of the aquifer, ρ_b is the aquifer material dry bulk density, and K_d is the adsorption distribution coefficient. K_d is often expressed as

$$K_d = K_{oc} f_{oc} \quad (7)$$

where K_{oc} is the distribution coefficient for partitioning of the solvent between water and organic carbon and f_{oc} is the fraction organic carbon in the soil. With substitutions, the expression for the elapsed time since a release to groundwater becomes

$$t = \left(\frac{\theta_e}{I K_I} \right) \left(1 + \frac{\rho_b K_{oc} f_{oc}}{\theta_e} \right) (L - 2\sqrt{\alpha L}) . \quad (8)$$

The contaminant plume length is related to the source term, groundwater velocity, and contaminant degradation.

Hydrolysis of Methyl Chloroform

Methyl chloroform (1,1,1-TCA) is unique in that its degradation is hydrolysis driven which can be used to date its release. The method assumes that the rate of chemical hydrolysis of methyl chloroform to acetic acid is known, as is the rate of the elimination reaction to form 1,1-dichloroethylene (1,1-DCE). Other assumptions include that the hydrolysis rate and groundwater temperature are constant, the biodegradation of TCA and 1,1-DCE and the effects of chromatographic separation are insignificant, and that different volatilization rates on the DCE/TCA ratio are negligible. Given these assumptions, the reactions describing the abiotic degradation of methyl chloroform begin as

which is followed by a substitution reaction yielding hydrochloric acid and acetic acid (CH_3COOH) as

Alternatively, the hydrogen can be eliminated to yield DCE (CCl_2) as

These reactions are considered to be first order and temperature dependent. As a consequence, the reaction can be described by the general form of the Arrhenius equation to describe the temperature dependence of the rate of methyl chloroform degradation where the first-order rate constant for TCA (k) is

$$k = A e^{-E_a/RT} \quad (12)$$

where A is the Arrhenius constant; E_a is the activation energy, estimated from laboratory data as 8.7×10^{13} s and 122.8 kJ/mol-°K respectively; R is the universal gas constant (8.3145×10^{-3} kJ/mol-K); and T is temperature (°K). The rate constant for the abiotic degradation of TCA is equal to the sum of the individual rate constants in the substitution and elimination reactions as

$$k = k_s + k_e \quad (13)$$

and

$$[TCA] = [TCA_{(t=0)}] e^{-kt} \quad (14)$$

and

$$[DCE] = \frac{k_e}{k} [TCA_{(t=0)}] (1 - e^{-kt}) \quad (15)$$

where t is time and the molar values of TCA and DCE are bracketed. Equations (14) and (15) solve for t as

$$t = \frac{1}{k} \ln \left(1 + \frac{k[DCE]}{k_e[TCA]} \right). \quad (16)$$

In Eq. (16), t is the estimated time that methyl chloroform entered the groundwater (i.e., without accounting for the time required to migrate through the vadose zone) and is obtained by substituting a single measured value for the molar ratio of $[DCE]/[TCA]$ and groundwater temperature or by substituting time series field measurements. The field estimate of the abiotic rate constant for k is estimated by plotting time series measurements.

When TCE is present and its biodegradation is significant, the *cis*-1,2 dichloroethene (*cis*-1,2 DCE) concentration from this process is approximately two orders of magnitude greater than the 1,1-DCE concentration. Since a small amount of TCE biodegrades to 1,1-DCE relative to the concentration of *cis*-1,2 DCE, this reaction usually affects the 1,1-DCE/TCA ratio only slightly.

Inverse Modeling

Inverse modeling is used to determine the historical distribution of observed contamination, identify a contaminant source, and/or to reconstruct the release history from a known source (Morrison 1999; Michalak and Kitanidis 2003, 2004; Clement 2011). Inverse models include techniques used to determine (1) the location and magnitude of a steady-state point source (Sciortino et al. 2000), (2) the addition of temporal variables to describe a source term(s), (3) the location or time of release of instantaneous point sources, and (4) the use of a function estimate to characterize the historical contaminant distribution, source location, or release history using either a deterministic or stochastic approach (Woodbury et al. 1998; Alapati and Kabala 2000; Aral et al. 2001; Neupauer and Wilson 2002; Butera and Tanda 2003; Morrison 2014). In stochastic approaches to the solution of inverse problems, the unknown parameters are described through probability distributions where the estimated uncertainty is recognized and its importance is often determined, in contrast to deterministic approaches, where a single value is acquired for the unknown parameters (Michalak and Kitanidis 2003).

The development of stochastic approaches where parameters are viewed as a jointly distributed random field is one means of accounting for the uncertainty in contaminant concentration estimates, release history, and release history in a statistical manner, especially if the uncertainty associated with the estimate is quantified (McLaughlin and Townley 1996). The application of inverse models to identify the source of a contaminant release or source loading is nonunique (*equifinality*) with a potentially large degree of uncertainty (Michalak 2001).

Conclusion

Numerous forensic techniques are available to identify the source of a contaminant release and/or bracket when it occurred. Wherever possible, the use of multiple corroborative forensic evidence should be considered in order to establish the most accurate estimate of the origin and date of a contaminant release into the environment.

[Hydrothermal mineral deposits](#); [Hydrothermal mineralization](#)

Definition

Hydrothermal ores are metal-rich mineral aggregates precipitated directly from hot aqueous solutions circulating through the upper part of the crust. The terms “ore” and “mineral deposit” are economic geology expressions that refer to a mass of rock which contains metals at economically extractable grade. The applicability of these terms can fluctuate as a function of metal market prices, availability of subsidy, or technological conditions.

Introduction

Understanding of the origin of hydrothermal ore deposits requires accurate knowledge about the source and interaction of five important components: heat, fluids, ligands, metals, and permeability. The combination of these factors might provide the conditions necessary for the formation of hydrothermal mineral deposits, including the (i) presence of hot aqueous solution to dissolve and transport minerals, (ii) presence of interconnected openings in the rock to allow the aqueous solutions to move, (iii) availability of sites for the deposits, and (iv) geochemical reactions that will result in deposition (Barnes 1997).

Hydrothermal fluids can be derived from multiple fluid sources in Earth's crust, and these sources and depositional processes have given rise to a variety of genetic classifications of hydrothermal ore deposits (Pirajno 1992). Magmatic–hydrothermal fluids originate from magmas as they cool and crystallize at various levels of the crust and give rise to porphyry-related Cu–Mo–Au deposits (e.g., Sillitoe 2010), skarn- and greisen-related Sn–W deposits (e.g., Meinert et al. 2005), intrusion-linked iron oxide Cu–Au deposits (e.g., Groves et al. 2010), Pb–Zn–Au–Ag-rich replacement, and epithermal Au–Ag ores (e.g., Hedenquist et al. 2000; Simmons et al. 2005). Metamorphic fluids with aqua–carbonic compositions ($\text{H}_2\text{O} + \text{CO}_2$), liberated during prograde mineral reactions, are generally associated with orogenic or shear-hosted Au deposits (Goldfarb et al. 2005). Saline connate fluids formed during diagenesis have been implicated in the formation of stratiform sedimentary rock-hosted Cu and Mississippi Valley-type Pb–Zn ores (e.g., Hitzman et al. 2005; Leach et al. 2005). Seawater circulating through the oceanic crust in the vicinity of active ridges and vented onto sea floor as black smokers forms Cu–Zn-dominated volcanic massive sulfide (VMS) or Zn–Pb-dominated sedimentary exhalative (SEDEX) deposits (e.g., Franklin et al. 2005). Circulation of near-surface meteoric waters can dissolve, transport, and redeposit metals, giving rise to different

*Email: istvan.marton@stockwork.ro

sedimentary rock-hosted deposits such as a variety of uranium ores (e.g., Cuney 2010). The establishment of distinct and well-based genetic hypotheses for several distinct hydrothermal ore deposits remains complicated or poorly understood. For example, multiple fluid sources were proposed for the well-studied Carlin-type Au deposits, including the involvement of magmatic fluid (Sillitoe and Bonham 1990), metamorphic and meteoric sources (Muntean et al. 2011), and a model involving deeply sourced magmatic and metamorphic fluids combined with convecting meteoric water resulting in the dissolution and transport of gold from different locations in the crust (Cline et al. 2005).

Accurate knowledge about the sources of heat that exert a major control on fluid circulation and metal solubility is a key factor to understanding the formation of hydrothermal mineralization. Therefore, low-temperature, radiometric thermochronological methods can potentially provide a unique insight into the mechanisms of ore genesis in the upper crust. Thermochronology can constrain the location, timing, and duration of mineralizing processes. It also can elucidate the relative roles of different heat sources such as metamorphism, magmatism, the burial of sediments, or the juxtaposition of high-temperature isotherms against cooler rocks, via rock uplift and exhumation. Furthermore, there is increasing academic and industry interest in improving our understanding of post-mineralization processes, which preserve or destroy ore deposits and their overlying rocks. Low-temperature thermochronology quantifies the cooling, and potential exhumation histories of rocks, and therefore has useful applications for ore preservation studies, especially when it is combined with other thermochronometric techniques. A comprehensive review of the applications of thermochronology to the study of porphyry ore deposits has been provided by McInnes et al. (2005). This entry presents descriptions and examples of thermochronological methods that have been applied to reveal various types of hydrothermal ore depositional environments.

Dating Hydrothermal Events

Temperature-sensitive radiometric dating techniques can be utilized very efficiently for deciphering the timing and duration of mineralization processes. Additionally, because each low-temperature thermochronometer characterizes a different range of temperatures, the application of multiple thermochronologic techniques is invaluable in constraining the time–temperature history of ore deposition. When thermochronometers are combined with geochronometers (e.g., U–Pb dating, Re–Os dating, or Rb–Sr dating), they can be utilized to the best advantage and can elucidate many aspects of ore deposit genesis, including intrusive emplacement, ore deposition, alteration processes, overprinting or retrograde hydrothermal events, erosion, and weathering.

Ar–Ar dating is regularly used to determine the timing of mineralization processes, as K-bearing minerals often form as part of the ore mineral paragenesis or as alteration minerals. Biotite, K-feldspar (adularia), muscovite, and alunite are commonly dated from various hydrothermal deposit types, including porphyry Cu–Mo–Au, epithermal Au–Ag, orogenic or shear-hosted Au, or Mississippi Valley-type Pb–Zn mineralization systems. The Ar–Ar step-heating technique can yield both the minimum age of host-rock crystallization (high-temperature steps) and the timing of younger thermal events (lower-temperature steps) on a single K-feldspar. It is therefore very effective to determine the timing of retrograde hydrothermal heating events and to estimate the cooling rates of the mineralizing systems. Recently, there has been increasing interest in dating sulfide minerals where K is present in mineral or fluid inclusions, as sulfides generally have very low diffusivity for Ar, and hence protects the inclusions from resetting. Promising examples include

concordant Ar–Ar ages that have been obtained for fluid inclusion-rich sphalerites from Fankou Pb–Zn deposit (Qiu and Jiang 2007) and for mica-bearing pyrites from Archean Kanowna Belle Au deposit (Philips and Miller 2006).

Fission-track thermochronology can be used for absolute dating; however, this is only possible for samples that have cooled rapidly and have remained undisturbed at, or close to, the surface since formation. Due to complicated thermal histories and because of the relative lack of apatite in hydrothermal ore paragenesis, fission-track analysis is rarely used for direct dating of hydrothermal systems. More commonly, apparent ages are obtained which are used for the reconstruction of the postmineral thermal history (cooling, exhumation, preservation).

(U–Th)/He dating of hydrothermal ore deposits has gained more and more focus with the development of new (U–Th)/He chronometers which have closure temperatures overlapping with hydrothermal conditions and which use minerals commonly occurring in hydrothermal ore paragenesis. As examples, concordant (U–Th)/He were obtained for epidote and garnet from skarn mineralization (Nicolescu and Reiners 2005), for specular hematite (Lippolt et al. 1993), for fluorite from the La Azul fluorspar deposit (Pi et al. 2005), and for titanite (Reiners and Farley 1999) and magnetite (Blackburn et al. 2007), respectively.

Mapping Thermal Footprints Related to Hydrothermal Fluid Flow

One of the main challenges facing exploration geologists investigating subsurface hydrothermal mineralization is the identification of the far-field expressions (footprints) of hydrothermal systems (Kelley et al. 2006). Traditionally, research on the footprints related to hydrothermal fluid flow focuses on mineralogical alteration products (i.e., visual alteration) and on the patterns of primary or secondary lithogeochemical dispersion halos, which are the result of progressive fluid–rock interaction. However, often these proximal footprints are subtle or are partially restricted to main fluid flux zones, which make it difficult to identify and map out concealed hydrothermal ores (Fig. 1). A commonly neglected aspect of hydrothermal fluid flow is the resultant heat transfer to rock within and around the fluid conduit. Heating is a product of advection (flow of heated fluid mass) and diffusion (conduction of heat through a fluid or rock mass). A thermal halo should develop around all hydrothermal deposits; the size of the halo being a function of the duration of hydrothermal flow, the magnitude of the fluid flux, the temperature difference between the thermal fluids and the country rock, and the size, shape, and density of the fluid conduits (Cathles et al. 2006). Recent studies demonstrate that these thermal haloes can be detected at distances up to several hundred meters around hydrothermal mineralization when studying stable isotope fractionation or the rate of annealing of fission tracks within the wall rock minerals (Arehart and Donelick 2006; Hickey et al. 2007; Barker et al. 2013). The extent of fission-track resetting is a nonlinear function of the duration and magnitude of the heating. As the magnitude and duration of conductive heating decreases outward from the hydrothermal fluid conduit, fission tracks close to the conduit will be reset to a greater extent than those farther away. The pattern of fission-track resetting will largely reflect the period and temperature of the fluid flow event that induced the conductive heating pulse.

Dating by apatite fission tracks (AFT; which reset as apatite is heated above 60 °C; Donelick et al. 2005), in combination with the apatite (U–Th)/He dating method (closure temperature ~70 °C; Ehlers and Farley 2003), is the most widely utilized thermochronometer for mapping low-temperature thermal fronts associated with channelized fluid flow. Studies of sedimentary rock-hosted gold deposits in the northern Carlin trend (USA) suggest that single-conduit focusing of 200–240 °C ore fluids over a relatively short duration ($\sim 10^4$ years) is capable of completely

Fig. 1 Idealized representation of hydrothermal and thermal footprint zones related to single fluid flow conduits in hydrothermal ore systems

resetting AFT ages at a distance of ~ 325 m, while a ~ 10 % change in AFT age relative to background occurs at a distance of ~ 800 m (Hickey et al. 2014). In systems where conduits are close enough for conductive thermal fronts to interact (double-sided slab heating), the 10 % resetting and total resetting fronts are able to completely propagate across slabs $\sim 1,100$ m (~ 10 % change in AFT ages relative to background) and ~ 700 m (complete resetting of AFT ages) wide, respectively (Hickey et al. 2014).

Genetic Aspects of Hydrothermal Mineralization: Possible Heat Sources

Since the stability of metal–ligand complexes is primarily controlled by temperature and generally enhanced by elevated temperatures, it is clear that the role of heat is critical during the leaching, transport, and deposition of metals by hydrothermal fluids. Generally, strong thermal gradients present the ideal conditions for the generation of high-grade magmatic hydrothermal ores, whereas more diffuse mineralization haloes would be expected for more slowly cooled igneous intrusions. Moreover, many authors have discussed the significance of thermally driven fluid flow during the formation of basin-related hydrothermal ore deposits. Therefore, the application of thermal history modeling to investigate possible heat sources and their gradients represents a powerful tool for understanding genetic aspects of ore deposition.

As illustrated by a case study from Eastern Rhodopes, Bulgaria (Fig. 2), Márton (2009) demonstrated that sufficient heat accumulated from multiple sources to sustain an ore-deposit-forming hydrothermal system. The relative roles of different heat sources resulting from metamorphism, magmatism, the burial of sediments in environment with high geothermal gradients, or the

Fig. 2 Model illustrating various possible fluids (blue arrows), metals (gray arrows), ligands (green arrows), and heat (red arrows; A magmatic, B burial, C high geothermal gradient) (sources associated with the formation of sedimentary rock-hosted gold mineralization from Eastern Rhodopes, Bulgaria (after Márton 2009))

juxtaposition of high-temperature isotherms against cooler rocks via rock uplift and exhumation were quantified using multiple thermochronometers and applying appropriate sampling profiles which consider the various geological processes.

Preservation and Exhumation of Hydrothermal Ore Deposits

Hydrothermal ore deposits that form in the shallow crust (<5 km) are frequently obliterated by erosion and reworking, particularly if they form in environments that are being exhumed (Wilkinson and Kesler 2007). The probability of exposure of a hypogene subsurface ore is clearly a function of the depth at which it formed and the rate at which it is exhumed toward the surface. Therefore, concealment of shallow, epithermal ore deposits by post-mineralization sedimentation represents a convenient way to preserve them for a longer time (Fig. 3). Thermal history modeling provides a means to quantify the timing, magnitude, and duration of heating and cooling events that occurred during the tectonic evolution of an area and is useful to establish a plausible exhumation history. In this context, low-temperature thermochronological data can be used as an exploration tool for the identification of shallow ore deposits in the crusts. Favorable targets can be represented by time–temperature results that corroborate ore emplacement depth, exhumation rate, and age-distribution characteristics.

Márton et al. (2010) integrated the results of $^{40}\text{Ar}/^{39}\text{Ar}$ step-heating analyses of hornblende, muscovite, biotite, and adularia, along with zircon and apatite fission-track analyses from upper and lower plate rocks of the Kesebir–Kardamos metamorphic core complex from the Eastern Rhodopes, Bulgaria, where Oligocene epithermal sedimentary rock-hosted Au mineralization was formed in upper plate position in close spatial relationship to detachment faults. The resulting thermal history models for the upper plate show that ore formation was followed by continuous sedimentation until ~33–30 Ma, which may account for the fact that the mineralized zones were preserved, and the exhumation of these deposits suddenly started with the onset of horst–graben formation at ~33–30 Ma. The steep, post-mineralization normal faults played a key role during the exhumation of the deposit representing the bounding structures of the exhumed gold deposits. Therefore, structural mapping should focus not only on the low angle detachment faults, which might be genetically related to ore formation, but also on post-mineralization faults, which exhumed the deposits.

LA–ICP–MS apatite U–Pb dating and fission-track thermochronology were also applied to determine the preservation potential of magnetite–apatite deposits in the Luzong and Ningwu

Fig. 3 Relationships between emplacement depth, erosion history (*upper panels*), and time–temperature evolution (*lower panels*) during the exhumation history of epithermal Au deposits (*red dots*). (**a**) The area experienced continuous exhumation since hypogene ore deposit formation, and the ore deposit was eroded in the past making the area unfavorable for present-day exploration, although potential supergene/placer ores might form in related river catchment zones. (**b**) After ore formation the early history of the area includes a burial period and subsequent exhumation. This scenario renders the area favorable for present-day ore exploration

volcanic basins, eastern China (Liu et al. 2014). Results suggest that although the metallogenic conditions of both basins were similarly favorable for the formation of the of magnetite–apatite deposits, the Luzong basin had better preservation potential and therefore more promise for development of the magnetite–apatite deposits.

Quantifying Fault Displacement in Mineralized Zones

The identification of postmineral faults and the reconstruction of fault displacement have major implications for the exploration of ore deposits, as it can reveal the tilting history of an explored area and allow identification of missing (faulted) portions of an ore deposit.

Under thermal steady-state conditions, where isotherms are fixed relative to the surface, changes in time–temperature profiles from a certain sampling profile reflect the movement of a sample with respect to the surface. In this situation, low-temperature thermochronometers can be used to constrain patterns of footwall denudation associated with fault-array evolution. Samples collected along fault-perpendicular footwall transects can be used to construct age versus elevation profiles that may constrain the timing of fault displacement as well as the magnitude and rate of footwall denudation. Vertical fault displacement and erosion must be sufficient to exhume the partial retention zone; otherwise, the fault displacement will not be resolved. Samples at higher structural levels pass through this temperature zone earlier than those located at lower levels, resulting in an age–elevation profile in which apparent cooling ages decrease linearly with elevation. For a purely vertical transect, the slope of the age–elevation profile defines the rate of footwall denudation and may constrain the timing of fault activity.

A well-documented example of postmineral fault displacement was provided at the Chuquicamata Cu–Mo deposit, where a significant portion of the western side of the ore body was dislocated by post-mineralization motion along the West Fault, a major N–S strike-slip feature that cuts through Northern Chile (McInnes et al. 1999). U–Th/He and fission-track data collected on both sides of the West Fault documented a clear offset, revealing the vertical component of displacement. Younger ages in the hanging wall (to the west) indicate that it has been exhumed relative to the footwall, and there has been ~600 m of vertical displacement along the West Fault. The results suggest that the missing portion of the Chuquicamata Cu–Mo deposit was not yet eroded during tectonic uplift and denudation and should still be present at an elevation of 3,600 m, 25–35 km along the strike (sinistral) of the current open pit at Chuquicamata.

Summary

Thermochronologic data provides important constraints on the role of different processes in the formation, preservation, and exhumation of hydrothermal ore deposits. Thermochronologic results integrated in time–temperature paths permit an assessment of the timing, magnitude, and duration of hydrothermal mineralization events in relation to magmatic, metamorphic, and sedimentary processes. The source of heat and the thermal-gradient footprints related to hydrothermal systems can be mapped using diverse thermochronometers. Resulting models of thermal history offer a quantitative framework for the evaluation of ore preservation potential of an area and for the economic assessment of different tectonic units from a mineralized belt.

Uranium Series, Opal

James B. Paces*

Geosciences and Environmental Change Science Center, U.S. Geological Survey, Denver Federal Center, Denver, CO, USA

Synonyms

U-series disequilibrium; $^{230}\text{Th}/\text{U}$ ages; Opaline silica

Definition

Uranium series dating. A geochronological method that uses intermediate decay products in the ^{238}U or ^{235}U radioactive decay chains to measure the length of time required to reach the current state of radioactive disequilibrium from an initial condition.

Opal. Amorphous or only partially crystalline hydrated silicon dioxide ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) precipitated from aqueous solutions in near-Earth-surface environments.

Mineralogy and Geochemistry of Opal

Opal is a common mineraloid found near the surface of the Earth that consists of silica containing nonstructural water ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$). Opal typically forms by precipitation of colloidal silica from silica-saturated aqueous solutions in response to decreases in temperature, neutralization of alkaline solutions, increases in salinity, or evaporative concentration. Sedimentation of colloidal microspheres (<500 nm) results in deposits of amorphous silica gel. Subsequent dewatering and diagenesis causes gels to solidify and gradually increase their structural ordering. Water contents typically range between 0.5 % and 10 % and tend to decrease with increasing crystallinity.

Opals have been distinguished on the basis of their degree of crystallinity determined by x-ray diffraction (Jones and Segnit 1971). These include amorphous opal (opal-A), disordered α -cristobalite with α -tridymite stacking (opal-CT), and more ordered α -cristobalite with minor tridymite stacking (opal-C). Progressive increases in the degree of ordering from opal-A through chalcedony (Fig. 1) have been observed in response to increasing temperature as well as increasing age (Kano 1983; Herdianita et al. 2000; Neymark et al. 2003).

Opal is most common in volcanic or sedimentary settings and is associated with alteration or weathering of silicate rocks. Materials display a wide range of colors (known as play of color), textures, opalescence, and luminescent properties. Opal is also classified as gem opal (also precious or noble opal) or common opal (also, potch opal) based on its ability to diffract visible light into a spectral array of colors (Smith 1998). Play of color is the property observed when well-sorted (~ 150 – 250 μm) opal microspheres are clustered into ordered arrays (Jones et al. 1964; Darraugh et al. 1965). Common opal forms when microspheres are less well sorted and cluster without orderly packing.

*Email: jbpaces@usgs.gov

Fig. 1 Relative x-ray intensity data over part of the diffraction pattern between 66° and 70° 2-theta for subsamples of opal dated by $^{207}\text{Pb}/^{235}\text{U}$ from a single subsurface secondary mineral crust at Yucca Mountain, Nevada. Data show progressive increases in peak structure and intensity with age until older subsamples show patterns similar to the quartz standard. Modified after Fig. 6 of Neymark et al. (2003)

Gailliou et al. (2008) documented the geochemistry of a variety of gem and common opals from various localities around the world. Typical impurities (elements with concentrations $>500 \mu\text{g/g}$) include Al, Ca, K, Mg, Fe, and Na, whereas common trace elements ($<500 \mu\text{g/g}$) include Ba, Sr, Rb, Mn, Ti, U, and Nb. Gailliou et al. (2008) found that the trace element chemistry in opal can be linked to that of the host rock, particularly for rare earth elements (REE), allowing geochemical fingerprinting of gem opals to their geographic origin. The most pertinent compositional data for the purposes of dating opal are concentrations of U relative to Th (for $^{230}\text{Th}/\text{U}$ dating) and U relative to Pb (for U–Pb dating). U concentrations in the 76 analyses from 13 localities reported by Gailliou et al. (2008) range from 0.01 to 131 $\mu\text{g/g}$, although U concentrations from hundreds to thousands of $\mu\text{g/g}$ have been reported from other localities (Ludwig et al. 1980; Paces et al. 2010, supplement). Like REE, tetravalent U and Th are largely insoluble in aqueous solutions; therefore, U/Th ratios in opal can remain similar to values found in host rocks (typically 0.1–0.5). However, hexavalent U can be highly soluble in oxidizing groundwater, especially as the uranyl ion (UO_2^{2+}) complexed with other anions such as CO_3^{2-} (Langmuir 1978; Porcelli 2008). Natural oxidizing, bicarbonate-rich surface water and groundwater commonly have U concentrations ranging from 0.1 to 20 $\mu\text{g/L}$, whereas Th and Pb remain insoluble (typically <0.02 and $<0.2 \mu\text{g/L}$, respectively). Consequently, opal formed under oxidizing conditions has the potential to have U/Th and U/Pb ratios favorable for dating due to lack of ^{230}Th or Pb incorporated during formation.

U-Series Disequilibrium Dating of Opal

Several geochronometers are available within the U-decay chain and rely on the growth or decay of various intermediate decay products including ^{234}U , ^{230}Th , ^{226}Ra , ^{231}Pa , and several shorter-lived products (see entry on “► U-series Dating”). The only two chronometers using intermediate decay products that have been applied to opal include the $^{230}\text{Th}/\text{U}$ method with a working range of about 0 to 400,000 years (400 ka) and the model $^{234}\text{U}/^{238}\text{U}$ method with a working range up to about

1,200 ka. Older opals (>100 ka) have been dated using U–Pb methods, although issues related to initial $^{234}\text{U}/^{238}\text{U}$ disequilibrium must be considered.

Initial Investigations of Opal as a Geochronometer

The ability for silica gel to concentrate U from groundwater was recognized during the late 1970s in uraniferous silica related to uranium ore deposits (Zielinski 1977, 1980). Experiments with uranium-bearing silica-saturated solutions indicated that dried silica gels contained U concentrations that were 400–1,000 times higher than U concentrations in source water (Zielinski 1980). U–Pb isotopic compositions were also investigated to evaluate the possible use of uraniferous opal and chalcedony as geochronometers. Ludwig et al. (1980) found that opal-CT with U concentrations of 84.5–3,940 $\mu\text{g/g}$ at Spor Mountain, Utah, USA, had low common Pb contents and high retention of U-daughter products. Two distinct $^{207}\text{Pb}^*/^{235}\text{U}$ age intervals were determined (where the asterisk denotes only the radiogenic ^{207}Pb derived from in situ decay of parental ^{235}U , obtained after subtraction of “common,” non-radiogenic Pb): 4.8–3.4 Ma for five analyses hosted in rhyolites dated at 39–6 Ma and 16–13 Ma for five analyses hosted in the Beryllium Tuff Member of the Spor Mountain Formation dated at 21 Ma. Furthermore, $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ratios for most analyses were consistent with samples having initial $^{234}\text{U}/^{238}\text{U}$ activity ratios (AR) in the range typically expected for thermal waters in young volcanic terrains. Based on results of HCl leaching experiments, clustering of $^{207}\text{Pb}^*/^{235}\text{U}$ ages and $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ consistent with expected initial $^{234}\text{U}/^{238}\text{U}$ AR values, Ludwig et al. (1980) concluded that Spor Mountain opals approximated a closed system for U and its daughter products and that U–Pb dating of opal as young as ~1 Ma was possible.

Szabo and Kyser (1985, 1990) found that uraniferous opal, identified by its bright yellow-green fluorescence under short-wavelength ultraviolet light, had elevated U concentrations (15–58 $\mu\text{g/g}$) and low Th concentrations ($^{230}\text{Th}/^{232}\text{Th}$ AR = 150–470) in subsurface veins and fracture coatings hosted in drill cores from 13-Ma volcanic rocks at Yucca Mountain, Nevada. The characteristic fluorescence coloration has been attributed to activation caused by trace amounts of U (Hanchar 1999). Attempts to obtain U-series dates for those opals by alpha-spectrometry were unsuccessful, despite the presence of U-series disequilibrium in 3 of 4 samples (see “► U-series Dating,” for description of method). Alpha-spectrometry methods required large samples (up to a gram or more) which were homogenized by pulverizing and heated for 8 h prior to digestion and U–Th purification. More recent investigations using isotope dilution thermal ionization mass spectrometry (ID-TIMS) on much smaller samples of similar opal from the same site suggest that the alpha-spectrometry data likely represent mixtures of younger and older material and have little true age meaning (see discussion of “Vadose-Zone Hyalitic Opal” below).

U-Series Dating of Pedogenic Opal

By the mid- to late 1990s, U-series dating by ID-TIMS was applied to pedogenic deposits in southern Nevada with a focus on opaline silica components of complex, laminated clast rinds (Ludwig and Paces 2002). Pedogenic opal in these soils typically forms hard, opaque, light tan- to brown-colored layers that contrast sharply with softer, lighter-colored carbonate. Scanning electron microscopy (backscatter imaging and energy-dispersive x-ray fluorescence) showed that rind layers can consist of dense, silica-rich material alternating with more porous calcite, as well as layers containing intimate mixtures of calcite and silica at very fine scales. Dilute acid leaching experiments on clast rinds demonstrated that U is enriched in the residual silica-rich phase relative to easily leached carbonate phase. This causes problems when attempting to date complex pedogenic material by the so-called leach/leach and leach/residue methods (Schwarcz and Latham 1989; Bischoff and Fitzpatrick 1991; Luo and Ku 1991) because both ^{230}Th and ^{234}U can be implanted from the higher-

Fig. 2 U-series dating results for a pedogenic rind off an alluvial clast from the Calico Mountains, California. **(a)** Cross-sectional map showing the distribution of carbonate- and opal-rich layers and ~30- μm -diameter spots analyzed by secondary ion mass spectrometry. **(b)** Th–U isotope evolution plot showing data (small circles) and 95 % confidence level uncertainties (error ellipses) for spots shown on rind in **(a)**. Ages range from 15 to 74 ka (isochrons shown as steeply sloping light gray lines at 25-ka intervals) with relatively uniform initial $^{234}\text{U} / ^{238}\text{U}$ activity ratios of ~1.2 (thick, blue, subhorizontal lines) (Modified after Figs. 5 and 6 of Maher et al. (2007))

U silica phase into the lower-U carbonate phase via alpha-recoil. Consequently, unsupported daughter isotopes in the more readily leachable phases are likely to have $^{230}\text{Th} / ^{238}\text{U}$ ratios without clear time significance regardless of whether they are treated as single data points, isochrons, or leach/residue pairs (Ludwig and Paces 2002, p. 495). Those authors concluded that total digestion of thin, opal-rich, detritus-poor layers produced the most reliable analyses with elevated U and $^{238}\text{U} / ^{232}\text{Th}$ values. Reported ages for opal-rich samples ranging from 10^4 to nearly 10^6 years were consistent with internal microstratigraphy within individual clast rinds as well as overall stratigraphic relations for samples from modern and buried horizons.

Maher et al. (2007) further investigated U-series dating of surficial deposits using secondary ion mass spectrometry (SIMS) to probe pedogenic opal at higher spatial resolutions. Primary beam spot sizes of ~30 μm allowed targeting of small, relatively pure authigenic silica with high U concentrations and U/Th ratios (Fig. 2a). This strategy has the benefit of minimizing corrections for initial ^{230}Th associated with detrital components, reducing sample size requirements, eliminating chemical preparation, and allowing evaluation of soil development at microstratigraphic scales (Fig. 2b). However, in order to obtain sufficient secondary ion beams of minor isotopes (^{234}U and ^{230}Th), silica-rich pedogenic cements with U concentrations greater than about 50 $\mu\text{g/g}$ were required for SIMS analyses. In contrast, pedogenic carbonate typically has U concentrations less than 10 $\mu\text{g/g}$. The imprecision caused by low count rates for minor isotopes can be offset by reduced uncertainty

associated with smaller detrital Th corrections. Maher et al. (2007) argued that although TIMS analyses yield higher analytical precisions, ages determined at finer spatial resolutions by SIMS analyses may have greater accuracy, especially for finely layered samples with complex growth histories.

U-Series Dating of Vadose Zone Hyalitic Opal

The need to understand the history of water movement through the unsaturated zone at Yucca Mountain, Nevada, which was intended to host a high-level nuclear waste repository, prompted substantial work with secondary mineral coatings lining fracture footwalls and lithophysal cavity floors. These coatings are dominated by deposits of coarsely crystalline calcite with smaller amounts of water-clear, hyalitic opal (Paces et al. 2001; Whelan et al. 2002). Opal forms small (<1–2 mm), finely layered, glassy hemispheres; globular masses; or thin sheets on calcite substrates. Although both phases precipitated from the same downward-percolating solutions, opal contains U concentrations that are 2–4 orders of magnitude higher than calcite (~5–300 µg/g U versus 0.005–0.04 µg/g U, respectively; Paces et al. 2001). Concentrations of Th are extremely low resulting in $^{230}\text{Th}/^{232}\text{Th}$ AR up to 10^6 . Initial attempts to date whole hemispheres of opal from mineral crust surfaces using ID-TIMS yielded ages ranging between about 40 and >600 ka that showed a suspicious negative correlation with initial $^{234}\text{U}/^{238}\text{U}$ AR (from 6 to 10 for the youngest samples to 1 and 2 for older samples). However, none of the analyses had unsupported ^{230}Th , implying little or no post-depositional uranium mobility. These features, plus an apparent positive correlation between age and sample size, suggested that Yucca Mountain opals do not fit the assumptions of simple, closed-system isotope evolution in an instantaneously deposited layer.

Instead, Neymark and Paces (2000) proposed a conceptual model of continuous deposition where opal precipitated at constant rates over long periods of time up through the present. Samples with finite thickness consist of a mixture of older and younger material that yield isotopic compositions reflecting addition of new layers with elevated $^{234}\text{U}/^{238}\text{U}$ at the same time that U-series compositions of previously deposited layers evolve by radioactive decay. Average ages calculated using continuous deposition equations combined with the typical thickness of 0.1–0.5 mm resulted in estimates of opal deposition rates between about 0.1 and 5.0 µm/ka. These conclusions are consistent with the observation that ages for the outermost mineral layers determined using geochronometers with progressively longer half-lives (i.e., ^{14}C , $^{230}\text{Th}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$) yield discordant, progressively older ages (Fig. 7 of Neymark et al. 2000).

To test the model of continuous deposition of Yucca Mountain opal, two methods of U-series dating at higher spatial resolutions were developed, including SIMS and in situ micro-digestion followed by ID-TIMS analysis (Paces et al. 2004). SIMS analyses utilized a primary oxygen ion beam to sputter metal and oxide ions from ~45-µm-diameter pits across profiles of layered opal hemispheres. Resulting $^{230}\text{Th}/\text{U}$ ages ranged from 34.4 to >300 ka, increasing progressively with depth below the outer surface. Uncertainties were substantially larger than previous ID-TIMS results due to the much smaller signals; however, $^{234}\text{U}/^{238}\text{U}$ versus $^{230}\text{Th}/^{238}\text{U}$ compositions followed trajectories expected for closed-system evolution unlike the scatter observed for whole-hemisphere results (Fig. 7 of Paces et al. 2004). Model $^{234}\text{U}/^{238}\text{U}$ ages ranging between 277 and 1,430 ka were calculated for older layers using the assumption that the average initial $^{234}\text{U}/^{238}\text{U}$ AR determined for spots younger than 200 ka remained uniform over time. Both $^{230}\text{Th}/\text{U}$ and model $^{234}\text{U}/^{238}\text{U}$ ages combined with microstratigraphic depths across two opal hemispheres yielded linear growth rates of 0.58 and 0.69 µm/ka. The second method, in situ micro-digestion, involved exposing the outer surface of hyalitic opal hemispheres to single or sequential HF digestion steps that removed between 1.5 and 3.8 µm of opal per step. Digestions were spiked with a mixed tracer solution of ^{236}U and

^{229}Th and taken to dryness. Because of the high purity of the hyalitic opal, chemical separations were not necessary prior to loading remaining salts onto carbon-doped, single Re filaments. U isotopes were measured by TIMS at lower temperatures prior to measurement of Th isotopes from the same filament at higher temperatures. As expected, the thinner outermost layers yielded younger ages (4.0–11.6 ka), and sequential digestions yielded an average growth rate of $0.68 \pm 0.22 \mu\text{m/ka}$ over the last 37 ka (compared to 0.69 ± 0.07 for the same hemisphere analyzed by SIMS). These investigations confirmed the continuous deposition numerical model proposed earlier and demonstrated that opal in this setting was formed at extremely slow growth rates over very long periods of time.

Subsequent investigations using SIMS analyses at even higher spatial resolution ($\sim 25 \mu\text{m}$ wide by $10 \mu\text{m}$ deep pits) demonstrated similarly slow, continuous growth rates in additional samples of Yucca Mountain hyalitic opal (Fig. 3; Paces et al. 2010). Systematic variations in cathodoluminescence intensity that follows growth banding were shown to be caused by variations in U concentrations from 5.4 to $550 \mu\text{g/g}$. Age-calibrated profiles of U concentrations were shown to correlate with regional climate records over the past 300 ka, indicating a clear chemical response of percolating water to near-surface, climate-driven processes. Nevertheless, the slow and relatively uniform opal growth rates over this time period were used to argue that water fluxes in the deep vadose zone were buffered from the large fluctuations in available surface moisture observed in other climate records in the region.

U-Series Dating of Opal by Laser Ablation ICPMS

Stirling et al. (2000) reported the first U-series analyses of a hyalitic opal from Yucca Mountain using laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS). Those authors were able to obtain uranium isotope compositions in secular equilibrium ($^{234}\text{U}/^{238}\text{U} \text{ AR} = 0.9997 \pm 0.0034$ [$2 \times$ standard error]) as expected for samples of three-million-year-old opal using a 266-nm Nd:YAG laser with a $150\text{-}\mu\text{m}$ -diameter spot size. Significant fractionation of U and Th was observed during initial experiments; however, the degree of fractionation was greatly reduced by changing ionization conditions in the plasma. More recent developments of laser ablation methods have further reduced analytical problems allowing $^{230}\text{Th}/\text{U}$ dating of carbonate, apatite, iron oxides, and silicate glasses with U concentrations as low as a few $\mu\text{g/g}$ (Eggins et al. 2005; Bernal et al. 2005; Grün et al. 2008). Application of these methods to opal in the future is likely to yield reliable ages allowing evaluation of growth rates, environmental conditions, and hydrologic processes associated with a wide variety of near-surface settings.

Summary

Opal is a very common product of secondary silica mobilization in near-surface hydrologic environments. If deposited from oxidizing solutions, it may incorporate high U concentrations with little or no initial ^{230}Th making it an ideal candidate for dating by U-series disequilibrium methods. Under near-surface conditions, opal can retain U-decay products for long periods of time ($> 10^6$ years). Most studies have focused on opal present in soils and thick vadose zones; however, wider recognition of its presence in these and other hydrologic settings will expand its application as a geochronometer.

$^{226}\text{Ra}/^{230}\text{Th}$ dating; $^{230}\text{Th}/\text{U}$ dating; Uranium-series isotope disequilibrium; U-series geochronology

Definitions

SIMS: Secondary ion mass spectrometry (SIMS) is a high spatial resolution technique that uses a focused beam of ions (primary beam) to bombard a sample surface and generate secondary ions that are accelerated into a mass spectrometer for measurement of isotopic abundances.

Magmatic differentiation: Physicochemical events, such as fractional crystallization, that modify the chemical composition of magmas.

Phenocryst: Relatively large crystal present in a finer grained crystalline or glassy groundmass.

Autocryst: A crystal that is spatially and temporally associated with a distinct pulse or increment of magma.

Antecryst: A crystal from an earlier pulse of magma which is incorporated by later pulses.

Xenocryst: A crystal incorporated from host rocks during transit and emplacement of magmas.

Introduction

Application of U-series dating to volcanic rocks provides unique and valuable information about the absolute timing of crystallization and differentiation of magmas prior to eruption. The ^{238}U – ^{230}Th and ^{230}Th – ^{226}Ra methods are the most commonly employed for dating the crystallization of mafic to silicic magmas that erupt at volcanoes. Dates derived from the U–Th and Ra–Th methods reflect crystallization because diffusion of these elements at magmatic temperatures is sluggish (Cherniak 2010) and diffusive re-equilibration is insignificant over the timescales ($\leq 10^5$ years) typically associated with pre-eruptive storage of nearly all magma compositions (Cooper and Reid 2008). Other dating methods based on elements that diffuse rapidly at magmatic temperatures, such as the $^{40}\text{Ar}/^{39}\text{Ar}$ and (U–Th)/He methods, yield dates for the cooling of magma at the time of eruption. Disequilibrium of some short-lived daughters of the uranium series such as ^{210}Po may be fractionated by saturation of a volatile phase and can be employed to date magmatic gas loss that is synchronous with volcanic eruption (e.g., Rubin et al. 1994).

Dating Volcanic Rocks Using U-Series Isochrons and Model Ages

Isochrons and model ages are most commonly employed for U-series disequilibrium dating of volcanic rocks. As in other methods, the use of U-series isochrons assumes that component minerals or a set of rocks are cogenetic, are coeval, share the same initial daughter activity, e.g., $(^{230}\text{Th})/(^{232}\text{Th})$, and isotopically evolve within a closed system. The U-series isochrons used for dating volcanic rocks are representations of parent-daughter nuclide evolution as a function of time:

$$(N_1) = (N_2)(1 - e^{-\lambda_1 t}) + (N_1)_0 e^{(-\lambda_1 t)},$$

where (N_1) is the daughter activity, (N_2) is parent nuclide activity, $(N_1)_0$ is initial daughter nuclide activity, λ_1 is decay constant of the daughter, and t is time. Parent and daughter nuclide activities are typically normalized to the activity concentration of a stable or relatively long-lived isotope of the daughter nuclide, e.g., ^{232}Th in the case of ^{238}U – ^{230}Th dating. Minerals or rocks satisfying the aforementioned assumptions form isochrons (Fig. 1) with an age-proportional slope = $(1 - e^{-\lambda_1 t})$. When parent and daughter reach secular equilibrium, the isochron slope is equal to unity (i.e., $(^{230}\text{Th})/(^{238}\text{U}) = 1$).

For volcanic rocks, U-series isochrons are typically constructed from phenocryst and melt (glass or crystalline groundmass) phases or geochemically variable suites of volcanic rocks. Model ages may be derived for single whole rocks or minerals by assuming the initial magnitude of parent-daughter disequilibrium. For example, U and Th are fractionated between crystals and their parent melt according to the crystal-melt partition coefficients for individual phases, resulting in variable deficits or excesses of ^{238}U or ^{230}Th (as well as the other shorter-lived daughters) in crystals and associated melt (i.e., a range of $(^{238}\text{U})/(^{232}\text{Th})$ values in Fig. 1). High-temperature crystallization does not result in measurable $^{238}\text{U}/^{234}\text{U}$ or $^{230}\text{Th}/^{232}\text{Th}$ fractionation. Hence, the activity of ^{230}Th can be directly compared to that of grandparent ^{238}U , and coeval minerals and melts will share the

Fig. 1 Schematic ^{238}U – ^{230}Th isochron for a single volcanic rock containing multiple phases (allanite, feldspar, melt, clinopyroxene [CPX], magnetite [Mt], and zircon) with variable U/Th. Gray lines link the isochronous phases at the time of crystallization (t_0) and subsequent periods of time (t_1 , t_2) as a consequence of ingrowth or decay of ^{230}Th . If crystallization at t_0 occurs shortly before eruption, the isochron effectively dates volcanism. If crystallization is protracted relative to ^{230}Th evolution, then the isochron predates volcanism

same initial $^{230}\text{Th}/^{232}\text{Th}$. However, fractionation of uranium isotopes can take place in lower-temperature aqueous environments, and volcanic rocks with measured $(^{234}\text{U})/(^{238}\text{U}) \neq 1.0$ indicate the presence of secondary alteration and/or recycling of crystals from older altered rocks.

After ~ 5 daughter half-lives, parent and daughter nuclides effectively reach secular equilibrium. In the case of ^{238}U – ^{230}Th , secular equilibrium occurs after ~ 350 ka, while in the case of ^{230}Th – ^{226}Ra , after ~ 8 ka. Accordingly, the U–Th and Th–Ra methods can potentially date crystallization with a resolution of hundreds to thousands of years. Th–Ra isochrons for volcanic rocks are complicated because Ra lacks a stable nuclide for parent-daughter normalization. Ba may be used as an imperfect analogue to Ra, but significant subequal Ra/Ba fractionation between minerals results in isochrons with kinked typology (Cooper et al. 2001). Consequently, theoretical or experimental limits on Ra/Ba partitioning are required to determine the initial $^{226}\text{Ra}/[\text{Ba}]$ of each mineral at the time of crystallization (Cooper and Reid 2008).

An internal isochron constructed from multiple minerals provides a crystallization date for the magma represented by that individual volcanic rock. An external isochron constructed from a suite of cogenetic volcanic rocks provides a date for the fractional crystallization responsible for the suite of related magmas. In each case, instantaneous crystallization or fractionation is assumed. As with other isochron methods, dating precision is maximized when minerals or rocks exhibit a large contrast in parent/daughter ratios. For example, isochrons pairing accessory minerals such as zircon and allanite, whose U/Th ratios vary by orders of magnitude, may yield late Pleistocene ages with $<5\%$ precision (Simon et al. 2009). To date volcanic eruptions, the crystallization or fractionation responsible for U-series isochrons must occur shortly before eruption. Examples are the coherent isochrons generated from major phases including feldspar, glass, pyroxene, and magnetite from late Pleistocene-Holocene andesitic and rhyolitic lavas at Puyehue-Cordon Caulle, Chile, and Segum Island, Alaska, USA, which yield ^{238}U – ^{230}Th ages that are indistinguishable from their associated $^{40}\text{Ar}/^{39}\text{Ar}$ eruption ages (Jicha et al. 2005, 2007).

Model ages may be calculated for individual volcanic rocks or minerals by assuming that $(^{230}\text{Th})/(^{238}\text{U})$ or $^{226}\text{Ra}/[\text{Ba}]$ is controlled by the initial magnitude of disequilibrium and the time elapsed since eruption. Limits on the initial magnitude of disequilibrium can be inferred from related samples that are effectively zero age. This approach is especially useful for volcanic rocks that lack substantial Th–U or Ra–Th variation and/or have few phenocrysts. For example, observed limits on the initial $(^{230}\text{Th})/(^{238}\text{U})$ and $(^{226}\text{Ra})/(^{230}\text{Th})$ values for mid-ocean ridge basalt (MORB) erupted from segments of the East Pacific Rise allow calculation of model ages for eruption, which in turn, yields spreading rates and recognition of youthful, off-axis volcanism (Rubin and Macdougall 1990; Zou et al. 2002). A similar approach using ^{210}Pb – ^{210}Po disequilibrium has been used to date MORB lavas younger than 2 years (Rubin et al. 1994).

Complexities in Dating Volcanic Rocks

Dating volcanic rocks by U-series disequilibrium is complicated when pre-eruption crystallization is protracted and/or recycling of “old” crystals is significant. Precise analyses of major phases using thermal or plasma ionization mass spectrometry require up to several grams of bulk material that may combine hundreds to thousands of crystals, and yield concentration-weighted mean ages integrating the entire crystallization interval (Cooper and Reid 2008). Accordingly, the presence of antecrysts and/or xenocrysts causes U-series dates to be skewed toward values older than eruption.

Scattered arrays of data on a mineral-isochron diagram imply crystal recycling or the mixing of magmas with different crystal populations (e.g., Pyle et al. 1988). Isochrons derived from analyses of multiple mineral and/or glass separates that exhibit little scatter suggest coherent age populations that are minimally skewed by recycled crystals (e.g., Jicha et al. 2005, 2007). Analyses of groundmass crystals or glass are likely to represent near-eruption crystallization and are targets for U-series dating of volcanic rocks (e.g., Bourdon et al. 1994). Small-volume basalts are unlikely to have significant residence in the crust, so their isochrons determined from phenocrysts and groundmass crystals are likely to effectively date eruption. For example, the ^{238}U – ^{230}Th isochron age for mafic lava recording the Laschamp geomagnetic excursion is indistinguishable from the ca. 41 ka derived from independent dating methods such as $^{40}\text{Ar}/^{39}\text{Ar}$ and layer counting of Greenland ice cores (Singer et al. 2009). Dates derived from isochron or model-age methods using whole-rock samples may be complicated by magma mixing where resulting isotopic compositions represent pseudo-isochrons or “errorchrons” that are in fact mixing lines between the two end members.

Resolving Near-Eruption Ages Using High Spatial Resolution Dating of Accessory Minerals

Individual accessory minerals with enriched concentrations of U and Th, such as zircon and allanite, are datable using the in situ sampling capability of ion microprobe analysis by secondary ion mass spectrometry (SIMS). Although analyses are not as precise as those determined using thermal or plasma ionization mass spectrometry, SIMS U–Th dating can reveal 10^3 – 10^5 -year age variations within single crystals, which allows crystal-by-crystal discrimination between autocrysts, antecrysts, and xenocrysts (Cooper and Reid 2008; Schmitt 2011). The final increment of crystallization preserved by U- and Th-rich minerals can be dated via SIMS analysis of unpolished faces on single crystals embedded in soft metal (Fig. 2). This approach samples the outermost few micrometers on single crystals and is superior in spatial resolution to the traditional SIMS approach of

Fig. 2 (a) Secondary electron image of SIMS analysis pit on the face of an unpolished euhedral zircon. White bar is 50 μm . Cartoon illustrates how the several micrometer depth resolutions of the SIMS primary beam are used to sample the final increment of zircon crystallization. (b) Late Pleistocene isochron from SIMS analyses of crystal faces on zircon and allanite from a rhyolitic tephra in California. Model ages for the interiors of the allanite are calculated assuming the same initial $(^{230}\text{Th})/(^{232}\text{Th})$ as the rims. The ca. 27 ka rim isochron age matches the tephra age from magnetostatigraphy (Modified from Vazquez and Lidzbarski 2012)

dating cross-sectioned crystals (Fig. 2). The euhedral faces of coexisting crystals are likely to be time equivalent and cogenetic and hence can yield isochron dates for near-eruption crystallization. Isochrons constructed using data from the rims of coexisting zircon and allanite in rhyolitic tephras from Mono Craters, east-central California (Fig. 2), yielded crystallization ages that agree with independent dating by magnetostratigraphy and the (U–Th)/He method (Vazquez and Lidzbarski 2012).

Summary

Volcanic rocks can be dated using several pairs of parent-daughter isotopes in the U-series decay chain. Dates ranging from several thousands to several hundreds of thousands of years are commonly obtained using isochron methods determined on multiple mineral phases within a single rock or analyses of multiple rock samples in a cogenetic suite. Model ages may also be calculated if reasonable assumptions about initial disequilibrium can be made. Resulting dates can reflect either eruptive ages or more convoluted stages of magma evolution depending on the nature of the crystallization processes that took place and the types of analyses that were conducted.

Neutron Activation Analysis

Ron Hancock*
Toronto, ON, Canada

Definition

Neutron activation analysis is a chemical analysis technique that may be used to determine the average (bulk) concentrations of major, minor, and trace elements in a sample. It may be used to measure the concentration of a single element or, more often, to measure the concentrations of many elements, as part of a chemical characterization of a set of samples to determine chemical similarities or differences. Samples may be liquid (aqueous or organic) or solid (e.g., animal tissues, ceramics, clays, glasses, paper, plants, plastics, lithics, metals).

The most common form of neutron activation analysis is instrumental neutron activation analysis. In this, a suitably encapsulated, weighed amount of the sample to be analyzed is sent, pneumatically or manually, into an irradiation site of a research nuclear reactor, and is bombarded by neutrons with a broad range of energies that the reactor produces.

Once the sample has been irradiated for an appropriate time, it is removed from the irradiation site and the induced radioactivity measured by counting the sample using a gamma-ray spectrometer. The result of counting produces a gamma-ray spectrum in which specific gamma-ray energies produce peaks, the areas of which are proportional to the amount of the element that is responsible for the gamma-rays.

To determine the actual amount of an element in a sample, peak areas are compared with calibrations taken from a stored library of information or from a similarly run substandard of the element.

There are three types of neutron activation reactions: (n, γ) , a neutron is absorbed by an atomic nucleus and a gamma-ray is emitted; (n, p) , a neutron is absorbed by an atomic nucleus and a proton is emitted; and (n, α) , a neutron absorbed by an atomic nucleus and an alpha particle is emitted. The first nuclear reaction is generated by low-energy (<0.1 eV or thermal) neutrons, and the other two are produced mainly by epithermal and fast (>1 MeV) neutrons. Although thermal neutron reactions are favored highly, some activation products may arise from elements of different atomic numbers. For example, ^{28}Al is produced preferentially by the thermal neutron reaction $^{27}\text{Al}(n, \gamma)^{28}\text{Al}$, by the epithermal neutron reaction $^{28}\text{Si}(n, p)^{28}\text{Al}$, and by the fast neutron reaction $^{31}\text{P}(n, \alpha)^{28}\text{Al}$. This means that while it is potentially impossible to analyze for Si, P, and Al in a matrix including large amounts of each, it is possible to use the activation product ^{28}Al to analyze for Al in alumina-silicate materials; for Si in silica-rich, or doped, materials; and for P in bones.

Only a minute fraction of the neutrons that hit a sample actually interact with nuclei of atoms in the sample to form artificial radioactivity. Elements form radioisotopes that emit one or more gamma-rays with discrete energies and that decay with characteristic half-lives, labeled short, medium, or long. For an analysis, knowledge of expected half-lives helps determine the irradiation time, the delay time before counting, and the counting time.

Uranium-Lead, Rubidium-Strontium, Kimberlite

Larry Heaman*

Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada

Introduction

Kimberlites are small-volume, highly gas-charged magmas derived from great depths in the mantle that, due to their explosive nature and fast ascent rates, have a great carrying capacity to entrain and transport material from the mantle to the Earth's surface. Some of the entrained material includes fragments of mantle rock (peridotite, eclogite, pyroxenite), which are invaluable for directly studying the nature of the deep Earth, and rare minerals that only form at great depth (e.g., diamond, majorite garnet). They are also the source of primary diamond deposits at the Earth's surface.

Determining the composition and emplacement age of kimberlites has long been a challenge because kimberlites are heterogeneous rocks consisting of a mixture of primary minerals that crystallize directly from the kimberlite magma and both mantle and crustal material that have been entrained during magma ascent. Figure 1a is a whole rock sample from the Monastery kimberlite illustrating the heterogeneous nature with mantle xenoliths (MX), crustal xenoliths (CX), and ilmenite megacrysts (ilm). In addition to the relative emplacement age constraint imposed by cross-cutting relationships with crust of known formation age, there have been several absolute radiometric dating methods applied to whole rock kimberlite samples and constituent minerals with varying degrees of success (e.g., Allsopp and Roddick 1984; Basu et al. 1984; Allsopp et al. 1986; Blackburn et al. 2008; Noyes et al. 2011), including K-Ar (whole rock, phlogopite), $^{40}\text{Ar}/^{39}\text{Ar}$ (phlogopite, clinopyroxene), fission track (zircon, apatite), U-Pb (zircon, perovskite, ilmenite, rutile), U-Th/He (apatite, zircon, titanite, magnetite, garnet), and Rb-Sr (phlogopite). In this contribution the methodology and limitations of two commonly used radiometric dating techniques for determining the emplacement age of kimberlites, U-Pb and Rb-Sr, will be reviewed.

U-Pb Geochronology of Kimberlite Minerals

The U-Pb technique is based on the radioactive decay of two long-lived uranium isotopes, ^{238}U and ^{235}U , to two different radiogenic lead isotopes, ^{206}Pb and ^{207}Pb , respectively, with decay constants of $1.55125 \times 10^{-10} \text{ year}^{-1}$ (half-life of 4.47 Ga) and $9.8485 \times 10^{-10} \text{ year}^{-1}$ (half-life of 0.704 Ga). This technique is unique compared to other geochronology methods in that each measurement derives an age from two distinct U-Pb clocks (Jaffey et al. 1971). For most U-Pb age determinations, a measure of the internal consistency of the age is the degree to which these two U-Pb clocks are in agreement, also known as the degree of concordancy, thereby making it possible to test if the system has been disturbed by post-crystallization processes. The ideal U-Pb chronometer is a mineral or whole rock that contains only uranium and no lead at the time of formation; some

(d) Phlogopite megacryst in Monastery kimberlite used for Rb-Sr dating

minerals approach this condition, such as zircon, baddeleyite, and monazite. The abundance of lead in a mineral at the time of crystallization is referred to as initial common lead, and the amount can be determined by measuring the abundance of ^{204}Pb , an isotope of lead that is not produced by radioactive decay.

For relatively young samples (e.g., Phanerozoic), the ^{238}U - ^{206}Pb chronometer is the most commonly used because the abundance of radiogenic ^{206}Pb is substantially higher than ^{207}Pb , due to a combination of the different decay rates of the two U parent isotopes and the two orders of magnitude difference in their abundance ($^{238}\text{U}/^{235}\text{U} = 137.82$, Hiess et al. 2010; revised slightly from 137.88, Jaffey et al. 1971). For these reasons, the ^{238}U - ^{206}Pb chronometer is least sensitive to any common Pb correction, so assuming there is no disturbance to the system (e.g., Pb-loss), this is the most commonly used method applied to kimberlite minerals and mantle materials. An excellent overview of the U-Pb dating technique has been recently published by Blair Schoene (2014).

There are a number of analytical techniques that have been used to determine U-Pb dates of kimberlites including isotope dilution thermal ionization mass spectrometry (IDTIMS; e.g., Heaman 1989; Smith et al. 1989; Heaman and Kjarsgaard 2000), laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS; e.g., Cox and Wilton 2006; Simonetti et al. 2008; Batumike et al. 2008; Yang et al. 2009; Wu et al. 2010), and secondary ion mass spectrometry

Fig. 2 Examples of four different methods to represent U-Pb results using five aliquots of perovskite from a single crystal: (a) concordia plot, (b) Tera-Wasserburg plot, (c) isochron plot, and (d) weighted average $^{206}\text{Pb}/^{238}\text{U}$ age

(SIMS; e.g., Kinny et al. 1997; Li et al. 2010; Chalapathi Rao et al. 2013; Wu et al. 2013). For IDTIMS analyses the sample material is dissolved in acids, U and Pb purified using anion exchange chromatography, and their isotopic compositions determined using a thermal ionization mass spectrometer (Heaman 1989). Ion beam dating techniques can be applied to isolated crystals secured in an epoxy mount or in situ by directly dating crystals in a petrographic thin section. The U-Pb results can be presented on a variety of plots including concordia ($^{207}\text{Pb}/^{235}\text{U}$ vs. $^{206}\text{Pb}/^{238}\text{U}$; Fig. 2a), Tera-Wasserburg ($^{238}\text{U}/^{206}\text{Pb}$ vs. $^{207}\text{Pb}/^{206}\text{Pb}$; Fig. 2b), isochron ($^{238}\text{U}/^{204}\text{Pb}$ vs. $^{206}\text{Pb}/^{204}\text{Pb}$; Fig. 2c), and weighted average $^{206}\text{Pb}/^{238}\text{U}$ age (Fig. 2d) diagrams. In most cases the method of calculating the dates does not affect the resulting ages as long as the amount of common lead is accurately known. For example, perovskite dates have been calculated for five aliquots of the same crystal by the various methods graphically portrayed in Fig. 2 resulting in ages that vary between 358.5 and 360.4 Ma but they all overlap within analytical uncertainty.

U-Pb Mantle Zircon

The occurrence of zircon (ZrSiO_4) in kimberlite has been known for a long time (Ahrens et al. 1967; Kresten et al. 1975), but the application of U-Pb mantle zircon dating to constrain the emplacement age of kimberlites can be attributed to the pioneering research of Gordon Davis and

colleagues at the Carnegie Institute of Washington in the 1970s (e.g., Davis et al. 1976; Davis 1977, 1978). Mantle zircon occurs as a sparse but relatively large (cm-size crystals) accessory mineral in kimberlites (Fig. 1b) and has been documented at a few kimberlite localities (Kresten et al. 1975). Figure 1b is a mantle zircon hosted within the Monastery kimberlite with a 1–2 mm wide reaction rim consisting dominantly of baddeleyite (white). Mantle zircons are commonly recovered during bulk sampling and final processing as a by-product of diamond mining due to its high density (4.7 g/cm^3) and fluorescence properties. Mantle zircon can occur as isolated rounded megacrysts of variable color but commonly honey-colored (Kresten et al. 1975), as inclusions in diamond (Kinny and Meyer 1994), or as an accessory mineral in mantle material entrained in kimberlite (Davis et al. 1976; Kinny and Dawson 1992; Chen et al. 1994; Hamilton et al. 1998; Konzett et al. 1998; Heaman et al. 2002). A very diagnostic feature of mantle zircon is the formation of baddeleyite-dominated reaction rims (white rim in Fig. 1b) that result from desilicification once entrained in kimberlite magma (Kresten et al. 1975; Heaman and LeCheminant 1992). The presence of these baddeleyite rims, large crystal size (mm to cm), and unusual chemical composition such as their typically low U and Th (<10 ppm) and Y (<100 ppm) concentrations (Heaman et al. 1990; Belousova et al. 1998; 2002) helps to distinguish mantle zircon from the more common crustal zircon xenocrysts in kimberlite.

The origin of zircon megacrysts in kimberlite is uncertain, but they form part of a megacryst suite that have been interpreted as high-pressure phenocrysts that crystallized directly in the kimberlite magma or more likely as mantle xenocrysts that originally formed as part of a magma cumulate or metasomatic veins in the mantle (Moore et al. 1992). Depending on their origin in the subcontinental mantle, they may belong to geological events that precede kimberlite magmatism. The common interpretation that mantle zircon U-Pb dates record the time of kimberlite eruption is based on the fact that these crystals reside in the lithospheric mantle at temperatures that exceed the closure temperature for Pb diffusion ($>900^\circ\text{C}$; Lee et al. 1997) and only begin to accumulate radiogenic lead once they are transported by the rapid ascent of kimberlite magma to lower temperature regions in the crust. It is likely that this assumption is valid in most cases (exceptions are noted below) and has guided the application of U-Pb mantle zircon geochronology to obtain ages of kimberlite emplacement. Although there are few well-studied examples that prove U-Pb mantle zircon megacryst dates record the timing of kimberlite emplacement, a detailed study using a variety of radiometric dating methods (U-Pb zircon, U-Pb perovskite, Rb-Sr phlogopite) applied to minerals contained in the Monastery kimberlite (Noyes et al. 2011) demonstrates excellent internal agreement between dates obtained on megacrysts and groundmass crystals, confirming the assumption that mantle zircon megacrysts can be used to accurately date the time of kimberlite emplacement.

However, there are a handful of examples where mantle zircon dates record pre-kimberlite eruption age information. Kinny et al. (1989) documented two age populations of mantle zircon in the Jwaneng DK2 kimberlite: a Permian population similar to the emplacement age of the kimberlite and a much older disturbed Archean population. In addition, Kinny and Meyer (1994) report a concordant 628 Ma U-Pb SHRIMP age for a zircon inclusion in diamond from the Cretaceous Mbuji Mayi kimberlite, Zaire, further evidence that mantle zircon can preserve its original formation age, at least when encapsulated in diamond. Other examples of U-Pb zircon pre-kimberlite emplacement ages have been documented from zircon contained in mantle xenoliths (Konzett et al. 1998; Hamilton et al. 1998; Heaman et al. 2002). In summary, there is unequivocal evidence that certain mantle zircons can preserve pre-kimberlite age information and are not always completely reset under high-pressure and high-temperature conditions of the subcontinental mantle, so some caution is required in interpreting U-Pb mantle zircon dates.

U-Pb Groundmass Perovskite

Perovskite (CaTiO_3) is a common accessory mineral in many kimberlites (abundance is typically <1 vol.% of the rock) and typically forms tiny (<100 μm), euhedral-subhedral, orange-brown cubes/octahedra. Figure 1c shows three examples of isolated perovskite crystals from kimberlite: EC, Elliott County, Kentucky; KL, Kirkland Lake, Quebec; and Benf, Benfontein sill, S. Africa. Perovskite paragenesis in kimberlite can be variable (Chakhmouradian and Mitchell 2000; Mitchell 2002), most commonly as isolated crystals in the groundmass and to a lesser extent as inclusions in other minerals, such as phlogopite and occasionally diamond (Hamilton et al. 2003; Bulanova et al. 2010); as reaction-induced rims on earlier formed Ti-minerals (e.g., ilmenite); as a cumulate mineral in sill-like bodies (e.g., Benfontein sill); as polycrystalline glomerocrysts; or as a string of crystals (necklace texture) nucleating on earlier formed phenocrysts/megacrysts (e.g., olivine, phlogopite, or spinel).

Kimberlitic perovskite typically forms stoichiometrically near end-member CaTiO_3 (Chakhmouradian and Mitchell 2000; Mitchell 2002) and contains elevated levels of several minor elements, including Fe, Na, Sr, Nb, Ta, and Th, and the light rare earth elements. The moderate amounts of Sr (500–4,000 ppm), Nd (1,000–10,000 ppm), and to a lesser extent Hf (50–200 ppm) in perovskite make it an ideal petrogenetic tracer; the isotopic composition of these elements has been used in a few studies to trace the mantle origin and evolution of kimberlite magmas (e.g., Heaman 1989; Paton et al. 2007; Yang et al. 2009; Malarkey et al. 2010; Zurevinski et al. 2011). Based on a fission track study of kimberlite minerals, Kleeman and Lovering (1973) showed that kimberlitic perovskite is enriched in uranium compared to other minerals in the groundmass, such as calcite.

U-Pb dating of perovskite is a preferred choice for dating kimberlite emplacement because in most cases it crystallizes directly from the kimberlite magma. Perovskite occurs in many kimberlites and related rocks (aillikite, carbonatite, lamproite, ultramafic lamprophyre), but very little is known about what controls perovskite crystallization in these magmas. Primary magmatic perovskite is most common in hypabyssal kimberlite and to a lesser extent in diatreme or crater facies kimberlite. Perovskite xenocrysts have been reported (Heaman 1989) but are rare because, unlike in the case of zircon, most crustal rocks do not contain perovskite. Based on more than 1,000 perovskite analyses, the range of U and Th/U in the majority of pure kimberlitic perovskite aliquots varies between 20–200 ppm and 1–40 ppm, respectively. Perovskite analyses with very high U (up to 1,500 ppm; Wu et al. 2013) or Th/U (up to 200; Heaman and Kjarsgaard 2000) have been reported but are considered outliers and may reflect the presence of high U and/or Th mineral inclusions (such as uraninite or thorite). The contents of U and Th are much higher in kimberlitic perovskite than meteoritic perovskite (Ireland et al. 1990) or diamond inclusion perovskite (Bulanova et al. 2010), which typically contain <10 ppm of these elements and can have $\text{Th}/\text{U} < 1$.

U-Pb dating of perovskite was pioneered in the 1980s (Kramers and Smith 1983; Smith et al. 1989; Heaman 1989) and since that time there have been more than 1,000 U-Pb perovskite dates reported for kimberlites utilizing all the U-Pb dating techniques (e.g., Heaman 1989; Smith et al. 1989; Kinny et al. 1997; Batumike et al. 2008; Yang et al. 2009; Li et al. 2010). There are three main challenges in dating perovskite: (1) the small grain size (often <50 μm), making it difficult to extract from the whole rock using conventional mineral separation techniques and difficult to analyze by ion beam U-Pb techniques (e.g., LA-ICPMS requires a 30–40 μm diameter spot for a precise analysis); (2) it contains a significant amount of common Pb (10–30 % of the total Pb), so any age calculation is sensitive to the common Pb correction; and (3) it can be easy to confuse with

other minerals (e.g., spinel, slightly tarnished sulfide) in a concentrate using a binocular microscope at the highest magnification. Some caution is necessary for kimberlitic “perovskite” analyses that contain low uranium contents (<20 ppm) and low Th/U (<1) because they likely represent mixtures of perovskite combined with one or more contaminants (this is not a problem for in situ techniques).

The amount of perovskite required for a precise analysis has dramatically decreased over the past 20 years and accurate U-Pb IDTIMS dates can be obtained on 10–20 µg aliquots (~1–100 crystals depending on grain size), and crystals as small as 15 µm in diameter have been successfully isolated from kimberlite whole rock and dated using this technique. Most of the in situ U-Pb perovskite dating studies of kimberlites have used either the LA-ICPMS (Batumike et al. 2008; Yang et al. 2009; Wu et al. 2010) or SIMS (Smith et al. 1994; Kinny et al. 1997; Li et al. 2010; Chalapathi Rao et al. 2013; Wu et al. 2013) techniques with analysis spot diameters typically on the order of 40 and 25 µm, respectively. Cox and Wilton (2006) report smaller diameter analysis spots (down to 10 µm) for U-Pb LA-ICPMS perovskite dates from the Oka carbonatite. The precision and accuracy of perovskite dating is limited by the uncertainty in the common Pb correction (not all studies propagate the uncertainty in the common Pb composition in the resulting age uncertainties). Most often the initial common Pb composition of perovskite is calculated from the two-stage crustal Pb evolution model of Stacey and Kramers (1975). Although it is unclear that this model is appropriate for kimberlites, it does approximate the Pb isotopic compositions of Group 1 whole rock kimberlite (Smith 1983). For a Jurassic perovskite containing 20 % total common Pb, the effect on a U-Pb perovskite age calculation using an average crustal Pb versus an average depleted mantle Pb is ~5 m.y. An alternative approach is to use a low $^{238}\text{U}/^{204}\text{Pb}$ primary mineral (e.g., titanomagnetite) that crystallizes directly from the kimberlite magma to constrain the initial Pb isotopic composition. For example, Burgess et al. (2012) showed that using an Earthtime calibrated tracer solution resulted in a more precise weighted mean $^{206}\text{Pb}/^{238}\text{U}$ date of 357.17 ± 0.27 Ma compared to the previously reported date of 356.5 ± 1.0 Ma (Heaman 2009) for fragments from the same Ice River perovskite crystal and that the accuracy of the date could be improved by using clinopyroxene ($^{238}\text{U}/^{204}\text{Pb} < 500$) to derive a more accurate estimate of the initial Pb isotopic composition.

U-Pb Dating: Other Minerals

Although groundmass perovskite and mantle zircon are the most common minerals used in dating kimberlites by the U-Pb method, there have been attempts to utilize other less common U-bearing minerals, such as baddeleyite (ZrO_2 ; Schärer et al. 1997; Heaman and LeCheminant 2000; Li et al. 2011), ilmenite (FeTiO_3 ; Noyes et al. 2011), and rutile (TiO_2 ; Cooper et al. 2008). There has been some success using other U-bearing minerals to date kimberlite emplacement but there is always a challenge to prove that the dates obtained reflect the time of kimberlite emplacement and not the age of mantle or crustal xenocrysts, potentially recording dates that significantly predate kimberlite eruption.

Rb-Sr Phlogopite Geochronology

The Rb-Sr dating technique is based on the beta decay of radioactive parent ^{87}Rb with a decay constant of $1.42 \times 10^{-11} \text{ year}^{-1}$ (Davis et al. 1977; half-life of 48.8 Ga) to daughter ^{87}Sr . The

geochemical behavior of Rb follows closely that of potassium because they are both monovalent and have similar ionic radii, so K-rich minerals, such as phlogopite ($\text{KMg}_3\text{AlSi}_3\text{O}_{10}(\text{F},\text{OH})_2$), are ideal for Rb-Sr geochronology because there is significant Rb but negligible common Sr substitution in the phlogopite lattice structure during crystallization. Therefore, a very high proportion of the strontium located in the phlogopite structure is ^{87}Sr produced by radioactive decay. Unaltered phlogopite in kimberlite occurs as bronze-colored macrocrysts/megacrysts (>5 mm in size), and/or as a groundmass mineral (<1 mm), and is commonly interpreted to have crystallized directly from the kimberlite magma. Figure 1d is an example of a phlogopite megacryst within Monastery kimberlite with well-developed cleavage. Mineral inclusions of perovskite and spinel are common. One cautionary note is that mica in kimberlite can also be xenocrystic, originating from disaggregated mantle or crustal xenoliths. In some cases mantle-derived phlogopite can still record the age of kimberlite eruption if the analyzed material resided at great depth in the mantle where radiogenic strontium could easily diffuse from the crystal until entrained by the kimberlite magma and transported to the surface. This would explain the identical Rb-Sr age results obtained for Wesselton groundmass phlogopite and phlogopite isolated from an entrained peridotite xenolith in the kimberlite (Allsopp and Barrett 1975). Although it is uncommon for both isotopic and geochemical information of analyzed phlogopites to be reported in the same study, several researchers have shown that the chemical composition of primary kimberlitic phlogopite is quite variable (e.g., Smith et al. 1978; Hunter et al. 1984; Mitchell 1986) but is distinct from phlogopite occurring in mantle xenoliths (Dawson and Smith 1975; Carswell 1975); noteworthy are the higher BaO, TiO_2 , and Al_2O_3 contents in the former.

Some of the early Rb-Sr phlogopite studies (e.g., Allsopp and Barrett 1975) noted that there is higher than expected common Sr contents in phlogopite. This led Brown et al. (1989) to develop an HCl leaching procedure that effectively removes the labile common Sr component within phlogopite (leaching in 1–2 N HCl at room temperature for 10–30 min). The explanation for the success of this treatment is that Sr-rich minerals, such as calcite, can occur along phlogopite cleavage planes (either as a primary magmatic or secondary alteration mineral) and the leaching step helps to dissolve and remove this common Sr component without influencing lattice-bound Rb and radiogenic Sr. Kimberlitic phlogopite can also be completely or partially altered to chlorite, and in these cases the analyses have significantly lower $^{87}\text{Rb}/^{86}\text{Sr}$ values than pristine phlogopite, increasing the uncertainty in the accuracy of the age determination.

Rb-Sr phlogopite dating of kimberlites and mantle xenoliths has been employed for more than 40 years, and over this time three approaches have been used: (1) phlogopite model dates, (2) combined phlogopite-whole rock “isochron” dates, and (3) phlogopite isochron dates. The procedure used in all Rb-Sr phlogopite dating studies is isotope dilution thermal ionization mass spectrometry where the selected material and a measured amount of a calibrated ^{87}Rb - ^{84}Sr tracer solution are combined in a Teflon digestion vessel together with a mixture of acids (5:1 $\text{HF}:\text{HNO}_3$) and heated on a hotplate for up to 48 h at 100 °C. Rb and Sr are purified using cation exchange chromatography and their isotopic compositions determined with a solid source thermal ionization mass spectrometer (Creaser et al. 2004). The precision of Rb-Sr phlogopite dates is typically better than 1 %, especially when the HCl leaching is conducted.

Phlogopite Rb-Sr Model Dates

As a result of the contrasting geochemical behavior of Rb and Sr in phlogopite, unaltered phlogopite typically has very high parent/daughter ratios ($^{87}\text{Rb}/^{86}\text{Sr} > 100$), and the highest

parent/daughter ratios are relatively insensitive to the choice of initial strontium isotopic composition. In samples where there is very little material to work with, a single Rb-Sr phlogopite analysis can be used to calculate a model date that is based on an estimate of the initial strontium isotopic composition. For example, if two possible $^{87}\text{Sr}/^{86}\text{Sr}$ initial ratio values of 0.705 and 0.710 are considered, then for phlogopites with $^{87}\text{Rb}/^{86}\text{Sr} > 300$ the shift on the model date is $\sim 0.3\%$, whereas for $^{87}\text{Rb}/^{86}\text{Sr} < 150$ the effect is $> 1\%$ depending on the assumed initial strontium isotopic value. For example, the phlogopite Rb-Sr model date of 50.8 Ma reported for the Grizzly pipe, NWT (Creaser et al. 2004), assuming an $^{87}\text{Sr}/^{86}\text{Sr}$ initial ratio of 0.705, increases to 52.8 Ma if the perovskite strontium isotope composition of 0.7043 is used to constrain the kimberlite magma composition (Sarkar et al. 2014).

Phlogopite-Whole Rock “Isochrons”

In some studies the age of kimberlite emplacement is estimated by measuring the Rb-Sr composition of both phlogopite (high Rb-Sr) and host kimberlite (low Rb-Sr), essentially using the whole rock kimberlite strontium isotopic composition as a proxy for the composition of the magma and the isotopic composition of phlogopite when it formed. The advantage of this approach is the significant reduction in the age uncertainty as multiple phlogopite analyses from a single sample may have low Rb-Sr or may not show a significant range in Rb-Sr. In one example from the Mark kimberlite in the Lac de Gras field, NWT, Davis and Kjarsgaard (1997) showed that three phlogopite analyses yielded an isochron age of 48 ± 7 Ma, whereas adding the whole rock kimberlite analyses yielded a similar age of 47.5 ± 0.5 Ma but with a reduced age uncertainty by nearly an order of magnitude. Some caution should be considered in interpreting these dates; whole rock kimberlite can contain a significant component of crust and/or mantle contamination which could yield a strontium isotopic composition that is not an accurate estimate for the kimberlite magma. The use of hypabyssal kimberlite is preferred as the whole rock anchor as this type of kimberlite typically contains the least amount of contamination. A better choice to anchor the isochron is to use a low $^{87}\text{Rb}/^{86}\text{Sr}$ mineral that crystallizes directly from the kimberlite magma. An ideal choice here would be groundmass perovskite (CaTiO_3); perovskite contains abundant strontium (> 500 ppm) and very low Rb (< 0.01 ppm) contents so there is negligible in-growth of radiogenic strontium. In most cases, groundmass perovskite faithfully records the primary kimberlite magma strontium isotopic composition (Heaman 1989), but there are examples where perovskite records a more complex crystallization history (Malarkey et al. 2010).

Phlogopite “Isochrons”

The Rb-Sr phlogopite “isochron” approach involves analyzing multiple aliquots from a single phlogopite megacryst or analyzing several phlogopite megacrysts from a single kimberlite. For this approach to be valid, the analyzed phlogopite megacrysts must have the same age, same initial strontium isotope composition, and be undisturbed by secondary post-crystallization (alteration). An example of the high precision that can be achieved using this method is the 59.7 ± 0.4 Ma (MSWD = 0.5) eight-point phlogopite isochron date reported for the Cobra South kimberlite, Lac de Gras field (Creaser et al. 2004). In this example the phlogopite analyses from four megacrysts displayed a large range in $^{87}\text{Rb}/^{86}\text{Sr}$ (28–281). With this level of precision, it is possible to investigate the detailed timing of kimberlite emplacement within a field or even a single pipe.

For example, based on high-precision Rb-Sr phlogopite dating of 27 Lac de Gras kimberlites, Creaser et al. (2004) documented at least four pulses of kimberlite magmatism occurred between 61 and 48 Ma.

Summary

Kimberlites are complex rocks containing a variety of minerals and rock fragments that either crystallized directly from the kimberlite magma, formed during alteration syn- and post-emplacment, or were entrained during transport of the magma to the surface from great depths in the mantle. As such, determining accurate emplacement ages for kimberlites has been challenging, especially by any whole rock dating technique. The U-Pb and Rb-Sr techniques have been successfully applied to minerals that are known to crystallize directly from the kimberlite magma (e.g., phlogopite and perovskite) or to have formed in the mantle but remained at temperatures higher than the closure temperature to diffusion of daughter elements until entrained in the kimberlite magma and carried rapidly to the crust (e.g., mantle zircon). Determining the temporal evolution of kimberlite emplacement is key to understanding the triggering mechanism for this magmatism and can constrain their geodynamic setting (Heaman and Kjarsgaard 2000; Heaman et al. 2003, 2004).

Definition

Method of dating recent sediment deposition and accumulation using down-core profiles of short-lived radioactive ^{210}Pb .

History

Roughly 50 years ago, a small group of scientists from Belgium and the USA, trying to better constrain ice sheet accumulation rates, attempted to apply what was then known about environmental lead as a potential geochronometer. Thus Goldberg (1963) developed the first principles of the ^{210}Pb dating method, which was soon followed by a paper by Crozaz et al. (1964), who examined accumulation history of Antarctic snow using ^{210}Pb . Shortly thereafter, Koide et al. (1972, 1973) adapted this technique to unravel sediment deposition and accumulation records in deep-sea environments. Serendipitously, they chose to work in a deep basin off California, where an independent and robust age model had already been developed. Krishanswami et al. (1971) extended the use of this technique to lacustrine deposits to reconstruct depositional histories of lake sediment and, maybe more importantly, contaminant inputs and burial. Thus, the powerful tool for dating recent (up to about one century old) sediment deposits was established and soon widely adopted. Today almost all oceanographic or limnologic studies that address recent depositional reconstructions employ ^{210}Pb as one of several possible geochronometers (Andrews et al. 2009; Gale 2009; Baskaran 2011; Persson and Helms 2011). This entry presents a short overview of the principles of ^{210}Pb dating and provides a few examples that illustrate the utility of this tracer in contrasting depositional systems. Potential caveats and uncertainties (Appleby et al. 1986; Binford 1990; Binford et al. 1993; Smith 2001; Hancock et al. 2002) inherent to the use and interpretation of ^{210}Pb -derived age models are also introduced. Recommendations as to best practices for most reliable uses and reporting are presented in the summary.

Fig. 1 The ^{238}U decay chain showing ^{226}Ra , ^{222}Rn , ^{210}Pb , and ^{210}Po . Half-lives are shown in parentheses where *a* years, *d* days, *hr* hours, *m* minutes, and μs microseconds

^{210}Pb Dating Principles

Pb-210 is a naturally occurring radionuclide of the ^{238}U radioactive decay chain and has a half-life ($t_{1/2}$) of 22.23 years (Fig. 1). In most environmental systems that have remained “closed” for more than about 120 years (five times the half-life of ^{210}Pb), ^{210}Pb is derived from its parent radionuclide, ^{226}Ra ($t_{1/2} = 1,600$ years), that is present in the material will reach a state of radioactive secular equilibrium. In such settings, ^{210}Pb is not a viable geochronometer. However, in more recently deposited sediment, ^{210}Pb may not be in equilibrium with parent isotope ^{226}Ra and may have an additional source unrelated to ^{226}Ra . First, a fraction of the observed ^{210}Pb is continuously produced by decay of ^{226}Ra and represents “supported” ^{210}Pb , which is considered time independent. The second fraction originates from the decay of atmospheric ^{222}Rn into ^{210}Pb and is called “excess” ^{210}Pb . After wet/dry deposition, rapid scavenging processes remove this radionuclide from the water column (Chanton et al. 1983; Crusius and Anderson 1995) via adsorption onto suspended particulates which may then become incorporated in sediment (Fig. 2). Bottom sediment thus contains a mixture of both supported and excess ^{210}Pb . This excess ^{210}Pb predictably decays with its 22.23 year half-life and can be used to establish recent sediment geochronologies (Goldberg and Bruland 1974; Appleby and Oldfield 1983) under ideal depositional conditions.

If both sediment accumulation and the flux of excess ^{210}Pb to a sediment surface are constant over time, and there are no postdepositional processes that redistribute excess ^{210}Pb present in the sediment, then a down-core profile of excess ^{210}Pb will follow a simple exponential curve that

Fig. 2 Conceptual illustration of the dominant sources and transport pathways for ^{210}Pb

tracks its decay. Although these two assumptions are not always observed in natural settings, this simple premise forms the underlying principle for use of ^{210}Pb as a geochronometer. More intricate models have been developed that address nuances in the flux of sediment and ^{210}Pb (Sanchez-Cabeza and Ruiz-Fernandez 2012), as well as the effects of postdepositional mixing (Pourchet et al. 1989), including bioturbation (Benninger et al. 1979; Nittrouer et al. 1983).

Goldberg (1963) first proposed the constant flux model, where the ^{210}Pb flux to sediment is assumed to be constant over time, while the sedimentation rate may vary. This model subsequently became known as the constant rate of supply (CRS) model (Appleby and Oldfield 1978; Benoit and Rozan 2001; Robbins 1978), which is still one of the most often used ^{210}Pb dating models (Sanchez-Cabeza et al. 2000; Persson and Helms 2011). This model assumes that the down-core excess ^{210}Pb activity, vertically integrated to a depth, x , or a cumulative dry mass, m , will equal the flux integrated over the corresponding time interval. Integrating to either x or m ,

$$A(x, m) = A_0 e^{-\lambda t} \quad (1)$$

where $A(x, m)$ is the cumulative residual unsupported or excess ^{210}Pb activity beneath sediment of depth x , or mass m , A_0 is the total unsupported ^{210}Pb activity in the sediment column, λ is the ^{210}Pb decay constant, $0.03114 \text{ year}^{-1}$, and t represents time. The age of sediment at depth x , m is then described by:

$$t = \left(\frac{1}{\lambda} \right) \ln \left[\frac{A_0}{A(x, m)} \right] \quad (2)$$

Unlike the CRS model, in the constant initial concentration (CIC) model, the ^{210}Pb supply varies directly in proportion to the sedimentation rate (Shukla and Joshi 1989). Here the age (t) of a sediment layer is related to the depth (m) by

$$t = m/s \quad (3)$$

where m denotes the mass depth in the core (g cm^{-2}) and s denotes the sedimentation rate ($\text{g cm}^{-2} \text{ year}^{-1}$). The unsupported ^{210}Pb activity ($A(m)$) will thus vary with depth in accordance with the formula:

$$A(m) = A(0)e^{-\lambda m/t} \quad (4)$$

where λ is the decay constant and $A(0)$ is the unsupported activity at the surface of the core. When plotted on a logarithmic scale, the resulting ^{210}Pb activity versus depth profile will appear linear, and the mean sedimentation rate, s , can then be determined using a least squares fit procedure. With these simple equations, ^{210}Pb often can be used as a reliable geochronometer under suitable depositional conditions, although volumes have been written on more elaborate models and their limitations.

Many processes influence the delivery of excess ^{210}Pb to the bottom sediment of a lake or ocean. For example, the atmospheric flux of ^{210}Pb varies by latitude, altitude, and season (Garcia-Orellana et al. 2006; Baskaran and Swarzenski 2007). Catchment size and geology impact scavenging efficiencies and ensuing transport rates of ^{210}Pb (Nittrover et al. 1983). Water column depth and residence times and suspended particle composition may also affect ^{210}Pb cycling (Turner and Delorme 1996). Based on Appleby (2008), the CRS model will likely produce valid geochronologies if sediment transport rates from the catchment are reasonably constant and produce a minor component of supported ^{210}Pb compared to atmospheric flux rates contributing to excess ^{210}Pb .

^{210}Pb Measurements

Traditionally, the analytical determination of ^{210}Pb was based on either radiochemical separation of ^{210}Pb and measurement of its short-lived beta-emitting daughter, ^{210}Bi ($t_{1/2} = 5.01$ day), or on alpha spectrometry of its indirect decay product ^{210}Po ($t_{1/2} = 138.4$ day) that was assumed to be in secular equilibrium with ^{210}Pb . While both of these methods are laborious, today's alpha-spectrometric systems often consist of sophisticated, integrated sets of multiple detectors so one sediment core can theoretically be counted in just a few days. Advanced planar- or well-type semiconductor detectors enable the gamma-spectrometric analysis of the 46.5 keV decay energy of ^{210}Pb with high relative efficiency (Zaborska et al. 2007). Because gamma analysis of sediment requires only minor (nondestructive) laboratory work, the use of gamma detectors has considerably reduced the effort for most routine ^{210}Pb determinations. In addition, the gamma-spectrometric method provides a concurrent determination of ^{226}Ra , which allows the activities of supported ^{210}Pb to be estimated. Ra-226 activity is determined by quantifying intermediate daughter radionuclides ^{214}Pb (at 295 and 352 keV) and ^{214}Bi (at 609 keV) after establishing their radioactive equilibrium with ^{222}Rn (Kirchner and Ehlers 1998; Swarzenski et al. 2006). Importantly, the gamma-spectrometric method also provides for the determination of ^{137}Cs ($t_{1/2} = 30.17$ year; 661 keV), an independent, nuclear bomb-produced geochronometer.

Based on our own laboratory experience, detection limits for ^{210}Pb are typically less than 10 mBq g^{-1} for well-type HPGe gamma detectors and are likely somewhat lower for planar

detectors that can accommodate much larger sediment sample sizes (~20–50 g). Thus, detection limits for gamma detectors may be considerably higher than those achievable with alpha-spectrometric counting of radiochemically separated ^{210}Po . As a consequence, gamma spectrometry may be of limited use in areas showing small atmospheric deposition rates of ^{210}Pb .

Prior knowledge of the analytical detection limits of the instrumentation as well as the sample size and geometry can affect the decision on how to best section a sediment core for ^{210}Pb analyses (Kirchner 2011). Because of the inverse relationship between particle surface area and particle size, muddy sediment usually contains the highest activities of adsorbed ^{210}Pb (Smith and Walton 1980). Thinner sediment layers expectedly provide a better time resolution of sedimentation rates but may compromise counting statistics if there is not enough excess ^{210}Pb present within a sediment layer. For a given flux of excess ^{210}Pb into the sediment, its activity concentrations are inversely related to the sedimentation rate (Alexander and Lee 2009). Thus, some prior estimate of the expected sedimentation rate is also desirable to guide the core sectioning. An independent estimate of sedimentation rate may be available, for example, from lithological analyses of the core (i.e., varves). Otherwise, the core should be sectioned into thin, consecutive layers and, starting with the youngest sediment, measured layer by layer until excess ^{210}Pb activities approach parent-supported activities. If ^{210}Pb activities approach instrument detection limits, the sediment layers can be combined prior to analysis.

After sectioning, each sediment layer is homogenized and weighed prior to and after drying at 105 C for at least 24 h (Swarzenski et al. 2006). The wet and dry weights provide water content information. The porosity (ϕ) of each sample is calculated as follows:

$$\phi = f_w / [f_w + (1 - f_w)\rho_w / \rho_s] \quad (5)$$

where f_w is the fraction of water in the wet sediment ($=1 - \text{dry wt.}/\text{wet wt.}$), ρ_w is the density of pore water (assumed to be 1.0 g cm^{-3}), and ρ_s is the density of dry sediment particles (assumed to be 2.5 g cm^{-3}). The cumulative mass depth (M) is calculated as follows:

$$M(\text{mg cm}^{-2}) = \sum [1 - \phi_i)\rho_s \delta x \quad (6)$$

where ϕ_i is the porosity at depth “ i ” and δx is the thickness of the layer (i.e., 1 cm). The dried sediment layers are pulverized using an agate mortar and pestle and prepared for subsequent analyses.

Three Examples of ^{210}Pb Profiles in Diverse Depositional Settings

Submarine basin – The San Pedro Basin is located in the Southern California Bight, adjacent to Los Angeles, California, USA. This marine basin acts as an efficient trap for both natural and anthropogenic materials. Due to the bathymetry of this deep basin, water circulation is restricted and, as a consequence, water residence times are long. Such a depositional setting is ideal for excess- ^{210}Pb -derived geochronologies. Previous work on sedimentation rates in the San Pedro Basin (Huh et al. 1990; Alexander and Lee 2009) corroborate the excess ^{210}Pb and ^{137}Cs geochronology shown in Fig. 3. Both down-core profiles of ^{137}Cs and excess ^{210}Pb indicate that the sediment has been accumulating at a rate close to 0.09 cm day^{-1} ; although finer scale sectioning would likely show a decline in the sedimentation rates around the turn of the twentieth century, coincident with intensified sediment discharge controls on land.

Fig. 3 (a) Excess down-core ^{210}Pb ($x\text{s}^{210}\text{Pb}$) and (b) ^{137}Cs profiles (in disintegrations per minute, dpm) and derived sedimentation rates in a deep submarine basin: San Pedro Basin, California. $60 \text{ dpm} = 1 \text{ Bq} = 27.027 \text{ pCi}$. In (a) *black* and *gray* symbols distinguish unique linear sediment rates. Summary parameters of the linear regression are represented as the slope (b) and r-squared (r^2) value

Alpine lake – Copper Lake is located in the North Cascades National Park, Washington State, less than 10 km from the USA-Canada border (Sheibley et al. 2012). The lake is at an elevation of about 1,600 m above mean sea level and has a surface area of 5.2 ha. The maximum depth of the lake is about 20 m. Figure 4 shows the down-core profiles of excess ^{210}Pb and ^{137}Cs for Copper Lake. The activities of both ^{137}Cs and excess ^{210}Pb are high and indicative of large atmospheric fluxes being delivered into a small basin.

Sinkhole lake – Lake Tulane (40 ha) is located in central Florida at an elevation of 35 m above mean sea level and contains one of the longest climate records for a lake in the USA (Grimm et al. 1993). As a sinkhole lake, Lake Tulane was formed when a limestone deposit catastrophically collapsed due to dissolution by groundwater. Today, the water budget of the lake is balanced by surface and groundwater contributions. Sustained groundwater seepage can also transport radionuclides such as ^{226}Ra . Figure 5 shows the down-core profiles of excess ^{210}Pb and total (supported) ^{210}Pb for Lake Tulane. There is a pronounced mixed layer – ubiquitous in sediment that contains an active biological community – which extends down to $\sim 10 \text{ cm}$. Excess ^{210}Pb systematically declines down core to yield two solid sedimentation rates, but at a depth of $\sim 40 \text{ cm}$, there is a notable inflection in the total (supported) ^{210}Pb activities. It is likely that this down-core anomaly is produced from ^{226}Ra -rich groundwater seepage (Brenner et al. 2004). Norton et al. (1985) concluded that similar anomalies observed in several high-altitude alpine lakes in Rocky Mountain National Park, Colorado, were the result of groundwater movement that likely impacted the distribution of ^{210}Pb .

Fig. 4 Excess ^{210}Pb and ^{137}Cs down-core profiles and derived sedimentation rates in an alpine lake: Copper Lake, Washington (Redrawn from Sheibley et al. 2012). In (a) white, black, and gray symbols distinguish unique linear sediment rates. Summary parameters of the linear regression are represented as the slope (b) and r-squared (r^2) value

Fig. 5 Excess ^{210}Pb (xs^{210}Pb) and total (supported) ^{210}Pb ($\text{tot}^{210}\text{Pb}$, solid black circles) down-core profiles and derived sedimentation rates in a sinkhole lake: Lake Tulane, Florida. Open triangles (Line 1) and open squares (Line 2) distinguish unique linear sediment rates. Summary parameters of the linear regression are represented as the slope (b)

Summary

During the last decade, there has been an unprecedented push to learn more about how the environment has changed over time. This interest is grounded in trying to better understand differences between natural- and anthropogenic-driven changes and how our environment may respond to such changes in the future. One of the most fundamental steps in establishing a record of environmental change is to first derive an accurate geochronology. The geochronologies generated by ^{210}Pb analysis can resolve the very recent past (last 100–200 years), with total (1σ) uncertainties varying from just under 1 year to around a decade (Baskaran 2011). However, ^{210}Pb geochronologies are not without inherent problems and uncertainties (Robbins and Edgington 1975; von Gunten and Moser 1993). The development of a ^{210}Pb geochronology should never become a routine exercise (Appleby and Oldfield 1992; Appleby 2008). Even some recent studies that employ ^{210}Pb as a geochronometer still fail to meet the minimum requirements identified by Oldfield and Appleby (1984). For example, some of these efforts may fail to adequately evaluate inconsistencies in competing ^{210}Pb models, or they may forego assessing ^{210}Pb model results against independent geochronologies (e.g., other radioisotope systems or varve counting). Lastly, some ^{210}Pb applications may ignore postdepositional mixing (Benninger et al. 1979; Berner 1980; Miguel et al. 2003) that can yield a surprisingly plausible down-core ^{210}Pb profile but which produces a geochronological model that is simply invalid (Kirchner 2011). That said, a carefully developed ^{210}Pb geochronology, and one substantiated in the peer-reviewed literature per recommendations outlined in Smith (2001) and Hancock et al. (2002), is invaluable in any recent environmental reconstruction. Sediment dating using ^{210}Pb methods will continue to be refined with new improvements in analytical and model capabilities.

^{231}Pa - ^{235}U dating; ^{226}Ra - ^{230}Th dating; ^{230}Th - ^{238}U dating; ^{238}U - ^{234}U dating; Uranium-series disequilibrium dating

Definitions

Uranium series: Any of the radioactive decay products produced from either of two long-lived isotopes of uranium (U) found in nature (^{238}U and ^{235}U) resulting in a sequence of shorter-lived radioactive daughter isotopes that can be used to provide age information based on the well-characterized decay constants for each isotope in the decay series and the fact that they can be fractionated due to differences between their chemical or nuclear properties.

Introduction

Over the past few decades, uranium decay series has emerged as a fundamental tool for dating recent geological events with an extremely wide range of applications. There have been several recent reviews about the geochronological applications of these isotopic tools (e.g., Bourdon et al. 2003). This entry presents first the analytical methods with a special focus on new techniques, the basic principles, and a few classical applications. Following that, we focus particularly on new applications in the field of low-temperature geochemistry and storage of minerals in magma chambers. Overall, it can be stated with some confidence that U-series dating has become a method that has brought fundamental advances in several subfields of Earth sciences dealing with recent processes. It is beyond the scope of this entry to give a comprehensive picture of all the applications that are available. Rather, the focus here is on the methodological aspects of this dating technique.

Basic Principles in U-Series Nuclide Dating

Dating based on U-series nuclides was an idea that was first introduced by Piggot and Urry in 1942, and most methods rely on relatively similar principles. There are two U-series decay chains: (1) ^{238}U decays to stable ^{206}Pb via a series of alpha and beta decays, whereas (2) ^{235}U decays to stable ^{207}Pb . In the case of a long-lived nuclide such as ^{238}U or ^{235}U (half-lives of ~ 4.5 Ga and 0.7 Ga, respectively), it has been shown by Bateman (1910) that after a time equivalent to six times the half-life of the longest-lived daughter, the U-decay chain reaches a state of secular equilibrium defined by an equality of all activities:

*Email: bernard.bourdon@ens-lyon.fr

$$\lambda_1 N_1 = \lambda_2 N_2 = \dots = \lambda_n N_n \quad (1)$$

where the subscript 1 indicates the parent nuclide (^{238}U or ^{235}U), λ_i is the decay constant for nuclide i , and N_i is the number of nuclides of i . The symbols used throughout this entry are given in Table 1. The intermediate daughter nuclides can fractionate from their parent nuclide owing either to different nuclear properties (e.g., ^{238}U – ^{234}U) or due to different chemical properties, which are used in most applications. If there is a fractionation between two nuclides in the chain, there is a so-called radioactive disequilibrium in the decay chain. The return to secular equilibrium is a function of time, and this property can be used for age determination (see Fig. 1). This principle is similar to other radiometric dating methods. However, in the case of U-series nuclides, the fact that the nuclides are short lived and produced by a parent nuclide (i.e., ^{238}U or ^{235}U) which is itself radioactive introduces an additional complexity. This means that following a fractionation event between two given nuclides, the dating method can only be operative as long as there is a detectable difference between the value measured for the daughter nuclide and the value reached at secular equilibrium, which is usually of the order of six half-lives. The dating methods based on U series can be divided into three main types that are described below (see a compilation in Table 2).

Table 1 Symbols used in the equations

Parameter	Meaning
D	Fractal dimension of mineral surface
f_α	Fraction of ejected daughter nuclides
λ_8	Decay constant of ^{238}U
λ_4	Decay constant of ^{234}U
λ_0	Decay constant of ^{230}Th
k_i	Release rate of nuclide i in year^{-1}
Q_α	α -Decay energy
M	Atomic mass

Fig. 1 Diagram showing the concept of secular equilibrium for ^{234}U , ^{230}Th , and ^{226}Ra and the time it takes for each to return to secular equilibrium starting from an activity ratio (with respect to ^{238}U) equal to zero

Table 2 Overview of U-series dating methods

Object to be dated	Method	Analytical technique	Age range	Indicative reference
Volcanic rocks	^{230}Th – ^{238}U	MC-ICP-MS	0–300,000 years	Condomines et al. (2003)

Dating Based on ^{238}U – ^{234}U Disequilibrium

The main principle behind the ^{238}U – ^{234}U dating method is that in low-temperature environments, ^{234}U is likely to fractionate from ^{238}U . The first part of the ^{238}U decay chain can be written as follows:

For most geological processes, the half-lives of ^{234}Th and ^{234}Pa are very short (24.1 days and 6.69 h, respectively). The cause of the fractionation between ^{234}U and ^{238}U is that the α -decay of ^{238}U is accompanied by a recoil displacement of the daughter nuclide (^{234}Th) during ejection of the α particle (helium nucleus). One can calculate the kinetic energy of the recoil nuclide assuming conservation of momentum of the two nuclides and show that it is a fraction of the total energy depending on the relative masses of the helium and the ^{234}Th atoms:

$$E_c^{234}\text{Th} = Q_\alpha \frac{M_\alpha}{M_\alpha + M_{234}\text{Th}} \quad (3)$$

where Q_α is the total energy of decay and M_α and $M_{234}\text{Th}$ are the masses of ^4He and ^{234}Th , respectively. The ^{234}Th is ejected from the site where ^{238}U had formerly resided, and this can have various consequences. If the ^{238}U resided near the edge of a grain, the ^{234}Th can be ejected out of the grain. Alternatively, it can be leached out of the grain more easily during weathering reactions relative to the original ^{238}U because it no longer is in a stable lattice site. Collectively, these processes are called the Szilard effect, and their consequences during leaching have been shown experimentally by Kigoshi (1971) for zircons. Experiments by Andersen et al. (2009) using minerals

in granite also illustrated the effect of dissolution on ^{234}U – ^{238}U fractionation. This fractionation between ^{234}U and ^{238}U is the reason why many continental waters including rivers and aquifers have an excess of ^{234}U relative to ^{238}U and why seawater has an elevated ($^{234}\text{U}/^{238}\text{U}$) (parentheses designate activity ratio here and throughout this entry) equal to 1.14 (Andersen et al. 2010). As the residence of uranium in the ocean is relatively long (on the order of 1 Ma), this activity ratio has remained relatively constant over the past million years. If a mineral forms from seawater or any water whose ($^{234}\text{U}/^{238}\text{U}$) is known and subsequently behaves as a closed system, the following equation can be used to calculate its isotopic evolution with time:

$$\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right)_t - 1 = \left(\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right)_{\text{initial}} - 1\right) e^{-\lambda t} \quad (4)$$

This equation can be inverted to obtain the time since the mineral last equilibrated with water provided the initial ratio is known.

Dating Based on ^{230}Th – ^{238}U and ^{231}Pa – ^{235}U Disequilibrium

The principle of this dating method is somewhat different from the ^{238}U – ^{234}U dating method as the fractionation resulting in radioactive disequilibrium between nuclides of Th, Pa, and U is caused by differences in their chemical properties in various environments (Fig. 2). In high-temperature environments, Th, Pa, and U behave as incompatible elements that are too large to be incorporated quantitatively in most mineral sites (Blundy and Wood 2003). However, as the ionic radii of Th and Pa are slightly larger than U, the mineral/melt partition coefficient of U is slightly greater than that of Th and Pa in many minerals. During partial melting of the mantle or during crystallization of magmas, Th and Pa are partitioned preferentially into the liquid phase relative to U, which makes the dating of these processes possible. In most cases, one can date crystallization of magmatic rocks using the isochron method described below.

In low-temperature environments, the chemical behavior of U, Th, and Pa is also different as U can be mobile in oxidizing environments while Th and Pa remain rather immobile and insoluble (Langmuir 1978). This is due to the fact that U can be oxidized to U(VI), which forms a soluble species, UO_2^{2+} , by hydrolysis with water. In contrast, Pa(V) and Th(IV) are very insoluble and

Fig. 2 Principle of ^{230}Th – ^{238}U isochron dating. The *black squares* represent a series of co-genetic samples characterized by an identical ($^{230}\text{Th}/^{232}\text{Th}$) ratio at $t = 0$. At time t , as each sample behaved as a closed system, they tend to return to secular equilibrium, i.e., ($^{230}\text{Th}/^{238}\text{U}$) = 1. The line of secular equilibrium is marked as the equiline

remain tightly bound to solids by adsorption. An important consequence is that U is enriched in seawater compared with Th, and in some authigenic (hydrogenic) minerals, U can be enriched while Th is virtually absent. All these characteristics often induce a large fractionation between Th, Pa, and U which is the basis for the ^{230}Th – ^{238}U and ^{231}Pa – ^{235}U dating methods.

Dating Based on ^{226}Ra – ^{230}Th Disequilibrium

As Ra and Th are also chemically distinct, they can fractionate from each other, which gives rise to various dating methods. In magmatic environments, it had been shown that Ra and Th have different partitioning behavior and since Ra has a larger ionic radius than Th, it is even more incompatible than Th in most minerals. There are, however, a few exceptions because some minerals have specific sites where +2 cations, such as Ca^{2+} , are favored. Recent experimental work has shown that the partition coefficients of Ra in plagioclase are greater than that of Th and that significant amounts of Ra can indeed be incorporated into this mineral (e.g., Fabbrizio et al. 2009).

Consequently, dating methods based on ^{226}Ra – ^{230}Th disequilibrium in minerals have been developed. Rubin and Macdougall (1990) and Volpe and Goldstein (1993) showed that if one assumes that Ra and Ba, both being large incompatible elements with +2 charges, are chemical analogs, then one can normalize the ^{226}Ra concentration by that of Ba and determine an age using an isochron method. The corresponding equation is similar to that used for ^{230}Th – ^{238}U isochron dating (see section [Dating Volcanic Rocks](#)).

Analytical Methods

Because of their low abundances in natural samples, the analytical methods used for measuring the daughter nuclides of U or Th require high sensitivity. Until the 1990s, the method of choice was nuclear spectrometry (alpha or gamma spectrometry), which was particularly well adapted for the analysis of the short-lived nuclides such as Ra, Po, or ^{210}Pb . However, for nuclides with a half-life exceeding a few thousand years (in particular ^{234}U , ^{230}Th , ^{231}Pa , or ^{226}Ra), the detection limit and duration of analysis make mass spectrometry a much more suitable method. The introduction of mass spectrometric methods for the analysis of these nuclides (Chen et al. 1986; Edwards et al. 1987) triggered a revolution in the sense that many applications have yielded substantially improved time resolution or has made possible a number of applications which only had marginal interest prior to collection of data by mass spectrometry. The first applications using mass spectrometric techniques employed thermal ionization mass spectrometry (TIMS), which enabled precise analysis of ^{234}U and ^{230}Th (Chen et al. 1986; Edwards et al. 1987) with detection limits of a few picograms for both U and Th. The basic methodology consisted of loading the Th- or U-bearing salts purified from digested solutions onto a single Re filament coated with a colloidal graphite solution for uranium or double/triple filament for Th (Goldstein and Stirling 2003).

An additional feature that made these analyses technically attractive was the development of high-abundance sensitivity filters. For the precise analysis of ^{230}Th , one issue is the large abundance of ^{232}Th relative to ^{230}Th . The collision of ^{232}Th ions with residual gas in the mass spectrometer creates a dispersion of energies causing formation of a tail on both sides of the ^{232}Th peak. In a standard magnetic-sector TIMS instrument, the abundance sensitivity around mass ^{232}Th is typically a few 10^{-6} at 1 amu, and this amount yields a significant contribution to the very much smaller ^{230}Th peak. The correction for this contribution is imprecise and produces significant errors on ^{230}Th measurements. In the nineties, new high-abundance sensitivity filters were developed, and these devices

improved the abundance sensitivity by a factor of approximately 10–100, which makes the correction negligible (Goldstein and Stirling 2003).

The TIMS method resulted in ion yields that ranged between 10^{-4} and 10^{-2} at most for U and Th (as compiled in Goldstein and Stirling 2003). Note that the larger figure given here (10^{-2}) was obtained for low amounts of U (or Th) loaded onto a filament. For many applications, this sensitivity was sufficient for samples with elevated U concentrations, but there could be analytical limitations for low-concentration samples (see section [Dating Volcanic Rocks](#)). In addition, the duration of the analysis (several hours each for separate U and Th runs) could be a limiting factor, particularly in cases where time series and large sample sets were important. This is particularly relevant in paleoclimate studies.

More recently, with the advent of multi-collector inductively coupled plasma mass spectrometry, or MC-ICP-MS (Luo et al. 1997; Turner et al. 2001), it has been possible to consistently obtain higher sensitivity (regardless of sample size) without compromising the abundance sensitivity. One should note, however, that the abundance sensitivity using the same filtering device as in TIMS was not as good owing to the differing ion properties in the TIMS and ICP-MS sources. In a TIMS source, the energy dispersion of the ions is limited to less than 1 eV, and thus, the abundance sensitivity filter, which sorts the ions according to their energy, works optimally. However, in the ICP-MS source, the energy dispersion of the ions out of the plasma is up to 10 eV, which means that the energy filtration is less efficient. As a result, for optimal collection with a yield greater than 90 %, the abundance sensitivity is typically 2×10^{-7} , which is usually sufficient for most analyses. As shown in Hubert et al. (2006), it is useful to determine the precise shape of the ^{232}Th tail for better precision of MC-ICP-MS analyses.

An additional feature that has emerged in the last few years is the possibility of measuring U-series disequilibria by laser ablation (LA) coupled to an ICP-MS, which affords considerable advantages for specific applications. Given that U and Th are generally present in minerals at trace abundances, it is a challenge to find samples for which the sensitivity of the LA-ICP-MS method is sufficient to yield reasonable uncertainties. The first convincing developments were done on samples with high U concentrations (a few hundred ppm) (Stirling et al. 2000; Eggins et al. 2005; Bernal et al. 2006). More recently, it has been shown that reliable results could be obtained dating coral with <5 ppm U using a 193 nm excimer laser coupled with an MC-ICP-MS (Potter et al. 2005). The main reason for using this frequency is that the elemental and isotope fractionation associated with this laser frequency is limited. It was hoped that the development of the femtosecond laser would also limit the degree of fractionation (Horn and von Blanckenburg 2007). A recent study of U–Th disequilibria in sphene using a femtosecond laser has shown that while the $^{230}\text{Th}/^{232}\text{Th}$ ratios could be measured accurately, it was more difficult to obtain precise results on Th/U ratios if the standard compositions did not match the matrix of the natural samples (Koornneef et al. 2012). Thus, an important conclusion from this research is that the production of high quality standards of equivalent composition and texture seems essential.

Classical Applications

Dating Volcanic Rocks

The most commonly used U-series method for dating volcanic rocks is based on ^{230}Th – ^{238}U disequilibrium. This represents an excellent alternative to the ^{14}C dating of charcoal associated with volcanic eruptions. With this disequilibrium method, the eruptive products themselves can be dated up to ages as old as 300,000 years. One should note, however, that the uncertainty in the age

determination is smaller for younger eruptions. For the purpose of this method, the assumption is made that there is no ^{234}U – ^{238}U disequilibrium caused by high-temperature processes. This assumption has most often been verified. An exception was described by Pietruszka et al. (2011) who found excess ^{234}U in volcanic rocks due to the effect of assimilation. For dating a specific eruption, one assumes that all the minerals formed from a given lava had uniform $^{230}\text{Th}/^{232}\text{Th}$ ratios and that all mineral phases remained closed to secondary mobility after cooling. One issue that has been pointed out numerous times is that some crystals may have actually grown earlier than the time of the eruption or that some crystals may be recycled (e.g., Bourdon et al. 1994). Overall, this method gives a reasonable approximation for the age of volcanic eruption. It has been possible in some cases to cross-check the validity of U-series ages with ^{14}C dating or $^{40}\text{Ar}/^{39}\text{Ar}$ dating.

The equation used for ^{230}Th – ^{238}U age determination is as follows:

$$\left(\frac{^{230}\text{Th}}{^{232}\text{Th}}\right) = \left(\frac{^{230}\text{Th}}{^{232}\text{Th}}\right)_0 e^{-\lambda t} + \left(\frac{^{238}\text{U}}{^{232}\text{Th}}\right) (1 - e^{-\lambda t}) \quad (5)$$

This equation can be used to fit a linear regression to a series of measurements of co-genetic samples in a $(^{230}\text{Th}/^{232}\text{Th})$ versus $(^{238}\text{U}/^{232}\text{Th})$ diagram (Allègre 1968). In this case, the slope can be used to yield an age via the following equation:

$$\text{Slope} = 1 - e^{-\lambda t} \quad (6)$$

For samples whose age is greater than about six half-lives of the daughter nuclide ^{230}Th (~450,000 years), the slope reaches a value indistinguishable from 1, in which case no age determination is possible.

Dating Authigenic or Biogenic Minerals

Upon formation of biogenic or authigenic carbonates, there is no incorporation of Th or Pa due to their low solubilities in aqueous solutions, while soluble U or Ra can be substituted into the CaCO_3 mineral lattice. As a consequence, the formation of carbonate leads to a large disequilibrium between ^{238}U and ^{230}Th and between ^{235}U and ^{231}Pa , which can be used for age determination. The equation for age determination when no initial ^{230}Th is present can be written as follows:

$$\left(\frac{^{230}\text{Th}}{^{238}\text{U}}\right) = 1 - e^{-\lambda_0 t} + \left(\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right) - 1\right) \left(\frac{\lambda_0}{\lambda_0 - \lambda_4}\right) (1 - e^{-(\lambda_4 - \lambda_0)t}) \quad (7)$$

In this equation, one makes the assumption that the $^{234}\text{U}/^{238}\text{U}$ ratio of the carbonate is known. If the carbonate is formed in equilibrium with seawater whose $^{234}\text{U}/^{238}\text{U}$ ratio arguably has remained constant over the last million years (Andersen et al. 2010), it is possible to have a cross-check of the ^{230}Th – ^{238}U age determination as the $^{234}\text{U}/^{238}\text{U}$ ratio decreases with time from its initial value inherited from seawater (see section [Dating Based on \$^{238}\text{U}\$ – \$^{234}\text{U}\$ Disequilibrium](#)).

In most cases, this ^{238}U – ^{234}U age is less precise than the ^{230}Th – ^{238}U or the ^{231}Pa – ^{235}U ages, but when the carbonates are older than about 150 kyr, the ^{238}U – ^{234}U method may become the best method to date carbonates (Andersen et al. 2008). In the case of marine carbonates, one important issue that controls the precision of the age is the extent to which the $^{234}\text{U}/^{238}\text{U}$ of the oceans has remained constant over time.

It has been found that in the case of relatively old corals, the methods described above do not produce reliable ages. Rather, there may be clear evidence for open-system behavior, and several

Fig. 3 Principle of concordia dating with ^{238}U – ^{234}U – ^{230}Th system for authigenic minerals such as carbonate. The notation $\delta^{234}\text{U}$, in per mil units, corresponds to $((^{234}\text{U}/^{238}\text{U}) - 1) \times 1,000$. At $t = 0$, the starting composition of the mineral is assumed here to have $(^{230}\text{Th}/^{238}\text{U}) = 0$. Each subhorizontal line corresponds to samples with initial $\delta^{234}\text{U}$ given on the y-axis. With increasing age, the samples evolve toward secular equilibrium ($\delta^{234}\text{U} = 0$, $(^{230}\text{Th}/^{238}\text{U}) = 1$). The subvertical lines (isochrons) correspond to samples of equal age

theoretical or empirical approaches have been derived to take into account the possible loss or addition of U (Cheng et al. 1998; Henderson 2002; Thompson et al. 2003). In what follows, we describe briefly the formalism adopted by Thompson et al. (2003) to describe open-system behavior. This open-system behavior can be described in a predictive manner by assuming it is due to the recoil effects during ejection of ^{234}Th and ^{230}Th . The differential equations describing the evolution of each U-series nuclide with time can be written as follows:

$$\begin{aligned} \frac{d^{238}\text{U}}{dt} &= -\lambda_8^{238}\text{U} \\ \frac{d^{234}\text{U}}{dt} &= -\lambda_4^{238}\text{U} + f_4\lambda_8^{238}\text{U} \\ \frac{d^{230}\text{Th}}{dt} &= -\lambda_0^{230}\text{Th} + f_0\lambda_4^{234}\text{U} \end{aligned} \quad (8)$$

where f_i represents the fraction of parent nuclide retained in the carbonate. This system of coupled linear differential equations can be solved analytically to calculate a time evolution of $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{238}\text{U}$ in the solid. It is possible that some samples may experience a loss of ^{234}U and ^{230}Th while others may gain these components. By analyzing a series of co-genetic samples, it may be possible to use this approach to derive a true age. Thompson et al. (2003) have shown that this method yielded reliable ages for old coral samples. However, it should be mentioned that Esat and Yokoyama (2010) argued that the apparent open-system behavior could be explained by small variations of $^{234}\text{U}/^{238}\text{U}$ in seawater over the past 150 kyr.

Several other applications have been developed to date authigenic minerals (see Table 2), including the use of gypsum (Sanna et al. 2010) (Figs. 3 and 4). The methodology is similar to those used to date carbonates, but the lower U concentrations and greater difficulty dissolving

Fig. 4 Principle of concordia dating with the ^{230}Th – ^{234}U and ^{231}Pa – ^{235}U systems for authigenic minerals such as carbonates. Compositions that plot along the *curved line* are assumed to form with initial abundances of $^{230}\text{Th} = ^{231}\text{Pa} = 0$ and evolved subsequently toward secular equilibrium at isotope ratios of unity. The *curves* are labeled with ages in kyr

gypsum may limit its geochronological applications. One should mention also an extensive literature about the ^{230}Th – ^{238}U and ^{231}Pa – ^{235}U dating of apatite that can be applied to bones and teeth (see review by Grün et al. 2010).

Dating Detrital Carbonates

In the case of carbonates containing a detrital component, there is usually some Th incorporated at the time of formation, which means that one can no longer use Eq. 7 that assumes that the carbonate is initially Th-free. In cases where Th contents are substantial, the only reliable dating method is to apply an isochron technique to a series of co-genetic samples in a manner similar to the method used for dating volcanic rocks. To obtain a reliable date, one needs to make the assumption that all the carbonate subsamples formed at the same time, t , and were characterized by a constant $^{230}\text{Th}/^{232}\text{Th}$ ratio. However, the method requires that the co-genetic samples have variable $^{238}\text{U}/^{232}\text{Th}$ and $^{234}\text{U}/^{238}\text{U}$ depending on the relative proportions of authigenic and detrital components in the form of a simple two-component mixture (Luo and Ku 1991; Bischoff and Fitzpatrick 1991; Ludwig and Titterton 1994). Luo and Ku (1991) have designed a method that allows the composition of the authigenic component to be determined. In this context, it can be shown that:

$$\left(\frac{^{230}\text{Th}}{^{232}\text{Th}}\right) = A \times \left(\frac{^{234}\text{U}}{^{232}\text{Th}}\right) + B \quad (9)$$

where

$$A = \left(\frac{{}^{230}\text{Th}^*}{{}^{234}\text{U}} \right)_a$$

$$B = \left(\frac{{}^{230}\text{Th}}{{}^{232}\text{Th}} \right)_0 e^{-\lambda_0 t} + \left[\left(\frac{{}^{230}\text{Th}^*}{{}^{234}\text{U}} \right)_d - \left(\frac{{}^{230}\text{Th}^*}{{}^{234}\text{U}} \right)_a \right] \times \left(\frac{{}^{234}\text{U}}{{}^{232}\text{Th}} \right)_d$$

where the subscripts *a* and *d* designate the authigenic and detrital component, respectively, and ${}^{230}\text{Th}^*$ represents the activity due to in situ decay of the authigenic or detrital component (subscripts *a* and *d*). Thus, by plotting $({}^{230}\text{Th}/{}^{232}\text{Th})$ versus $({}^{234}\text{U}/{}^{232}\text{Th})$, one can obtain the value of *A* and derive directly an age using the equation used for authigenic samples (Luo and Ku 1991). This method has proven useful in some cases but depends on the assumption of constant initial ${}^{230}\text{Th}/{}^{232}\text{Th}$ for all the samples considered for the isochron. It has proven more reliable using total sample dissolution rather than leaching methods so that fractionation of Th and U caused by laboratory artifacts is avoided.

Dating Young Sediments

For dating young sediments, a commonly used approach is the ${}^{210}\text{Pb}$ dating method (Appleby and Oldfield 1978). In the oceans, ${}^{210}\text{Pb}$ is produced by the decay of ${}^{226}\text{Ra}$ within the ${}^{238}\text{U}$ decay chain. Furthermore, Pb is less soluble than Ra and is particle reactive. As a consequence, ${}^{210}\text{Pb}$ adsorbs onto sinking particles and shows an excess relative to values expected from the ${}^{226}\text{Ra}$ that is present in young sediments. The excess ${}^{210}\text{Pb}$ decays away as sediments age at a rate depending on the half-life of ${}^{210}\text{Pb}$ (22 years). Therefore, all of the excess of ${}^{210}\text{Pb}$ decays in about 100 years, which is the approximate range of this dating method. This method can be applied both to lake or ocean sediments.

Emerging Applications of U-Series Dating

Over the past few decades, thanks to analytical improvements, there has been a flurry of new applications of U-series dating methods both for low-temperature and high-temperature geological processes. Most of these applications have taken advantage of new possibilities afforded by modern analytical methods, using either smaller sample sizes, better precisions, or the possibility of in situ analyses. The sections below present some of these applications without attempts to be totally exhaustive.

Dating Surface and Subsurface Processes

By examining the fractionation between U, Th, and Ra in products of weathering in rivers and soils, it is possible to determine a timescale of chemical weathering or an age for the inception of weathering. Alternatively, it is possible in some cases to directly date the formation of authigenic phases formed as a result of secondary reactions. As recently reviewed in Chabaux et al. (2003), Chabaux et al. (2008), and Vigier and Bourdon (2011) and following the early work of Rosholt et al. (1966), Rosholt (1983), and Latham and Schwarz (1987) on soils, it is possible to calculate an age of weathering using simple kinetic models for the removal of ${}^{238}\text{U}$ relative to ${}^{230}\text{Th}$ or the removal of ${}^{234}\text{U}$ relative to ${}^{238}\text{U}$. By combining a kinetic model with mass balance considerations (Vigier et al. 2001; Dequincey et al. 2002), there are enough equations relative to unknown parameters such that an age can be calculated. This approach has been shown to be imperfect, but a comparison with other methodologies, such as those based on ${}^{10}\text{Be}$, has shown that these ages

provide good estimates of the timescale involved (Dosseto et al. 2008b). The basic equations that have been developed are as follows:

$$\frac{d^{238}\text{U}}{dt} = -k_8^{238}\text{U}_s \quad (10)$$

$$\frac{d^{234}\text{U}_s}{dt} = \lambda_8^{238}\text{U}_s - (k_4 + \lambda_4)^{234}\text{U}_s \quad (11)$$

where $^{238}\text{U}_s$ and $^{234}\text{U}_s$ represent a number of moles of ^{234}U and ^{238}U present in the solid phase, λ_4 and λ_8 are the decay constants for ^{234}U and ^{238}U , respectively, and k_4 and k_8 are the rates of release of ^{234}U and ^{238}U , respectively. A similar equation can be written for ^{230}Th in the solid. If both data for the solid phase and the aqueous phase are available, one can derive an age by solving these equations iteratively. An additional degree of complexity was introduced by Ghaleb et al. (1990) who used the following equation:

$$\begin{aligned} \frac{d^{238}\text{U}_s}{dt} &= -k_8^{238}\text{U}_s + F_8 \\ \frac{d^{234}\text{U}_s}{dt} &= \lambda_8^{238}\text{U}_s - (k_4 + \lambda_4)^{234}\text{U}_s + F_4 \end{aligned} \quad (12)$$

where F_8 and F_4 represent an input flux of ^{234}U and ^{238}U , respectively. Also, it is possible to use these equations to obtain a timescale of weathering provided some assumptions are made.

Dating of Pedogenic Cements and Hydrogenic Materials

The dating of pedogenic minerals uses an “isochron” approach that is different from the classical method used for volcanic rocks: a series of subsamples are assumed to be co-genetic and represent a binary mixture of authigenic cement, containing no ^{232}Th , and a fraction of detrital component that contains ^{232}Th . Each subsample is then assumed to evolve as a closed system. A modified isochron method was initially developed by Bischoff and Fitzpatrick (1991) and Ludwig and Tinterington (1994) when a detrital component is present (see section [Dating Authigenic or Biogenic Minerals](#)). The basic assumption is that $^{232}\text{Th}/^{238}\text{U}$ – $^{230}\text{Th}/^{238}\text{U}$ – $^{234}\text{U}/^{238}\text{U}$ data from a series of co-genetic samples containing variable amounts of a homogeneous detrital fraction can be used to obtain the $^{230}\text{Th}/^{234}\text{U}$ and $^{234}\text{U}/^{238}\text{U}$ ratios of the detritus-free fraction, which can then be used to extract a meaningful age following the classical method of age determination in a Th-free carbonate. As argued by Candy et al. (2005), a careful sample selection and characterization is required to obtain coeval samples (immature calcrete) because mature calcretes tend to form over long timescales. In the study of Sharp et al. (2003) and Candy et al. (2005), the dating of pedogenic carbonates was used to study the evolution of alluvial terraces. Sharp et al. (2003) used carbonate rinds formed at the surface of clasts and by correcting for the contribution of a detrital component, were able to determine an “age” stratigraphy within individual rinds. A recent study of Neymark (2011) on calcretes has shown that the effect of recoil loss using the formalism of Thompson et al. (2003) (see section [Dating Authigenic or Biogenic Minerals](#) for details) required significant correction for calcretes older than 250 ka.

The development of laser ablation multi-collector inductively coupled plasma mass spectrometry (LA-MC-ICP-MS) (Bernal et al. 2006 and see above) has enabled great advances in U-series dating methods that were inspired by the early work of Short et al. (1989). Short et al. (1989) showed it was

Fig. 5 Diagram illustrating the possibility of dating an open system with the ^{238}U – ^{234}U – ^{230}Th system according to the formalism of Thompson et al. (2003). This approach assumes that daughter nuclides can be redistributed within a mineral due to the effect of recoil ejection. In this context, it can be shown that isochronous samples should fall on a subvertical line anchored on the closed-system point. Thus the measurements of several such samples can yield an age. The subvertical lines correspond to points of equal age (labels are given in kyr)

possible to date Fe/Mn oxy-hydroxides with U–Th disequilibrium assuming the oxides formed with no initial Th. However, samples usually include a detrital component that requires correction prior to age calculation. One method for extracting age information from these materials is to plot $^{238}\text{U}/^{232}\text{Th}$ versus $^{234}\text{U}/^{232}\text{Th}$ and $^{234}\text{U}/^{232}\text{Th}$ versus $^{230}\text{Th}/^{232}\text{Th}$, where the slopes in these diagrams represent the $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{234}\text{U}$ values, respectively, of the detrital-free component (as described in section [Dating Authigenic or Biogenic Minerals](#)). It should be noted that in the Short et al. study, the two components were separated by leaching, a method that has been argued to be troublesome (Candy et al. 2005).

Using such an approach, it was possible for Bernal et al. (2006) to date Fe oxy-hydroxides using LA-MC-ICP-MS techniques. It should be noted that the soils in the study of Bernal et al. (2006) were developed on a U-rich protolith and thus the secondary hydroxides that formed were enriched in uranium (approximately 100 ppm) relative to common soils. The principle used for dating was based on the assumption that there is initially no ^{230}Th present in the pedogenic Fe oxy-hydroxides and that all ^{230}Th grew in situ with time. The data generally shows that rinds of nodules yield younger ages than their cores, as expected. The typical uncertainties obtained on the measured $^{230}\text{Th}/^{238}\text{U}$ ratios are on the order of 2–4 % (internal error), but the variability of the measurements along a depth profile suggests that the actual uncertainties might be larger.

A similar type of application was employed to date hyalitic opal using ^{238}U – ^{234}U – ^{230}Th disequilibrium, via in situ analysis by microdigestion or ion microprobe (Paces et al. 2004) (Fig. 5). As the opal was relatively rich in U and poor in Th, it was possible to date the micro-laminated material with the same method as that described for biogenic carbonates. Paces et al. (2010) were able to obtain ages that correlated with the microstratigraphic depths of sampling, indicating a well-behaved closed system. In some cases, this method can be coupled with U–Pb dating to extend dating to older ages (Neymark and Amelin 2008).

Dating of Weathering Rinds

Weathering rinds represent specific textures observed at the surface of clasts undergoing weathering, and many studies have focused on understanding how they formed and on establishing the rates of formation of these structures. U-series disequilibria offer an additional dating option because the formation of the rinds has been shown to be associated with an uptake of uranium (and no uptake or loss of Th) and because the rind may subsequently behave as a closed system. One can use the following equation to obtain an age:

$$\left(\frac{^{230}\text{Th}}{^{238}\text{U}}\right)_t = 1 + \left[\left(\frac{^{230}\text{Th}}{^{238}\text{U}}\right)_0 - 1\right]e^{-\lambda_0 t} + \frac{\lambda_0}{\lambda_0 - \lambda_4} \left[\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right)_t - 1\right] \left(1 - e^{(\lambda_4 - \lambda_0)t}\right) \quad (13)$$

Equation 13 is essentially similar to Eq. 7 except that it takes into account a nonzero initial abundance of ^{230}Th . This means that weathering rinds can be dated and the study of Pelt et al. (2008) has shown that it is even possible to obtain a depth profile with older ages at the outer parts of the rinds while zero ages are found at the basalt/weathering rind transition. Dating results showed a thickening of the rind with time and allowed a determination of a rate of rind formation. Furthermore, this rate is in agreement with a mass balance approach using major element chemistry and experimental data (Sak et al. 2010; Navarre-Sitchler et al. 2011). A second study by Ma et al. (2012) confirmed these earlier findings and suggested that the rate of rind formation is sensitive to the curvature of the starting material, as expected from numerical models by Sak et al. (2010).

Sediment Production: Comminution Ages

The production of sediments is accompanied by a breakdown of solid rocks into particles. The particles can be characterized by a size distribution, and it has been shown that much of the original rock mass may end up as fine-grained material. If the particles are small enough relative to the

Fig. 6 Principle used for dating sediment production and transport using the comminution age model developed by DePaolo et al. (2006). In small enough particles, the energy imparted to the daughter nuclide of ^{238}U (^{234}Th) is sufficient to eject a fraction of the daughter nuclides (f_α) out of the particle. This ultimately leads to a deficit of ^{234}U in the solid particle that increases over time and can be used to obtain a date. The various curves were drawn for different values of f_α that are labeled accordingly

distance of recoil of ^{234}Th in silicate minerals (approximately 30 μm), then a sizeable fraction of recoiled ^{234}Th can be ejected out of mineral grains, provided the parent nuclide was located close enough to the edge. This concept has been utilized by DePaolo et al. (2006) to derive an age of sediment production that was termed “comminution age” (Fig. 6). Once the grains have reached their final size, it takes about five to six half-lives of ^{234}U (248 kyr) for the system to reach secular equilibrium. The differential equation describing the evolution of the system is:

$$\frac{d^{234}\text{U}_s}{dt} = \lambda_8^{238}\text{U}_s - \lambda_8 f_\alpha^{238}\text{U}_s - \lambda_4^{234}\text{U}_s \quad (14)$$

where f_α represents the fraction of ^{238}U lost by recoil. This is equivalent to having a smaller decay constant for ^{238}U . Starting from a grain at secular equilibrium, this leads to a deficit in ^{234}U which will eventually reach a new state of secular equilibrium after five to six half-lives of ^{234}U . The solution of this equation can be written as:

$$\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right)_s = \left(\left(\frac{^{234}\text{U}}{^{238}\text{U}}\right)_s^0 - (1 - f_\alpha)\right)e^{-\lambda_4 t} + (1 - f_\alpha) \quad (15)$$

There have been a number of attempts in the literature to derive meaningful ages using this method. Dosseto et al. (2010) showed that the variations in comminution ages were variable over climatic cycles in a given basin. The study of Lee et al. (2010) has shown that the ages obtained with this method were of the right order of magnitude and correlated well with an established stratigraphy using a totally independent geochronological method. However, resulting ages can differ, sometimes by up to a factor of two, which indicates that some issues need to be solved for this method to be fully applicable. First, one important aspect is to calculate the value of f_α , representing the fraction of ejected daughter nuclides. If the grains are assumed to be spherical, then the value of f_α can be calculated as:

$$f_\alpha = \frac{3\lambda_r L}{2d_p} \quad (16)$$

However, the surface of minerals is generally more complex, and it is possible to take the roughness of the surface into account to determine an effective value of f_α , as originally proposed by Semkov (1991) for calculating the emanation of radon:

$$f_\alpha = \frac{1}{4} \left[\frac{2^{D-1}}{4-D} \left[\frac{a}{R} \right]^{D-2} \right] R \cdot S_{BET} \rho_s \quad (17)$$

where D is the fractal dimension of the surface, a the diameter of the adsorbate molecule (N_2), R the recoil length, ρ_s the density of the solid, and S_{BET} the measured *BET* surface area. This approach was used by Bourdon et al. (2009) to study ^{234}Th recoil effects in a carbonate environment. This approach was further validated by Aciego et al. (2009) who demonstrated that if the value of f_α was calculated using Eq. 16, then the ^{234}U recoil ages of dust in ice core agreed with calibrated ages (see below). This result means that, at least for the mineral dust found in ice core, the conceptual approach is valid. This leads to a second potential issue with this method. In order to extract a representative value of the $^{234}\text{U}/^{238}\text{U}$ in the grains, the grains need chemical treatment to remove adsorbed uranium or secondary minerals formed at the surface. Unfortunately, this leaching may

lead to a laboratory fractionation of ^{234}U from ^{238}U and thereby artificially modify the calculated ages (Andersen et al. 2009; Hussain and Lal 1986). Handley et al. (2013) have examined the various sources of uncertainty and shown that the resulting uncertainty amounts to approximately 200 kyr. Clearly, this method is very promising but requires further development to fully understand natural versus laboratory effects.

Sediment Transport Time

In large river basins, the transport of sediments from the source (i.e., soils) to the oceans can last over timescales that are comparable with the half-life of U-series nuclides. In addition to the method proposed by DePaolo et al. (2006) that relies on ^{234}U – ^{238}U fractionation in small sediment particles, an additional method was first proposed by Dosseto et al. (2006b) based on a study of the Amazon basin. If the removal of uranium during sediment transport is sufficiently fast compared with the timescale of transport, one should observe an increase of $^{230}\text{Th}/^{238}\text{U}$ with time from sediment source to storage. Such a relationship was observed along the Amazon river, and using the formalism developed by Vigier et al. (2001), the transport time of the sediment could be estimated (see section [Dating Surface and Sub-Surface Processes](#)). Subsequent studies by Granet et al. (2007, 2010) have obtained similar results for Himalayan rivers, which suggest again that significant weathering takes place during transport. One potential caveat of this method is the effect of ^{230}Th adsorption onto particles during transport. However, Dosseto et al. (2006b) argued that this effect should be coupled with a decrease in $^{226}\text{Ra}/^{230}\text{Th}$ during transport, which was not observed. This approach was extended by Granet et al. (2010) to studies of different size fractions of sediments, and it was shown that the small grain size sediment travel faster than the coarser grain, as expected.

Dating Ice Cores

The basic concept for dating ice cores using U-series nuclides was introduced by Fireman (1986) and further developed by the work of Goldstein et al. (2004). The dust that is incorporated in ice contains uranium at sufficient levels such that recoil of ^{234}Th results in an accumulation of measurable amounts of ^{234}U in the ice phase over time. Thus, if one carefully melts the ice and separates the dust, it is possible to determine when the dust was trapped in the ice. The amount of ^{234}U accumulated in the ice depends on the amount of dust present in the ice, the concentrations of uranium in the dust, and time. The application of such a methodology has several important requirements: (1) a careful separation of liquid and solid phases that avoids adsorption of uranium onto the dust during the melting of the ice. This aspect was studied by Goldstein et al. (2004) who developed a method utilizing EDTA in a buffer solution, which provided an efficient separation, (2) an extremely careful evaluation of the processing blanks as large samples are needed, (3) excellent sensitivity for the mass spectrometric measurements due to the small amounts of ^{234}U recoiled in the ice (Aciego et al. 2009, 2011), and (4) an accurate determination of the efficiency of ^{234}Th recoil (f_α) into the ice from a given particle. The typical grain size of dust in ice core is approximately 1–2 μm , and as the dust is sorted by wind transport, the grain size distribution is relatively narrow. As explained in section [Dating of Weathering Rinds](#), the recoil efficiency (f_α) is a parameter that needs to be determined quantitatively in order for the dating method to be functional. Aciego et al. (2011) applied the approach of Semkow (1991) to determine f_α for dust in ice core using a specifically designed device to measure BET surface area in small-sized samples (a few mg). Aciego et al. (2011) analyzed a series of samples from the Dome C ice core in Antarctica and found that by measuring the accumulated ^{234}U in the ice, a precise age could be determined. The resulting U-series ages matched those determined independently using the calibrated age-versus-depth curve established by Parrenin et al. (2007).

Dating of Magma Storage

There have been two main avenues of development for determining the ages of phenocrysts and the timescale of magma storage using U-series methods. First, the analysis of accessory minerals with either in situ methods or with fine-scale sampling makes it possible to directly estimate crystallization ages. Second, by comparing analyses of $^{226}\text{Ra}/^{230}\text{Th}$ in minerals with that of the melt in equilibrium, it is possible to estimate the timescale of magma crystallization.

Dating of Accessory Minerals

The relatively high concentrations of U and Th in accessory minerals such as zircon, monazite, xenotime, and apatite make them an obvious target to determine ages of crystallization in magmatic systems. Among these, zircon has been shown to have remarkable properties for geochronology for the U–Pb system, and it was a logical extension to use it with U-series disequilibria. A specific advantage of zircon is that the U–Th partitioning in zircon relative to the melt yields a large fractionation (Blundy and Wood 2003) making this mineral ideally suited for dating. Using a single analysis of zircon together with a whole-rock analysis, one can derive an age using a “two-point” isochron approach. For example, Charlier et al. (2005) were able to determine ages of zircons by separately analyzing the cores and rims of zircon in the Taupo volcanic zone using MC-ICP-MS. Results showed a protracted history of crystallization of more than 90 ka that was not revealed by whole-rock analysis. In a second, more extensive study of the Taupo volcanic zone, Charlier and Wilson (2010) were able to obtain a wide age distribution of zircons in various eruption centers and showed that large volcanic complexes involve recycling and assimilation of older crystal mush. These geochronological data can be coupled with trace element analyses so as to obtain an integrated time history of the chemical evolution of a volcanic system (e.g., Klemetti et al. 2011). More recently, Schmitt (2006) analyzed zircon from the Laacher See volcanics and was able to show that these minerals formed late in the crystallization sequence. In contrast, Schmitt et al. (2010) used secondary-ion mass spectrometry (SIMS) to analyze U–Th disequilibria in pyrochlore found in carbonatites from the same volcanic system and obtained U–Th isochrons that showed that the lifetime of the magma chamber was approximately 10–20 ka, in agreement with an earlier study by Bourdon et al. (1994).

$^{226}\text{Ra}/^{230}\text{Th}$ Dating of Phenocrysts and Magma Storage Times

Initial attempts to use ^{226}Ra – ^{230}Th disequilibrium to date volcanic events were based on the idea that because ^{226}Ra had no stable isotope, one could use Ba as its chemical analog, and a Ra/Ba dating technique similar to Th–U dating (see section [Dating Volcanic Rocks](#)) was proposed (Rubin and Macdougall 1990; Volpe and Goldstein 1993). For young volcanic systems, this method yielded ages that were significantly older than the age of eruptions, but it was unclear to what extent the age determinations were reliable. Since then, Ra and Ba partitioning data has been determined experimentally (rather than theoretically as in Blundy and Wood 2003), and it is now known that Ba and Ra have distinct partition coefficients in minerals that incorporate those elements (Fabbrizio et al. 2009).

In parallel, a method for direct dating of plagioclase phenocrysts was developed by Cooper et al. (2001) (Fig. 7). This method yields timescales of plagioclase crystallization assuming that the mineral had grown in equilibrium with the melt and that it evolved in a closed system since then. By comparing the measured $^{226}\text{Ra}/\text{Ba}$ ratios in plagioclase with values expected using predicted partition coefficients for Ba and Ra between plagioclase and melt, it is possible to determine the time that must have elapsed since crystallization. Stelten and Cooper (2012) used a combination of Ra/Ba dating of plagioclase and U–Th disequilibrium dating of zircons in the same rhyolitic system

Fig. 7 Illustration of the ^{226}Ra –Ba dating of plagioclase phenocrysts developed by Cooper et al. (2001). The plagioclase is assumed to have formed in chemical equilibrium with the magma having an initial $(^{226}\text{Ra}/\text{Ba}_0)$. The magma and plagioclase then evolve as closed system until time t . The negatively sloped lines represent the values of $(^{226}\text{Ra}/\text{Ba})$ measured in the melt (*blue*) and the values of $(^{226}\text{Ra}/\text{Ba})$ calculated for the melt based on the plagioclase (*green*) as a function of $e^{\lambda_{\text{st}}}$. The intersection corresponds to the time when the plagioclase formed

to demonstrate the existence of distinct magmatic pools with both old and young ages. Their study also illustrated that the dating of phenocrysts is not straightforward in long-lived systems. There have been refinements of this method since then (Cooper and Reid 2003, 2008), and it is now more clear what requirements are needed, given that in some cases, the ages were not what was expected. The study of Sims et al. (2013) on phenocrysts from Mount Erebus volcano in Antarctica has shown that this method was sensitive to the degree of magma replenishment in a magma chamber and that the data could be better interpreted assuming an open magmatic system.

Another method that has been developed in parallel is the dating of magma storage time based on Ra–Th systematics in whole rocks. The study of Vigier et al. (1999) on the Ardoukoba eruption in the Asal rift, Djibouti, has shown that over the same eruption, different pools of magmas were erupted. Furthermore, these magmas showed a negative correlation of Ra/Th with Th indicating that the most differentiated magmas had lower Ra excesses. This could not be explained by assimilation of older magmas or by plagioclase crystallization. This approach was extended to other magmatic systems by Blake and Rogers (2005). Studies by Yokoyama et al. (2006) and Chekol et al. (2011) have shown that ^{226}Ra – ^{230}Th systematics were sometimes affected by crustal assimilation and that simple radioactive decay is not always sufficient to describe the evolution of ^{226}Ra in the melt.

Summary

Radioactive disequilibrium in the uranium decay series (either ^{238}U or ^{235}U) is caused by fractionation processes that can occur between isotopes within the chain based on differences in their nuclear or chemical properties. Because the intermediate daughter products are themselves radioactive, the U-series nuclides will tend to return to a state of secular equilibrium at rates that depend on the decay constants of each isotope. As a result, a number of geochronometers have been developed that can be used to date a wide variety of materials at timescales ranging from decades to over a million years.

These methods have been devised to date near-surface processes including deposition of authigenic and biogenic precipitates, development of soils, rates of rock weathering and rates of mineral comminution, deposition of young sediments, and sediment transport times, as well as processes occurring at depth within the crust and mantle including dating of young volcanic rocks or dating of crystal residence times in magma chambers. Emerging studies have taken advantage of advances in analytical capabilities that allowed analysis of low-level samples with greater precision or higher spatial resolution. The field of U-series dating has now become a mature technique for dating Quaternary geological or archeological materials of increasing diversity.

Aquifer Characteristics (U-Series)

Don Porcelli*

Department of Earth Sciences, University of Oxford, Oxford, UK

Definition

Groundwater concentrations of naturally occurring isotopes in the ^{238}U , ^{235}U , and ^{232}Th decay series that are used to identify and quantify a range of aquifer characteristics.

Essential Concepts

The radionuclides ^{238}U , ^{235}U , and ^{232}Th decay in a series of shorter-lived radionuclides, and these decay series (Fig. 1) provide an important tool for investigating various aquifer characteristics, including chemical parameters, flow patterns, and transport of actinides. The relationships between the radionuclides in groundwater provide the potential for readily quantifying parameters of water/rock interaction from direct measurements of waters alone, with trace element source terms and bulk adsorption coefficients inferred from comparison between the different radionuclides.

The point of comparison for groundwater radionuclides is the secular equilibrium generally occurring within minerals, in which the activities (the number of atoms times the decay constant) of all the radionuclides in a decay series are the same. When this is disrupted by an event or process that changes the relative proportions of the isotopes within a decay series, the activity of each isotope will evolve until it again reaches equilibrium with its parent isotope, over a time of several half-lives of the isotope itself. Within groundwaters, activities vary widely between the radionuclides (which are therefore in disequilibrium), as shown in Fig. 2, due to the contrasting chemical behavior of the elements involved. The highest activities are for ^{222}Rn , which, as a noble gas, does not react with the aquifer solids. The actinide U, which is soluble in oxidizing waters, is often present in intermediate activities that are moderated by removal onto aquifer rocks by adsorption and, in some cases, precipitation. The alkaline earth element Ra and the actinide Th are strongly depleted due to water/rock interactions. Both of these elements have very short-lived as well as longer-lived isotopes, and so their isotope compositions reflect processes occurring over a range of timescales. The concentration of each isotope is also controlled by the rate at which it is supplied. Ongoing processes that maintain a steady-state supply of each isotope will maintain disequilibrium between parent and daughter isotopes; however, when there are changes in hydrodynamic conditions, activity concentrations will adjust to the new steady-state supply over a time of several half-lives of the daughter isotope. Overall, since the isotopes in each decay series are tied to one another by decay systematics, with daughter nuclide productions and distributions dependent upon parent distributions, combined studies of the elements in these series can generate considerable information regarding radionuclide water/rock interactions.

It is generally difficult to quantify aquifer parameters that control trace element behavior by direct measurements. Host rocks typically cannot be as readily sampled as groundwater, and average values for rocks recovered from boreholes are difficult to obtain. Some of this information has been

*Email: don.porcelli@earth.ox.ac.uk

Fig. 1 The isotopes of the ^{238}U , ^{235}U , and ^{232}Th decay series. The isotopes in *bold* are those most commonly measured in groundwater studies. The *dashed arrows* indicate where isotopes have been *left out* that have very short half-lives and so are measured only in rare cases. Radioactive half-lives are given below each isotope in units of billions of years (Ga), thousands of years (ka), years (a), or days (d)

Fig. 2 The ranges of activity concentrations (in becquerels per liter or decays per second per liter) measured in three aquifers are shown side by side for select isotopes in the ^{238}U decay series (after Porcelli 2008). There are wide variations for each isotope reflecting site conditions and between isotopes reflecting the different chemistries of the elements

sought from aquifer tests using experimentally introduced tracers and from laboratory experiments on aquifer materials, but these studies are labor intensive and necessarily limited in scale of both time and space. Measurement of radioactive decay series isotopes allows a number of aquifer characteristics to be investigated including mixing of groundwater into marine and surface water reservoirs, tracking of groundwater flow, estimating radionuclide migration rates, determining recent precipitation, locating redox boundaries within an aquifer, and dating groundwater within an aquifer.

The Supply of Radon and Other Radionuclides by Recoil

As shown in Fig. 1, some radionuclides are produced by high-energy α decay, while some are produced by low-energy β decay. In the former, decay is sufficiently energetic that during decay, the daughter isotope is propelled $\sim 100 \text{ \AA}$ (10^{-8} m) through the mineral in which it was produced, possibly resulting in expulsion from the mineral. It is a physical process, in contrast to the chemical processes affecting the radionuclides involved. Short-lived nuclides in groundwater are supplied primarily by this mechanism as well as by decay of dissolved and adsorbed parent isotopes. The recoil rate is therefore a key parameter. For long-lived nuclides in the decay series, weathering of U- and Th-bearing minerals may also be significant.

Fig. 3 Recoil rates of nuclides in the ^{238}U decay series are determined from ^{222}Rn concentrations. Applied to ^{234}Th , the extent of adsorption of Th can be calculated. The isotope ^{234}U is supplied by both recoil and weathering, which leads to $^{234}\text{U}/^{238}\text{U}$ activity ratios (designated as $^{234}\text{U}/^{238}\text{U}$) in groundwater of greater than 1

The radionuclide that is simplest to understand is ^{222}Rn (Fig. 3). Since Rn is an unreactive noble gas, groundwater ^{222}Rn is entirely dissolved, and this can be directly measured in waters pumped to the surface. It is removed only by decay and not by adsorption or precipitation. The main supply is from recoil caused by α decay of ^{226}Ra that is contained in minerals with ^{238}U . The recoil rate is simply equal to the rate at which ^{222}Rn is removed by decay. Therefore, the recoil rate can be determined simply from the rate of decay of dissolved ^{222}Rn , and this can then be used to determine the recoil rate of other nuclides.

The fraction of the total ^{222}Rn produced in the aquifer solids that is supplied to groundwater through recoil is dependent upon the size of the ^{226}Ra -bearing grains, with small grains having a larger proportion of the contained ^{226}Ra within recoil distance of grain surfaces. Measured ^{222}Rn groundwater activities have been obtained that correspond to as much as ~10 % of the total amount produced in the aquifer rock. Where the proportion of recoil ^{222}Rn in groundwater is this large, parental ^{226}Ra is typically interpreted to reside in very small mineral grains or in secondary surface coatings.

Adsorption of Ra, Th, and U

Another important parameter determining element behavior in an aquifer is the bulk adsorption coefficient, which is the ratio of atoms adsorbed onto surfaces to the atoms in solution. This is approximately equal to the retardation factor, which is the ratio of the rate of groundwater flow to the rate of element migration. Therefore, elements with a high partition coefficient, and so high retardation factor, migrate correspondingly slower. This parameter can be determined for each isotope from the rate of recoil and its groundwater concentration and so can provide overall rates of transport of Ra, Th, and U as well as of water/rock interaction processes affecting these elements. This is regardless of the actual mechanisms involved, and so the information complements small-scale physical chemistry studies that can identify the controlling processes.

The case for ^{234}Th is shown in Fig. 2b. When the ^{234}Th concentrations dissolved in groundwater and adsorbed on mineral surfaces are in steady state, the input from recoil is equal to the removal rate by decay in solution and on the surfaces. If the recoil rate is known from the concentration of ^{222}Rn , then the adsorption coefficient of ^{234}Th , and so of the element Th, can be determined. Similarly, the adsorption coefficients of Ra, Po, Pb, and U can also be determined. It should be noted that the supply of any daughter nuclide is dependent not only upon recoil from parent atoms within primary minerals but also by removal onto adsorption sites and incorporation into secondary minerals.

Precise calculations therefore are somewhat more complex, since weathering, recoil, adsorption, and precipitation have affected the distribution of the parent isotope in the decay series, which in turn is dependent upon the effects of parent isotopes further up the decay chain. Mathematical treatments of simple aquifer models can be found in Krishnaswami et al. (1982), Ku et al. (1992), and Porcelli (2008).

Using these methods, the Ra partition coefficients in various freshwater aquifers have been determined to be in the range of 10^3 – 10^4 . In saline aquifers, the adsorption of Ra drops substantially due to competition for adsorption sites. In freshwater aquifers, Th is generally adsorbed 10^1 – 10^2 times more efficiently than Ra. Values for U in the same aquifers of $\sim 10^3$ have been found, though elsewhere there is evidence for much lower adsorption (see Porcelli 2008). Values for Po vary as much as 10^1 – 10^6 , and Pb has been found to have values of 10^{-2} – 10^1 times those of Po (Porcelli 2014).

Interpreting U Isotope Compositions

The ($^{234}\text{U}/^{238}\text{U}$) ratio (the ratio of activities of the two isotopes, as denoted by the parentheses) can provide useful information on aquifer characteristics and serve as a groundwater tracer. While the concentrations of ^{238}U in groundwaters are controlled by weathering (like other, stable trace elements), which generally releases U with ($^{234}\text{U}/^{238}\text{U}$) = 1, the concentration of ^{234}U is controlled by both weathering and recoil (Fig. 3). The decay of ^{238}U produces ^{234}Th , which can be recoiled out of mineral grains and which then produces ^{234}U by low-energy β decay. The ($^{234}\text{U}/^{238}\text{U}$) ratio therefore reflects the ratio of the rate of recoil to the rate of weathering. The recoil flux is generally simply proportional to the surface area and U concentration of U-bearing grains. The weathering rate is controlled by the composition of the host grains and groundwater chemistry. It is also proportional to the surface area and U concentration.

A number of aquifer conditions will have predictable effects on the ($^{234}\text{U}/^{238}\text{U}$) ratio and U concentration of groundwater. Differences in the minerals that contain U will affect both ($^{234}\text{U}/^{238}\text{U}$) ratios and U concentrations, since it will change the rate at which U is released by weathering. Similarly, changes in groundwater chemistry can change the weathering rate of minerals. Differences in the U precipitation rate will result in different U concentrations, but not in different ($^{234}\text{U}/^{238}\text{U}$) ratios. Differences in the adsorption coefficient of U, e.g., due to changes in pH or the presence of adsorbing minerals, will have no effect on the U isotope composition. Differences in the surface area of U-bearing minerals, e.g., by differences in average grain size or in the abundances of U-bearing minerals, will affect recoil and weathering of U equally and so will not change the ($^{234}\text{U}/^{238}\text{U}$) ratio of the water.

Applications

The systematics of isotopes within the U and Th decay series provide a range of tools, useful over different timescales, which can be used to trace groundwater, identify aquifer processes, and quantify water/rock interactions. Examples include:

Determining marine groundwater discharge. There can be significant discharge of groundwater offshore and into shallow coastal waters, and this can be identified with Ra isotopes. Saline coastal groundwaters are enriched in the long-lived ^{226}Ra and especially ^{228}Ra compared to seawater. The

short-lived ^{223}Ra and ^{224}Ra isotopes are also enriched in saline and fresh groundwaters and highly depleted in seawater. Assuming that the concentrations in coastal waters are in steady state, from estimates of the water residence time, the influx of groundwater-derived Ra, and so groundwater fluxes, can be determined. The ($^{228}\text{Ra}/^{226}\text{Ra}$) ratio can also be used to identify groundwater sources, since younger groundwaters, or aquifers recently flushed by saline water intrusion, have higher ratios since it takes longer for ^{226}Ra concentrations to build up outside minerals. Short-lived ^{222}Rn can also be used to evaluate very recent groundwater inputs. These methods have been used to successfully map groundwater discharge across large coastal areas (Charette et al. 2008).

Tracking groundwater flow. In freshwater systems, U isotopes may be used to trace groundwater flow and mixing, while Ra and Th are too strongly adsorbed to be useful as water tracers. Aquifers with different characteristics may generate different groundwater ($^{234}\text{U}/^{238}\text{U}$) ratios that can serve as fingerprints and so can be used in hydrologic studies to identify mixing and flow patterns. For example, older groundwaters in aquifers with low weathering rates may have higher ($^{234}\text{U}/^{238}\text{U}$) ratios than those in shallow aquifers so that the location and magnitude of fluxes into overlying waters can be identified. Similarly, where there are aquifers composed of very different rock types with different weathering release rates of U, ($^{234}\text{U}/^{238}\text{U}$) ratios can be used to trace groundwater mixing. This can include identifying higher velocity flow paths where waters enter an aquifer with distinctly different characteristics (Roback et al. 2001).

Identifying groundwater inputs to surface waters. Similarly, the contributions of waters from different groundwaters into lakes and rivers can be identified using ($^{234}\text{U}/^{238}\text{U}$) ratios, especially when coupled with other tracers such as $^{87}\text{Sr}/^{86}\text{Sr}$ ratios. This can include the relative proportions of inputs from shallow and deep aquifers or from aquifers of different rock types and watersheds along a river (Riotte and Chabaux 1999).

Estimating pollutant radionuclide migration rates. Determination of the behavior of naturally occurring U and Th can be used to predict the mobility of released anthropogenic actinides and so can be part of site risk assessments for nuclear facilities. Naturally occurring nuclides are present in very low concentrations, so that the measured extent of adsorption cannot be directly extrapolated to pollutants with much higher concentrations and possibly accompanied by changes in aquifer chemistry. However, they still provide a baseline for establishing the relevant adsorption factors and may remain relevant for lower levels of contamination (Porcelli 2008).

Determining “recent” mineral precipitation. The nature of minerals precipitating within an aquifer reflects the chemical conditions of the groundwaters. While rocks within aquifers generally are composed of primary minerals having U and Th decay series nuclides within secular equilibrium, secondary minerals that incorporate radionuclides from groundwater will initially show substantial secular disequilibrium. The resulting ^{230}Th - ^{234}U - ^{238}U compositions can be used to date the hydrogenic minerals and so determine the timing and history of precipitation from migrating solutions.

Locating redox boundaries. Under reducing conditions, U forms relatively insoluble U^{4+} and precipitates as UO_2 . As groundwater moves past a redox boundary, groundwater U concentrations drop and the enhanced recoil rates from fine-grained U oxides increase the ($^{234}\text{U}/^{238}\text{U}$) ratio, providing a way for mapping aquifer redox fronts from U isotope distributions (Osmond and Cowart 2000).

Dating groundwaters. There have been various studies that used U isotopes for dating groundwaters. If the ^{238}U concentration along a flow line is constant or varies in a clearly defined way and the recoil input of ^{234}U is constant, then the ($^{234}\text{U}/^{238}\text{U}$) ratio evolves primarily by decay and can be used to determine the age of the groundwater (Ivanovich et al. 1991). However, such conditions rarely are evident. For shorter timescales, Ra might be used. In highly saline

groundwaters where Ra is not adsorbed and where the recoil inputs of Ra isotopes are constant, then the ^{228}Ra activity will increase over $\sim 20\text{a}$ until it reaches a steady state, and so can be used to date young waters (Kiro et al. 2013). In principle, the longer-lived isotope ^{226}Ra can be used for waters with ages up to $\sim 5\text{ ka}$.

Summary

Isotopes in the ^{238}U , ^{235}U , and ^{232}Th decay series chains provide numerous tools to study aquifer processes. With a wide range of half-lives, these isotopes can be used to investigate very rapid processes such as adsorption as well as longer-term processes from precipitation to basin-wide aquifer flow. The elements represented in the decay series also have a range of chemistries, providing investigative methods that are applicable to different aquifer aspects and conditions. This includes the strongly adsorbed elements Th, Pb, and Po, the relatively mobile U, and Ra, which is only strongly adsorbed in fresh waters. There are some fundamental aspects of radionuclide behavior that require further investigation, including the reversibility of adsorption, factors that may affect release from minerals by recoil or leaching, and the effect of colloids. Progress in these fields, as well as new aquifer studies, will undoubtedly lead to new methods for extracting information on aquifer characteristics from the decay series.

Bones (U-Series)

Alistair W. G. Pike*

Department of Archaeology, University of Southampton, Southampton, UK

Synonyms

²³⁰Th/U dating of bone; U-series disequilibrium dating of bone; U–Th dating of bone

Definition

Uranium-series dating: A geochronological method that uses intermediate decay products in the ²³⁸U or ²³⁵U radioactive decay chains to measure the length of time required to reach the current state of radioactive disequilibrium from an initial condition.

Bone: A dense, semirigid, porous, calcified connective tissue forming the major portion of the skeleton of most vertebrates consisting of an organic matrix, largely collagen, and a mineral phase of nonstoichiometric carbonate hydroxyapatite Ca₁₀(PO₄)₆(OH)₂.

Introduction

Uranium-series disequilibrium dating of carbonate precipitates provides one of the most precise (and accurate) dating methods for the last 500 ka and has found application in archaeology for dating flowstone floors that cap or bracket archaeological deposits (e.g., Schwarcz and Blackwell 1992) or that are associated with cave paintings (Pike et al. 2012). The restricted range of contexts where suitable carbonate samples are associated with cultural layers, however, limits its applicability to archaeological chronology. Because of this, considerable effort has been made to attempt to apply the U-series method directly on archaeological bone.

Living bone is a composite of protein (largely collagen) and nonstoichiometric carbonate hydroxyapatite (often referred to as bioapatite). It contains only traces of uranium (<a few ppb), whereas archaeological bone can contain many 10 s of ppm. Unlike calcite flowstones, bone is an open system; it gains most of its uranium from the burial environment, and any attempt to calculate a U-series date from measurements of ²³⁴U, ²³⁸U, and ²³⁰Th requires the application of a model of this uptake.

The Early Uptake Assumption

Early attempts at U-series dating of bone simply treated it as an approximation to a closed system, using the “early uptake” (EU) assumption – that the uranium was taken up by the bone initially over a short period of time relative to its age. A comparison of radiocarbon dates (between 10 and 30 ka) with EU U-series dates on bones showed an overall average underestimation in the U-series dates of

*Email: a.w.pike@soton.ac.uk

2,700 years and appeared initially to support the EU assumption (Szabo 1980). Given most of the bones were only slightly older than 10 ka, however, this is still a significant underestimation. While use of the EU assumption was widespread in early attempts to date bone, often with very mixed results (e.g., Szabo et al. 1973), a chemical or physical mechanism for it was not formally proposed until the work of Rae and Ivanovich (1986). It had previously been proposed (e.g., Szabo 1980) that the primary mechanism for incorporation of uranium in bone was by substitution for Ca^{2+} in the bone mineral hydroxyapatite. Because of differences in their ionic radii, this necessitated the reduction of U^{6+} to U^{4+} . In most burial environments, uranium is in the mobile U^{6+} (uranyl) rather than the immobile U^{4+} form (Gascoyne 1982), but Rae proposed that the conditions needed for reduction would be present in archaeological bone as a result of the decomposition of the bone's organic matrix – collagen – into its constituent amino acids. This mechanism would explain not only how the uranium was fixed in the bone through reduction to U^{4+} and substitution for Ca but also how uranium can be incorporated early in the burial history of a bone after which further uptake ceases. Collagen is rarely found in bones older than a few tens of thousands of years and almost never in bones older than 100 ka. Therefore, according to Rae's proposal, the uptake of uranium should be limited to the early stages of burial history of a bone – the period while the collagen is degrading. While this mechanism seemed plausible, Rae herself found dates calculated using the EU assumption to give mixed results, especially from open-air (non-cave) sites (Rae et al. 1989), and also noted that some bones appeared to give older than expected results, probably as a result of the loss of uranium unaccounted for in the EU model. The few further systematic studies comparing EU U-series dates with expected ages were unable to substantiate EU behavior as a general feature of bone (e.g., see Pike and Pettitt 2003).

Open-System Modeling Using $^{230}\text{Th}/\text{U}$ and $^{235}\text{U}/^{231}\text{Pa}$

In parallel, there were a number of attempts to model the open-system behavior of bone using combined $^{230}\text{Th}/\text{U}$ and $^{235}\text{U}/^{231}\text{Pa}$ measurements (e.g., Szabo and Malde 1969; Szabo et al. 1973; Szabo and Collins 1975; Szabo 1979). Lacking a geochemical model of uranium-bone interactions, these models were generally straightforward mathematical assumptions, albeit with plausible physical implications. For example, a model proposed by Szabo and Rosholt (1969) with later modifications by Chen and Yuan (1988) incorporated uranium uptake in two stages: an initial period of rapid uptake followed by a second later episode of either uptake or loss of uranium. Using isochronous samples (e.g., multiple bones from a single archaeological layer) that were assumed to have been affected by the second migration at the same time but to different extents, they calculated a corrected age from $^{230}\text{Th}/\text{U}$ and $^{235}\text{U}/^{231}\text{Pa}$ (see Cheng et al. 1998 for more on U/Pa systematics). While this method was used to provide chronologies for a number of key sites in China, which in turn raised the intriguing possibility of chronological overlap between *Homo erectus* and archaic *Homo sapiens* (Chen and Zhang 1991), subsequent redating of the sites with U-series and other techniques has shown the ages of the *H. erectus* sites to be much older than estimated by Cheng and Yuan's model (e.g., Grün et al. 1998; Shen et al. 2001; Zhao et al. 2001).

The Diffusion-Adsorption Model

A key development in the understanding of uranium uptake mechanisms in bone was the work of Millard and Hedges (1995, 1996). In contrast to Rae's explanation for EU which required

the reduction of U^{4+} to U^{6+} , in vitro experiments by Millard and Hedges found uptake of uranyl (i.e., U^{6+}) in protein-free hydroxyapatite and measured a partition coefficient between hydroxyapatite and uranyl solution of 10^4 – 10^6 , in agreement with estimations from observations on archaeological bone. Drawing on mathematical models of diffusion developed by Crank (1975), they proposed an explicit geochemical model of uranium uptake, the diffusion-adsorption (D-A) model, where diffusion was the dominant transport mechanism of uranyl ions into bone pores where it was subsequently adsorbed onto the large ($>100 \text{ m}^3 \text{ g}^{-1}$) surface area of bioapatite.

Using formulations given by Crank (1975), Millard and Hedges proposed the diffusion equation for simultaneous diffusion and adsorption as

$$\frac{\partial C}{\partial t} = \frac{D}{(R+1)} \frac{\partial^2 C}{\partial x^2}$$

where C is the uranium concentration at a point x in the bone, D is the diffusion coefficient reduced for diffusion in a porous medium such as bone, and R is the volumetric partition coefficient which is related to the partition coefficient (K_d) by $R = K_d/p$ where p is the specific porosity of the bone. Both D and R can be related to the physical structure of bone (e.g., volume, size distribution and tortuosity of bone pores, and the internal surface area).

Using a modification of Crank's equation for diffusion in an infinite planar slab and assuming a linear adsorption isotherm, they derive the concentration (ppm), Z , at a point x :

$$Z_{(x)} = pRC_1 \left(1 - \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} e^{\left[\frac{-D(2n+1)^2 \pi^2 t}{(R+1)4l^2} \right]} \cos \left[\frac{(2n+1)\pi x}{2l} \right] \right)$$

where x is the distance from the center of the slab (cm), t is the time of burial, C_1 is the environmental concentration of uranyl (ppm), and l is half the thickness of the bone (cm). To simplify this, Millard and Hedges use three reduced dimensionless parameters:

$$Z' = Z/pRC_1 \quad x' = (x-l)/l \quad t' = tD/(R+1)l^2$$

Under this scheme, Z' represents the fraction of the equilibrium concentration of uranium in the bone, since at equilibrium the concentration of uranium, Z , is pRC_1 . The parameter x' represents the fractional distance from the center of the bone section and takes a value of -1 to 1 . The parameter t' is a function of both time and D/R . Young bones or bones with lower D/R give smaller t' .

Not only can the D-A model predict the rate of accumulation of uranium in bone, but it also predicts the distribution ("profiles") of uranium and uranium-series isotopes transversely across a bone (Fig. 1). Under constant geochemical conditions, the model predicts the diffusion of uranium from the outer and inner (medullary) surfaces of the bone, leading to U-shaped uranium profiles, and an increasing underestimation of closed-system U-series dates toward the center of the bone. Over time, these uranium concentration profiles gradually flatten until the adsorbed uranium in the bone is at equilibrium with uranium in the groundwater. The parameter t' can be estimated from the measured uranium concentration profiles and U-series isotope profiles generated for different values of t and compared to observations to yield a date.

Furthermore, since adsorption is a reversible process, the D-A model can also predict the leaching of uranium from the bone (e.g., in response to a decrease in uranium concentration in the groundwater) and the overestimation of U-series dates calculated using the EU assumption that many

Fig. 1 Simulated U concentration profiles (i) and “date profiles” (ii) across a transverse section of bone predicted by the D-A model under constant geochemical conditions for a 100-ka-old bone. Different curves show the effects for different values of the model parameter t' , which is a function of time and parameters intrinsic to a particular bone. For a given bone, diffusion of U from the edges of the bone leads to a U-shaped U profile that gradually flattens over time until an equilibrium concentration is reached between U in the bone and U in the groundwater. The pattern of apparent closed-system dates shows increased underestimation toward the center of the bone, except where bones equilibrate rapidly (i.e., $t' \gg 1$)

researchers had observed. After initial uptake, a decrease in uranium concentration in the groundwater will lead to desorption of uranium and diffusion in the opposite direction (i.e., out of the bone) and lead to $\cap$ - or M-shaped uranium concentration profiles. As a consequence, $^{230}\text{Th}/^{238}\text{U}$ activity ratios become elevated toward the surface of the bone due to the preferential loss of U relative to Th resulting in overestimates of closed-system U-series dates and elevated initial $^{234}\text{U}/^{238}\text{U}$ activity ratios. Similarly, an increase in the U concentration of the groundwater will lead to increased uptake and characteristic steep gradients of U profiles (Fig. 2).

Pike et al. (2002) compared U concentration and U-series isotope profiles in archaeological bone to those predicted by the model. They found that where both uranium concentration and U-series isotope profiles were U-shaped and agreed with the profiles predicted by the D-A model, open-system dates (calculating using the D-A model) agreed well with control dates. However, these

Fig. 2 Simulated U concentration profiles (i) and “date profiles” (ii) across a transverse section of bone predicted by the D-A model for different U uptake regimes for a 30-ka-old bone. Shown in (i) are U concentration profiles predicted for diffusive uptake under constant conditions with the bone nearing equilibrium with the groundwater, i.e., $t' \rightarrow 1$ (A-1); diffusive uptake under constant conditions with the bone far from equilibrium, i.e., $t' \ll 1$ (A-2); leaching of uranium after initial uptake (B); and a recent increase in the uptake of uranium, “recent uptake” (C). Simulated date profiles across the same bone are shown in (ii). Diffusive U uptake under constant conditions (A-1) shows apparent closed-system dates decreasing toward the center of the bone section, although dates are not as underestimated as for bones further from equilibrium with the groundwater (A-2). The leaching of U after initial uptake increases the $^{230}\text{Th}/\text{U}$ resulting in apparent closed-system dates that overestimate the true age, especially toward the outer and inner surfaces of the bone (B). Recent increased U uptake (C) gives underestimated apparent closed-system dates and can lead to a characteristic $\cap$ distribution of dates

bones were in the minority of those examined; many did not appear to have experienced constant geochemical environments. Bones that exhibited leached profiles as well as those that had taken up uranium at an increasing rate (deemed “recent uptake”) were present, as well as those with irregular profiles that may have experienced complex changes in burial geochemistry or diagenetic processes over long timescales. However, Pike’s et al. approach was to reject U-series results from these profiles and only accept results with profiles that conformed to straightforward predictions of the D-A model.

Sampling and Development of Laser Ablation Methods

U concentration and isotope profiles were made on a transverse section, usually a few mm thick, and cut from the bone using a diamond saw. Ideally, this would be a mid-shaft section of long bone for uptake to approximate to the one-dimensional diffusion in an infinite planar slab which is the basis of the D-A model. Other geometries (e.g., of teeth) have been considered (Pike and Hedges 2001), and Crank (1975) gives equations which could be incorporated to adapt the D-A model to radial diffusion and other phenomena. Initially, Pike et al. (2002) used inductively coupled plasma mass spectrometric (ICP-MS) U concentration measurements on 6–10 subsamples drilled from each cross section to create uranium concentration profiles and screen bones for U-series measurement. A second set of subsamples were drilled from selected bones for thermal ionization mass spectrometer (TIMS) measurement of U-series isotopes. This proved analytically costly, and slow, and was subsequently replaced by a method that used laser-ablation multi-collector ICP-MS (Eggins et al. 2003, 2005). For bones with a few ppm of uranium or more, U concentration and U-series isotope profiles could be measured simultaneously using laser ablation, at far higher spatial resolution than by drilling samples (in some cases, several hundred $^{238}\text{U}/^{230}\text{Th}$ per bone section), and typically in less than an hour per bone. Precision on an individual measurement was far poorer than for TIMS, but this is outweighed by the increased precision and accuracy afforded by fitting predicted profiles to data-dense measured profiles. The precision on modeled dates largely depends on the goodness of fit of the measured profiles to the model's predictions and is typically 2–10 % (e.g., see Pike et al. 2005). Millard and Hedges' model was later refined to allow for the evolution of $^{234}\text{U}/^{238}\text{U}$ in the bone within a groundwater with constant $^{234}\text{U}/^{238}\text{U}$ (Sambridge et al. 2012), though as yet it remains unclear to what extent there is exchange between adsorbed uranium and the groundwater, and therefore the evolution of $^{234}\text{U}/^{238}\text{U}$ during uranium uptake remains a significant uncertainty which presumably affects the accuracy of D-A dates where $^{234}\text{U}/^{238}\text{U} \gg 1.0$.

Applications

Because of their size and availability, the majority of applications have been on faunal bones, for example, to constrain the ages of biostratigraphic faunal assemblage zones in the United Kingdom (e.g., Pike et al. 2005) or as a proxy for the age of hominin bones or activity from the same archaeological layer (e.g., Storm et al. 2013), but the ability to date very small samples using laser ablation has opened up the possibility of dating valuable human fossils. These have included direct U-series dates on the Omo-Kibish 1 modern human skull from Ethiopia, confirming the Ar–Ar dating of sediments that suggest an age of close to 195 ky (Aubert et al. 2012), supporting genetic models of the appearance of modern humans in Africa c. 120–220 ka ago (e.g., Ingman et al. 2000). The method has also been used to produce dates of relevance to understanding the migrations of modern humans out of Africa, in particular in regions where the first appearance of modern humans predate the c. 40–50 ka limit of radiocarbon dating, such as a human metatarsal dated to 67 ± 1 ka in Callao Cave, Luzon, Philippines (Mijares et al. 2010), or where collagen preservation is poor, for example, for the Niah Cave deep skull from Borneo dated to 35.2 ± 0.3 ka (Barker et al. 2007; Reynolds et al. 2013). In Europe, several studies have used the method to constrain the timing of the disappearance of the Neanderthals (Walker et al. 2008; Daura et al. 2010; Zilhao et al. 2011), although some of the U-series results were used only to corroborate other dating methods.

Future Directions

One of the key obstacles to more widespread adoption of U-series methods of dating bone is the number of bones that are rejected as unsuitable for dating on the basis of their measured profiles. A large proportion of these are at equilibrium and show uniform U concentration and U-series isotope profiles. A value for t' cannot be estimated from a uniform profile, and thus the rate of equilibration cannot be determined. This is important since diagenetic changes in the bone may increase the rate at which equilibrium is established, raising the possibility that a bone may have re-equilibrated with geochemical changes that would have resulted in the loss or further uptake of uranium (phenomena normally spotted by characteristic profiles). Thus dates from equilibrium profiles are only of use to corroborate other dating methods (e.g., Walker et al. 2008). However, the recent development of ICP methodologies to measure ^{231}Pa at high precision will enable combined U–Th–Pa concordance dating of these samples (e.g., see Cheng et al. 1998) and even perhaps the measurement of $^{235}\text{U}/^{231}\text{Pa}$ profiles to further refine the D-A method.

Summary

Bone is an open system and gains (or loses) uranium from the burial environment, and therefore a model of uranium migration is required to calculate a U-series date from the measured $^{230}\text{Th}/\text{U}$. Early models, based on simple mathematical assumptions, did not yield consistent results, but some success has been had using an explicit geochemical model based on the processes of diffusion and adsorption (the D-A model). The D-A model predicts the spatial distribution of U and U-series isotopes across a bone section, and where these “profiles” indicate the bone has experienced relatively constant geochemical conditions, an open-system date can be calculated.

Carbonates, Lacustrine (U-Series)

Mordechai Stein*

Geological Survey of Israel, Jerusalem, Israel

Synonyms

[Aragonitic lake sediments](#); [Calcitic lake sediments](#); [Lake carbonates](#)

Definition

Method of dating late Quaternary geological events (typically up to ~600 ka) by U and Th isotopes in primary calcium carbonates (e.g., aragonitic corals, calcitic speleothems, aragonitic or calcitic lake sediments). The method is based on the radioactive decay of ^{238}U to its daughters ^{234}U and ^{230}Th . The radiometric “clock” measures the time that is required for a particular carbonate system to reach the condition of secular equilibrium after chemical fractionation between soluble U and insoluble Th in waters (e.g., seawater). The isotopes of U and Th can be measured by α -counting or mass spectrometric methods.

Introduction

The U-series dating method is the principal means to establish precise chronologies of late Quaternary geological events by analyses of primary carbonates, those that precipitate chemically from marine and continental water bodies: corals, speleothems, lacustrine sediments, and travertines. Examples are chronologies of sea level changes, coastal tectonic movements, and coastal hydrology (e.g., Edwards et al. 1986; Stein et al. 1993; Lazar and Stein 2011), as well as patterns of continental climate changes by dating primary lacustrine carbonates or cave speleothems (cf. Kaufman 1971; Kaufman et al. 1998; Winograd et al. 1988, 1992; Schramm et al. 2000; Haase-Schramm et al. 2004; McGee et al. 2012; Torfstein et al. 2013a, b). The possibility of obtaining precise U–Th ages on corals stems from the nearly complete chemical separation between U (soluble) and Th (insoluble) in seawater, which results in “clean” precipitation of U within the coral aragonitic skeleton (no initial ^{230}Th and negligible amount of detritus). Lake carbonates, however, typically contain significant amounts of non-authigenic U and Th, and possibly authigenic (hydrogenous) Th, which must be considered in age evaluations (cf. Ku and Liang 1984; Luo and Ku 1991; Kaufman 1993; Lin et al. 1996).

U–Th Dating of “Pure” and “Dirty” Carbonates

The ^{234}U – ^{230}Th dating method is based on the deviation of the intermediate daughter isotopes in the ^{238}U decay series from the state of secular equilibrium. The initial state of the disequilibrium

*Email: motistein@gsi.gov.il

condition is produced when U and Th fractionate in a hydrologic environment such as seawater or lake water. This fractionation reflects the distinctly different chemical affinity of U and Th. While U forms soluble complexes in water with various salinities and pH values, Th typically is removed by absorption onto surfaces of sedimentary particles. Thus, the $[^{230}\text{Th}/^{238}\text{U}]$ activity ratio approaches zero in calcium carbonate (CaCO_3) precipitated from the water. Furthermore, the carbonate incorporates U according to the specific partition coefficient that depends on the type of the CaCO_3 mineral phase (e.g., aragonite or calcite) and environmental factors such as water temperature and pH (cf. Lazar et al. 2004).

The condition of secular equilibrium in the decay series

is achieved because the half-life of the parent isotope ^{238}U is much longer than the intermediate daughter isotopes in the series. For the pair ^{234}U – ^{230}Th , the condition of secular equilibrium is typically achieved after ~ 500 ka. The ^{234}U – ^{230}Th “clock” measures the time elapsed from the incorporation of U within the CaCO_3 and the present day (provided that it is less than the time required to achieve secular equilibrium). The incorporation of U in the carbonate mineral phases follows the chemical separation between U and Th in seawater or lake water that leaves the U in solution (as uranyl ion complexes) and removes Th attached to settling particles. Assuming that the precipitated carbonate remained closed with regard to U and Th mobility and that the initial $^{230}\text{Th}/^{238}\text{U}$ is negligible (this may not be the case in system of “dirty carbonates” an issue elaborated below), the equations governing the decay of ^{238}U and ^{230}Th ages that allow the calculation of single ages are (modified after Kaufman and Broecker 1965):

$$\begin{aligned} \left[^{230}\text{Th}/^{238}\text{U} \right]_{\text{act}} &= 1 - \exp(-\lambda_{230}T) + \delta^{234}\text{U}(0)10^{-3} \times [\lambda_{230}/(\lambda_{230} - \lambda_{234})] \\ &\times [1 - \exp((\lambda_{234} - \lambda_{230})T)] \end{aligned} \quad (1)$$

$$\delta^{234}\text{U}(T) = \delta^{234}\text{U}(0) \exp(\lambda_{234}T) \quad (2)$$

where T represents the age, in years, since mineral formation, $[^{230}\text{Th}/^{238}\text{U}]_{\text{act}}$ represents the ratio of ^{230}Th and ^{238}U activities, and λ_{230} and λ_{234} represent radioactive decay constants in years^{-1} for ^{230}Th and ^{234}U , respectively. $\delta^{234}\text{U}(0)$ is defined as the measured activity value $[^{234}\text{U}/^{238}\text{U}]_{\text{act}}$ recalculated relative to the secular equilibrium value of 1.00 and given in per mil units (‰; i.e.,) $\delta^{234}\text{U} = ([^{234}\text{U}/^{238}\text{U}]_{\text{act, sample}}/1.00) - 1 \times 1,000$. Similarly, $\delta^{234}\text{U}(T)$ is the initial value of $[^{234}\text{U}/^{238}\text{U}]_{\text{act}}$ calculated at the time of isolation of the specific mineral system (e.g., precipitation of lacustrine aragonite or formation of aragonitic coral, or calcitic speleothem, or travertine). In general, we expect that, for samples representing a simple closed-system evolution, the initial $\delta^{234}\text{U}(T)$ value should reflect the value present in the ambient hydrologic system. Thus corals deposited in seawater will have $\delta^{234}\text{U}(T)$ of ~ 150 (Edwards et al. 1986; Chen et al. 1991; Stein et al. 1993), whereas primary aragonite deposited from the hypersaline lakes in the Dead Sea basin will have $\delta^{234}\text{U}(T)$ of ~ 500 (Haase-Schramm et al. 2004; Torfstein et al. 2013b). Decay constants used in the calculation of the ages are $\lambda_{230} = 9.158 \times 10^{-6}$; $\lambda_{232} = 4.9475 \times 10^{-11}$, $\lambda_{234} = 2.8263 \times 10^{-6}$, and $\lambda_{238} = 1.55125 \times 10^{-10}$ per year (Le Roux and Glendenin 1963; Jaffey et al. 1971; Cheng et al. 2000).

The basic assumptions behind Eq. (1) are *No initial* ^{230}Th is present in the sample and *all of the U* is derived from the ambient water in the depositional habitat. These assumptions hold well for corals,

which typically contain negligible amounts of detrital Th (typically in the range of 0.3–1 pmol/g e.g., Chen et al. 1991; Stein et al. 1993), but rarely holds for other carbonates. Possible interferences in obtaining a true age from measured isotope ratios are U and Th contributed from admixed detritus present in the sample and the possible presence of initial Th in the authigenic (or primary) component.

Correction for the “Detrital” U and Th by the “Isochron” Method

Correction of the U and Th concentrations in “dirty carbonates” is often done by plotting the U and Th activity ratios of a set of coeval samples containing various amounts of detritus on the Rosholt- or Osmond-type “isochron” diagrams. These diagrams are used to identify the $^{230}\text{Th}/^{238}\text{U}$ and $^{234}\text{U}/^{238}\text{U}$ activities of the “pure primary carbonate.” The $^{230}\text{Th}/^{238}\text{U}$ and $^{234}\text{U}/^{238}\text{U}$ activity ratios of the “detritus-free carbonate” is retrieved from the slopes of “Rosholt”-type diagrams (plots of $^{230}\text{Th}/^{232}\text{Th}$ vs. $^{238}\text{U}/^{232}\text{Th}$ and $^{234}\text{U}/^{232}\text{Th}$ vs. $^{238}\text{U}/^{232}\text{Th}$ activity ratios, respectively) or the y-intercepts of “Osmond”-type diagrams (plots of $^{232}\text{Th}/^{238}\text{U}$ vs. $^{230}\text{Th}/^{238}\text{U}$ and $^{232}\text{Th}/^{238}\text{U}$ vs. $^{234}\text{U}/^{238}\text{U}$ activity ratios, respectively). Alternatively, a “single sample” correction method subtracts the detrital U and Th contributions using either an assumed or measured isotopic composition from individual sample data. The “isochron” approaches have advantages over the single sample correction method when there is a large variation in the mixing proportions of coeval detritus and carbonate samples (cf. Bischoff and Fitzpatrick 1991; Haase-Schramm et al. 2004; Kaufman 1993; Ludwig and Titterton 1994; Torfstein et al. 2013a). Such a set of samples may display a large range of values along a line in “isochron” diagrams and the composition of the detrital end-member may not have to be explicitly assumed.

Correction for Initial Hydrogenous Th

Correction for initial hydrogenous Th in the primary carbonate phase cannot be done by the isochron method. This component might be determined empirically by using a sample of known age determined by independent means (e.g., by ^{14}C ages of organic material). Any apparent difference in the U–Th age could be attributed to the presence of initial ^{230}Th (after correcting for the detritus component). In this case, the extra initial ^{230}Th is corrected by subtracting this component from the detritus-corrected values. Alternatively, the fraction of the hydrogenous Th can be retrieved from analyses of trace element chemistry of specific samples (e.g., Th/Zr ratios, as detailed in Haase-Schramm et al. 2004).

The following sections describe two case studies where U–Th chronologies were established for lacustrine sequences: the last glacial Lake Lisan in the Levant-Dead Sea basin and Lake Bonneville in the western US Great Basin. Other examples of lacustrine deposits that were dated by the U–Th are described by Israelson et al. (1997), Ku et al. (1998), and Lin et al. (1996), among others.

U-Series Dating of Lake Lisan (Last Glacial Dead Sea)

Lake Lisan occupied the tectonic depressions along the Dead Sea Transform fault in the Levant region of the eastern Mediterranean during the last glacial period. The lake comprises Ca-chloride brine that requires the supply of bicarbonate ions to precipitate primary carbonate. This is furnished

by the annual freshwater input. Turbulent mixing across the epilimnion (upper water layer) and hypolimnion resulted in precipitation of primary aragonite (Stein et al. 1997). The excellent preservation and high U concentrations (~3 ppm) of the aragonite make it useful for ^{234}U – ^{230}Th dating. The pioneering attempts in applying this method to Lake Lisan sediments were made by Kaufman and colleagues using α -counting techniques (Kaufman 1971; Kaufman et al. 1992). They showed that, unlike coral samples, the Lisan aragonites are associated with a detrital U and Th component that should be corrected out prior to calculation of ^{234}U – ^{230}Th and applied the “isochron” methods to perform these corrections. With the development of the TIMS method for analyzing U and Th isotopes in small carbonate samples, Schramm et al. (2000) and Haase-Schramm et al. (2004) measured U and Th abundances in a stratigraphic section of the Lisan Formation (PZ1 section at Perazim Valley), corrected for detritus U and Th and hydrogenic Th and established an age-height chronological model for the time interval of 70–14 ka BP. Recently, Torfstein et al. (2013a) used the plasma machine (ICP-MS-MC) to analyze the U and Th isotope in several stratigraphic sections of the Lisan Formation in the Dead Sea-Jordan Valley and established an integrated multi-site U–Th chronology for the Lisan Formation. The U–Th Lisan chronology has been used for paleoclimate and paleoseismic studies and for calibrating the radiocarbon time scale in the last glacial time interval (Haase-Schramm et al. 2004; Bartov et al. 2003; Kolodny et al. 2005; Torfstein et al. 2013a, b).

U-Series Dating of Lake Bonneville

Lake Bonneville, which occupied the Bonneville Basin of the northeastern Great Basin (USA), experienced a lake level history very similar to the Levant-Lake Lisan, approaching its highest stands during the last glacial ~26 ka BP and commenced its deglacial retreat after ~16 ka BP (Oviatt et al. 1990, 1992). Nevertheless, the reconstruction of lake paleohydrology and paleolimnology suffered from lack of accurate chronologies (e.g., uncertainties in the radiocarbon reservoir ages). Recently, new chronological constraints on the glacial and postglacial history of the lake were achieved by U–Th dating of lacustrine cave carbonates (McGee et al. 2012). The cave carbonates provide a promising new archive of past hydrologic changes in the Bonneville Basin. The carbonates precipitated within caves (e.g., Cathedral and Craners caves), crevices, and other protected spaces flooded by Lake Bonneville during its high stand in the last glacial period. The caves are located at similar elevations approximately 100 m above the modern Great Salt Lake and almost 200 m below Lake Bonneville’s highstand shoreline. Precise U–Th ages determined on the cave carbonates indicate a minimal (~200 y) radiocarbon reservoir age in the lake and allows ^{14}C dating to be used for age control in portions of the deposits less suitable for U–Th dating. The combined U–Th and radiocarbon data document the timing of the lake’s transgression between 26 and 18 ka and a large influx of fresh water during Heinrich Stadial 2. This was reflected by a hiatus in calcite deposition. Calcite deposition resumed at ~16.4 ka, suggesting that basin overflow had ceased by this time. The lake’s deglacial regression began ~16 ka. Cessation of this second phase of deposition at 14.7 ± 0.2 ka, coincident with the Bølling-Allerød warming, may reflect the lake’s drop below Cathedral Cave’s elevation. Overall, the Great Basin (USA) Bonneville lacustrine system and the Dead Sea-Lake Lisan (Levant) show very similar responds to the global climate, which demonstrates the great potential in performing precise U–Th dating on the lacustrine carbonate deposits.

Concluding Comments

U–Th dating of lacustrine (authigenic or primary) calcium carbonates is a prime method of achieving accurate and high-resolution chronologies for the geochemical-limnological evolution of late Pleistocene lakes. However, the lake carbonates are typically “contaminated” by detrital U and Th and initial hydrogenous Th. Application of the “isochron methods” (e.g., Rosholt- or Osmond-type diagrams), combined with stratigraphical considerations, independent dating methods, such as radiocarbon over the past 50 ka, and oxygen isotope chronologies, helps to derive reliable and high-resolution chronologies for the lacustrine sequences.

Carbonates, Marine Carbonates, (U-Series)

C. H. Stirling*

Department of Chemistry, University of Otago, Dunedin, New Zealand

Synonyms

Coral dating; ^{238}U - ^{234}U - ^{230}Th dating; U-series chronology; U-Th dating

Definition

U-series nuclides. Nuclides of the ^{238}U , ^{235}U , and ^{232}Th radioactive decay chains, which begin with the above radioactive nuclides and end with a stable isotope of lead.

Fractionation. The fractional gain or loss of one element relative to another (*elemental fractionation*) or one isotope relative to another of the same element (*isotopic fractionation*) during geological events.

Decay constant. The proportionality constant of a radionuclide defining the number of atoms decaying over a given period of time compared with the number of atoms present initially.

Mass spectrometry. An analytical technique that produces spectra of the masses of molecules or atoms used to determine the isotopic composition of a sample. Particles are ionized in the instrument source followed by physical separation based on their mass-to-charge ratio.

Introduction

For the last 800 millennia, climate has oscillated between cool ice ages and warmer interglacial conditions with a periodicity of about 100 thousand years. For example, during the “Last Deglaciation” between about 21 and 6 thousand years ago (ka), more than 50 million cubic kilometers of ice melted from the major continental ice sheets, raising the sea level by ~130 m (Lambeck et al. 2002). The waxing and waning of the ice sheets, fall and rise in sea level, and the cooling and warming of Earth’s climate are faithfully preserved as compositional changes in marine sediment records (Lisiecki and Raymo 2005) (Fig. 1a). These archives provide continuous, high-resolution records of past climate change but lack critical information on absolute timing because they cannot be directly dated, relying instead on model chronologies (Milankovitch 1941) that require further validation. As a result, the exact mechanisms driving the Earth’s natural climate cycles remain uncertain. Obtaining reliable, absolutely dated records of past climate change is critical for understanding how Earth’s natural climate cycles work. These data can provide a firmer basis for assessing the role of anthropogenic effects, such as greenhouse gas emissions, in modifying climate, thus improving twenty-first-century climate projections.

In-built clocks based on the decay of radioactive elements that are present in minute quantities in rocks and sediments allow an absolute chronology to be assigned to geological records. One of the key dating methods used in paleoclimate research takes advantage of the natural radioactive decay of

Fig. 1 (a) The LR04 deep-sea sediment oxygen stable isotope ($\delta^{18}\text{O}$) record, which comprises a stack of 57 globally distributed deep-sea records and provides a combined signal of deep-ocean temperature and global sea level for the past 5.3 million years (Lisiecki and Raymo 2005). The past 700 thousand years of this record is shown and has been assigned a timescale by direct correlation with model chronologies. Glacial-interglacial climate episodes are defined by “marine isotope stage” (or MIS) terminology, whereby even- and odd-numbered MIS intervals refer to glacial and interglacial periods, respectively. Distinct oscillations between warm interglacial periods (high $\delta^{18}\text{O}$ values) and cool glaciations (low $\delta^{18}\text{O}$ values) are apparent. Centennial- and millennial-scale climate variability is also evident. (b) Photograph of an elevated “Last Interglacial” fossil coral reef, within a few meters of the present shoreline, along the coast of Western Australia which formed around 125,000 years ago. Fossil corals within the reef framework can be directly dated using the U-series dating method

uranium (U) to thorium (Th) in U-bearing minerals, such as calcium carbonate. This technique, commonly referred to as the U-series dating method (Broecker 1963), has been widely applied to the following shallow-water marine carbonate archives in the reconstruction of past climate. Results have provided constraints on the precise timing, duration, and magnitude of key climate episodes:

1. *Shallow-water reef-building corals*. These archives grow close to the sea surface, providing valuable information on both sea-level and ocean-water temperature fluctuations, particularly during interglacial sea-level high stands when reefs grow prolifically (Broecker 1963; Edwards et al. 1987). The stratigraphic and morphological structures of the reef, combined with the height-age relationships of fossil corals within the reef framework, can be used to reconstruct the reef's growth history and, in turn, derive local sea-level curves for the study locality (Fig. 1b).
2. *Calcium carbonate slope sediments*. Calcium carbonate sediments, such as those swept from the banks of the Bahamas, yield continuous sea-level and climate records, especially during interglacial periods when the banks are flooded and sediment accumulation rates are high. Records are derived by combining the U-series ages of the carbonate fraction of the sediment with the oxygen stable isotope signatures of foraminifera (marine plankton) that have been deposited simultaneously (Slowey et al. 1996).
3. *Submerged coastal speleothems (stalagmites and stalactites)*. These archives are currently found below sea level in coastal caves. Calcium carbonate growth occurs during sea-level low stands when the caves are emergent, whereas growth ceases during flooding by rising sea levels. Important information on the timing, duration, and elevation of sea-level low stands and marine transgressions can be obtained by dating the carbonate preserved on either side of a growth hiatus (Richards and Dorale 2003).

The U-series dating method has also been applied to deepwater marine carbonates, including deep-sea solitary corals and chimney deposits (Teichert et al. 2003; Robinson et al. 2005).

Basic Principles of the U-Series Chronometer

The U-series dating method utilizes the natural radioactive decay of ^{238}U to its longest-lived intermediate daughters, ^{234}U and ^{230}Th , and subsequent decay, via a series of short-lived nuclides, to stable ^{206}Pb as follows:

Half-life	4.5 billion years	24 days	1 min	245 thousand years	76 thousand years	Stable
-----------	-------------------	---------	-------	--------------------	-------------------	--------

The respective 245,000 and 76,000 year half-lives of ^{234}U and ^{230}Th make the U-series system particularly useful for dating climate events spanning the last 600,000 years.

U-Series Nuclides in the Modern Global Ocean

For the U-series system, a state of *radioactive equilibrium* occurs when the activities, or rates of decay or in-growth, of ^{234}U and ^{230}Th , and all other intermediate daughters in the ^{238}U decay chain, are equal and identical to the activity of ^{238}U . This condition is achieved after five or six half-lives of the daughter isotope, provided that the system is left undisturbed without being subjected to parent-daughter fractionation events. In this state, the activity ratios between ^{238}U and its ^{234}U and ^{230}Th daughters, referred to as $[\text{}^{234}\text{U}/\text{}^{238}\text{U}]_{\text{act}}$ and $[\text{}^{230}\text{Th}/\text{}^{238}\text{U}]_{\text{act}}$, respectively, are invariant and equal to unity, irrespective of the time elapsed. After this point, the system cannot be used as a dating tool. Importantly, the U-series dating of marine carbonates becomes possible because chemical and nuclear processes continuously disrupt the state of U-series radioactive equilibrium in modern

hydrological systems. This gives rise to the following two conditions of *radioactive disequilibrium* in the marine environment, allowing the $[\text{}^{234}\text{U}/\text{}^{238}\text{U}]_{\text{act}}$ and $[\text{}^{230}\text{Th}/\text{}^{238}\text{U}]_{\text{act}}$ ratios of marine minerals to evolve to a new equilibrium state as a predictable function of time:

1. There is an extreme chemical fractionation between U and Th in the oxygenated modern ocean. In particular, U is present in its highest U(VI) oxidation state and forms uranyl complexes that are highly soluble in seawater. In contrast, Th exists as relatively insoluble species in the Th(IV) oxidation state, yielding negligible levels of dissolved Th in the global ocean (Ivanovitch and Harmon 1992).
2. The state of radioactive equilibrium between ^{238}U and ^{234}U is also disrupted due to internal damage to mineral grains during the energetic decay of ^{238}U . As a result, the ^{234}U daughter nuclide is often only loosely bound to the mineral structure, making it more susceptible to preferential leaching during weathering than lattice-bound ^{238}U (Ivanovitch and Harmon 1992). Consequently, seawater contains an ~15 % excess of ^{234}U over ^{238}U (i.e., seawater $[\text{}^{234}\text{U}/\text{}^{238}\text{U}]_{\text{act}} = 1.15$) compared to the radioactive equilibrium value of 1.00 due to steady-state input by river water loaded with dissolved U from continental weathering processes (Edwards et al. 2003).

U-Series Nuclides in Modern Marine Carbonates

During the formation of marine carbonates, the ^{238}U , ^{234}U , and ^{230}Th isotopes are removed from seawater, together with other dissolved metals, and incorporated into the mineral structure. Thus, newly formed corals, speleothems, and aragonitic slope sediments contain U with a “disequilibrium” initial $[\text{}^{234}\text{U}/\text{}^{238}\text{U}]_{\text{act}}$ ratio of 1.15, but no significant ^{230}Th (Edwards et al. 2003). Following calcium carbonate formation, the U-series nuclides become isolated from the steady-state ocean (where decaying nuclides are continuously resupplied from riverine and other sources), allowing the ^{234}U and ^{230}Th intermediate daughters to evolve to a new equilibrium state with their ^{238}U parent as a predictable function of the time elapsed since the mineral developed. Thus, for every marine carbonate sample, both the radioactive decay of ^{234}U and the simultaneous in-growth of ^{230}Th toward radioactive equilibrium with ^{238}U can be expressed as a function of its U-series or ^{230}Th age, denoted by T, provided that (1) $[\text{}^{234}\text{U}/\text{}^{238}\text{U}]_{\text{act}}$ and $[\text{}^{230}\text{Th}/\text{}^{238}\text{U}]_{\text{act}}$ can be reliably measured and (2) the decay constants for ^{234}U and ^{230}Th (λ_{234} and λ_{230} , respectively) are accurately known. This relationship is shown in Fig. 2 and Eq. (1), and T can be calculated iteratively (Edwards et al. 1987):

$$1 - \left[\frac{^{230}\text{Th}}{^{238}\text{U}} \right]_{\text{act}} = e^{-\lambda_{230}T} - \left(\left[\frac{^{234}\text{U}}{^{238}\text{U}} \right]_{\text{act}} - 1 \right) \left(\frac{\lambda_{230}}{\lambda_{230} - \lambda_{234}} \right) \left(1 - e^{(\lambda_{234} - \lambda_{230})T} \right) \quad (1)$$

The ^{230}Th age will accurately reflect the “true” age of the sample, provided that (1) no initial ^{230}Th existed in the sample at the time of its formation and (2) no further gain nor loss of the U-series isotopes takes place other than by “closed-system” radioactive in-growth and decay (Edwards et al. 1987). The latter assumption is sometimes violated, especially in older samples affected by secondary alteration, which tends to disturb the U-series isotopes, offsetting the ^{230}Th age from the true sample age.

Analysis of the U-Series Isotopes

Chemical procedures using ion-exchange resins to selectively adsorb and desorb the elements of interest are typically adopted to isolate “pure” U and Th from the calcium carbonate matrix of the

Fig. 2 (a) Plot showing the isotopic evolution of $[^{234}\text{U}/^{238}\text{U}]_{\text{act}}$ and $[^{230}\text{Th}/^{238}\text{U}]_{\text{act}}$ values as a function of time (T). Isochrons (straight, steeply sloping lines) are shown at 50, 100, 200, 300, and 500 ka. The red curve starting at $[^{234}\text{U}/^{238}\text{U}]_{\text{act}} = 1.15$ and $[^{230}\text{Th}/^{238}\text{U}]_{\text{act}} = 0$ gives the “seawater evolution path” for a sample formed in the marine environment with U equivalent to the $[^{234}\text{U}/^{238}\text{U}]_{\text{act}}$ composition of seawater but no Th at the time of its formation. (b) Isotope evolution curve for $[^{234}\text{U}/^{238}\text{U}]_{\text{act}}$ starting at an initial value of 1.15 evolves by radioactive decay towards the radioactive equilibrium value of 1.0 with time. (c) Isotope evolution curve for $[^{230}\text{Th}/^{238}\text{U}]_{\text{act}}$ starting at an initial value of 0 evolves by radioactive in-growth towards the radioactive equilibrium value of 1.0. Age resolution of the U-series dating method decreases with increasing sample age due to the progressive decrease in separation between isochrons, as demonstrated by the two data points shown in (a) for 125,000- and 200,000-year-old samples measured with identical levels of precision

sample (Goldstein and Stirling 2003). This purification procedure enables the $[^{234}\text{U}/^{238}\text{U}]_{\text{act}}$ and $[^{230}\text{Th}/^{238}\text{U}]_{\text{act}}$ ratios to be reliably determined, free of analytical artifacts such as isobaric or molecular interferences.

Analytical measurements of $[^{234}\text{U}/^{238}\text{U}]_{\text{act}}$ and $[^{230}\text{Th}/^{238}\text{U}]_{\text{act}}$ have an associated uncertainty, which, by convention, is reported at the 2-sigma level. Propagation of these uncertainties through the above U-series age equation results in ^{230}Th -age errors that become proportionally larger with increasing sample age, as radioactive equilibrium is approached and the rate of radioactive decay and in-growth of ^{234}U and ^{230}Th slows down (Fig. 2). This progressive loss in the resolution of the U-series chronometer with increasing age demonstrates the importance of achieving the highest analytical precisions possible.

To this end, the U-series dating method has benefitted enormously from ongoing innovations in technology that have occurred over the past 30 years. In particular, the advent of thermal ionization mass spectrometry (TIMS) in the 1980s and, more recently, multiple-collector inductively coupled plasma mass spectrometry (MC-ICPMS) in the late 1990s to U-series isotopic analysis dramatically reduced sample-size requirements, shortened analysis times, and improved measurement precision compared with earlier decay-counting techniques using alpha spectrometry (Goldstein and Stirling 2003). Ongoing design improvements in instrumentation over the last 10 years have continued to enhance U-series analytical performance (Stirling and Andersen 2009). As a result, ^{230}Th -age uncertainties of ± 800 years in 120,000-year-old samples and $\pm 3,000$ years in 300,000-year-old samples can now be routinely achieved. Some recent studies have further improved ^{230}Th -age uncertainties to better than $\pm 1,000$ years in 300,000-year-old samples (Stirling and Andersen 2009).

U-Series Dating to Marine Carbonates: Windows into Past Climate

Over the past two decades, the U-series dating of marine carbonates has provided crucial new constraints on the absolute timing and duration of key climate intervals throughout the past 600 thousand years of the Earth's climate history. At the young end of the dating range, U-series measurements have been used to determine the timing and frequency of El Niño events, occurring over the past few centuries (Edwards et al. 2003). In the $< 50,000$ -year range, coupled U-series and $^{14}\text{C}/^{12}\text{C}$ measurements for deep-sea corals have been used to constrain ventilation and circulation patterns of oceanic water masses and how they regulate global climate (Robinson et al. 2005). Furthermore, U-series measurements for drilled fossil coral reefs have been used to calibrate the ^{14}C chronometer for the past 40,000 years (Edwards et al. 2003). These drill-core coral data also provide a continuous record of sea-level rise and climate change for the "Last Deglaciation," extending from the peak of the last glacial maximum to the onset of the present interglacial warm period, from around 21 to 6 thousand years ago (Edwards et al. 2003; Deschamps et al. 2012). These results are discussed in more detail as follows:

The Last Deglaciation: Collectively, records from core drilled at coral reefs show evidence for several distinct "meltwater pulses" rather than continuous melting during the Last Deglaciation due to episodic periods of rapid ice sheet retreat. The largest of these events, referred to as "meltwater pulse" (MWP)-1A, occurring around 14 thousand years ago, produced an extremely rapid sea-level rise of ~ 20 m over 300 years, which is in excess of 40 m/1,000 years and approximately ten times faster than present melting rates. This was succeeded by the abrupt "Younger Dryas" cooling event, involving a transient return to full ice age conditions at ~ 12 ka before renewed sea-level rise. These abrupt centennial- to millennial-scale oscillations in climate and sea level appear synchronous with large-scale reorganization of North Atlantic thermohaline circulation, an oceanic conveyor belt exporting heat from the tropics to the poles. However, there is no consensus on the geographic source of meltwater during deglaciation nor exact underlying mechanisms controlling rapid sea-level and climate change. Recent U-series dating of drill core from fossil corals at different locations worldwide provides high-resolution "fingerprinting" of MWP-1A and implicates a substantial contribution of meltwater from the ice sheets of both northern and southern hemispheres (Deschamps et al. 2012). This suggests that melting of both the Greenland and Antarctic ice sheets will be highly sensitive to sustained global warming in the coming decades and may already be contributing to present day sea-level rise.

Prior to the last 50,000 years, a wealth of information is available only for the Last Interglacial period, occurring around 125 thousand years ago (discussed below). This is primarily because marine carbonates that formed close to modern shorelines during this time are relatively accessible for study today (Stirling and Andersen 2009).

The Last Interglacial period: The Last Interglacial interval, occurring from approximately 128 to 116 thousand years ago (Stirling and Andersen 2009), represents that the last time global sea levels were at or near modern levels and, by inference, the last time global climatic conditions, as well as the size and configuration of the major ice sheets, were similar to those in the present day. The Last Interglacial period has therefore been identified as a suitable analogue of the present climate system in order to speculate on future climate trends. Importantly, the Last Interglacial temperatures are likely to have been similar to, or slightly warmer, than the preindustrial state. Therefore, a reliable assessment of the timing, duration, and amplitude of global sea levels during the Last Interglacial is crucial for assessing the stability of the today's ice sheets in response to climate warming of a few degrees. Dutton and Lambeck (2012) have recently compiled all available U-series data for the Last Interglacial fossil reefs, demonstrating that the Last Interglacial global sea levels peaked between 5.5 and 9 m above the present sea level. These amplitudes require smaller ice sheets in both Greenland and Antarctica relative to today, implying a strong sensitivity of the cryogenic system to only minor climate warming.

Marine carbonates formed earlier than 125,000 years ago are prone to secondary alteration. Going forward, one of the key challenges faced by the U-series community is to acquire reliably dated climatic records for earlier interglacial periods that could represent more suitable analogues of the present climate system than the Last Interglacial period, such as “marine isotope stage” 9, 11, or 15 (Fig. 1) (Stirling and Andersen 2009).

Summary

The U-series dating of marine carbonates is based on the natural radioactive decay of ^{238}U to its longest-lived intermediate daughters, ^{234}U and ^{230}Th . This technique has been used to provide reliable, accurately dated records of past sea-level and climate change for the past 600,000 years of the Earth's history, especially for the past 130,000 years of the last glacial-interglacial cycle. This, in turn, has facilitated a more complete understanding of the mechanisms driving the Earth's natural climate cycles, which have helped to inform projections of twenty-first-century climate change.

Definition

Archaeological carbonate speleothems: Deposits of secondary carbonate minerals (usually calcite or aragonite consisting of CaCO_3) that formed in caves containing artefacts or other evidence of past human or hominid occupation

Introduction

U-series dating such as U-Th (or $^{230}\text{Th}/\text{U}$) is a well-established, accurate, and precise method with a wide range of applications in earth sciences, palaeoclimate research, and archaeology (Bourdon et al. 2003). U-series dating can be used to determine the age of materials that formed with a well-constrained radioactive disequilibrium between U and its daughter isotopes, including precipitates of calcium carbonate (CaCO_3) in cave environments, i.e., speleothems like stalagmites, stalactites, or flowstones. U-series dating is essential for palaeoclimate research using speleothems but is less commonly used for archaeological applications. However, cave environments are often associated with archaeology and archaeological finds. Excavations in caves often exhibit stratigraphic relationships with speleothem formation. Where a stratigraphy can be unambiguously established between archaeology and CaCO_3 formation, U-series dating provides a powerful chronological tool and can be applied to constrain minimum and/or maximum ages for associated archaeological finds.

Basic Principles of U-Series Dating of Speleothems

U-Th dating can be applied to materials like secondary CaCO_3 that incorporate disequilibrium between U (^{238}U and ^{234}U) and the daughter isotope ^{230}Th at the time of formation. For example, speleothems such as stalagmites or flowstones precipitate from percolating waters entering a cave. The water also contains trace elements dissolved from host rock above the cave, including U, which are subsequently incorporated in the CaCO_3 . The key for U-Th dating is the difference in solubility between U and Th which leads to elemental fractionation in the percolating water. In contrast to U, Th is largely insoluble and thus not incorporated in secondary carbonates when they form from drip waters in cave environments. Thereafter, ^{230}Th starts to build up until radioactive equilibrium is reached. The return of isotope activities to equilibrium allows quantification of time, i.e., the present $^{230}\text{Th}/^{238}\text{U}$ and $^{234}\text{U}/^{238}\text{U}$ activity ratios enable calculation of the time since formation.

The reliability of U-Th ages strongly depends on whether the dated material has remained as a so-called closed system, i.e., U and Th isotopes are neither lost nor gained after precipitation, and whether any initial ^{230}Th was present. Presence of initial (or detrital) Th is tested by determining the

*Email: dirk.hoffmann@eva.mpg.de

abundance of common Th (^{232}Th) in the sample. In case of significant amounts of ^{232}Th , a correction for initial ^{230}Th needs to be applied by mathematically subtracting an assumed or measured detrital component or by using “isochron” methods (Ludwig and Titterton 1994).

A single U-Th age does not provide a means of confirming that the dated material represents a closed system. However, there are ways to check reliability of U-Th ages of speleothems with respect to closed-system behaviour. The most rigorous test is to employ the alternative ^{235}U -series chronometer and measure $^{231}\text{Pa}/^{235}\text{U}$ in addition to $^{230}\text{Th}/\text{U}$ on the same material (Cheng et al. 1998). However, U-Pa dating requires much larger sample sizes due to the significantly smaller concentrations of ^{235}U relative to ^{238}U ($^{235}\text{U}/^{238}\text{U} = 0.0073$) and thus cannot be employed in all cases, especially where sample size is limited. Alternatively, where open-system behaviour cannot be excluded, it is recommended to perform repeat U-Th analyses of coeval samples. If dating results on different subsamples are concordant, the system can be regarded as closed. Stalagmites, flowstones, or other carbonates that form with internal stratigraphic constraints provide an additional possibility to check reliability by comparing ages of subsamples precipitated successively along a growth axis, which must become progressively younger from bottom to top.

U-Series Isotope Measurements and Sample Sizes

The applicability of U-series methods depends on availability of sufficient suitable material for dating. In many cases only small samples of less than 100 mg CaCO_3 are available, making the sample size critical. Recent advances in thermal ionization mass spectrometry (TIMS) and multi-collector inductively coupled plasma mass spectrometry (MC-ICPMS) instrumentation and protocols not only led to very high precision measurements of U-series ratios (Andersen et al. 2004; Potter et al. 2005) but also greatly reduced the sample size needed for a precise U-Th age. Currently, sample sizes between 10 and 100 mg are sufficient in most cases (Hoffmann 2008; Hoffmann et al. 2009). Overall, the ability to work on small samples in the range of 10 mg is now the key to many applications in archaeology where only very small sections or thin layers of CaCO_3 are found to have direct stratigraphic relations to archaeological finds.

U-Series Age Constraints for Excavations in Cave Environments

U-series dating has been applied to speleothems from archaeological sites for over 40 years employing alpha spectrometry (e.g., Fornaciari 1968; Schwarcz and Blackwell 1983; Blackwell et al. 1983), TIMS (e.g., Shen et al. 2001; Zhao et al. 2001) or more recently MC-ICPMS techniques (e.g., Mercader et al. 2009; Clark-Balzan et al. 2012; Hoffmann et al. 2013). Generally, sediment fillings in caves containing archaeology can often be found on top of flowstone formations or are covered by a layer of flowstone or in some cases both. Flowstone thus formed before or after artefact-hosting sediments accumulated, and U-series dating of such speleothems provides maximum or/and minimum ages for bracketed sediments. Similarly, stalagmites that form locally on top of sediments at a drip site or that are covered by sediment fill also may provide age constraints for the sediments. The stratigraphy between carbonate deposits and archaeology bearing sediments is essential; only carbonates with unambiguous relationships provide diagnostic ages of the target sediments and should be analysed.

For capping flowstones, the lowest layer is closest in age to the underlying sediment, and for underlying flowstones, the uppermost layer. However, the layers in contact with sediments are also

Fig. 1 Example of subsamples and U-series results for a section of flowstone (see text for details)

most prone to incorporation of silicate detritus (dirt) within the carbonate matrix and therefore do not necessarily yield the best dating results. Thus, in most cases, subsamples of detritus-poor carbonate should be taken from a layer within several mm of the flowstone–sediment boundary. It is generally recommended to target subsamples from the most pristine and cleanest parts of the speleothem. It is also essential to perform repeat analyses of a single growth layer and/or a suite of subsamples along the growth axis to verify the presence of closed-system behaviour. In samples that contain high detrital components, “isochron” methods may need to be applied (Ludwig and Titterton 1994).

An example of a 3 cm thick flowstone section is shown in Fig. 1. A cross section of the flowstone was cut and polished for better visibility of growth layers which can clearly be distinguished by colour differences between lighter and darker bands. The top of the flowstone is less dense with a microcrystalline structure and dirt inclusions indicating that this part of the specimen is not suitable for U-Th dating. The bottom of the flowstone is denser but also shows substantial amounts of dirt incorporated in the calcite. Five subsamples were obtained from this section by sawing cuts parallel to growth layers using a diamond wire saw and breaking off small solid pieces using a scalpel (subsamples 3–7). Two additional powder samples (subsamples 1 and 2) were drilled from the top of the section with a handheld micro drill.

The measured $^{230}\text{Th}/^{232}\text{Th}$ activity ratios shown in Fig. 1 indicate the degree of contamination with detrital material. Typical bulk earth detritus has a $^{230}\text{Th}/^{232}\text{Th}$ activity ratio of 0.8 ± 0.4 . The value of 1.5 for the topmost subsample confirms that this part of the section has high dirt content. Consequently, the resulting U-Th isotope data are dominated by the detrital component, and a reliable U-series age cannot be calculated for this subsample. Subsample 2 also shows a high detrital component; however, an age can be calculated for this analysis using a bulk earth Th-correction, although the large correction leads to high dating uncertainty. The results of subsamples 3–6 have $^{230}\text{Th}/^{232}\text{Th}$ activity ratios >400 indicating that negligible detritus is included. Calculated ages require little correction and are in stratigraphic order indicating reliable results. In the case of this flowstone, U-Th dating constrains the underlying sediments to be older than 500 ka and the overlying to be younger than 150 ka.

Buried stalagmites, stalactites, or soda straws have also been suggested to provide age constraints for sediment fills in caves (Schwarcz and Blackwell 1992; St Pierre et al. 2009). Speleothem fragments such as broken soda straws can often be found mixed into cave sediments and must have formed prior to the sediment accumulation. U-series ages of these materials thus can provide a maximum age of the sediment in which they are found.

U-Series Age Constraints for Artefacts and Cave Art

In cave environments, artefacts (bones, tools) or archaeologically relevant sections such as painted cave walls may become exposed to percolating waters and subsequently covered by secondary carbonates. In most cases, only very thin layers of CaCO_3 are found on artefacts, which poses a major restriction for application of U-series dating. Reliable U-series ages can only be obtained where sufficient amounts of CaCO_3 can be removed from the artefacts and where the CaCO_3 has unambiguous stratigraphic relations to the artefacts. Since the calcite formation postdates the archaeology, its age provides a minimum age constraint. For example, Frank et al. (2002) constrained the age of Trojan artificial water-supply tunnels by dating calcite that formed on the tunnel walls. Fu et al. (2008) used calcite coatings to constrain the age of human skeleton fragments from northeastern China.

U-series dating of calcite formations covering cave art was first suggested by Schwarcz and Blackwell (1992) as a future application to provide minimum ages for the underlying art. In most cases, the amount of calcite coating cave art with unambiguous stratigraphic relationship is limited, and availability of sufficient sample size was the major obstruction of U-series dating of cave art. A few studies on cave art dating using TIMS have been published, e.g., Bischoff et al. (2003), Plagnes et al. (2003), or Pike et al. (2005). Dating cave art using U-series methods is now possible for a much wider range of paintings (motifs) again due to the significant reduction of sample material needed for precise U-series measurements (Hellstrom 2012). This enables to work on very small carbonate samples allowing dating of tiny samples scraped from calcite layers covering cave art (Fig. 2). For example, calcite crusts coating cave paintings from over 50 motifs in northern Spain have been dated using this method yielding minimum ages between 500 a and 40,800 a (Pike et al. 2012).

Fig. 2 Sampling of calcite crusts covering cave art: after identification of suitable calcite formation with clear stratigraphic relationship to the cave painting, first the surface of the section is scraped off to remove potential dust contamination and expose the calcite surface for inspection of mineral structure. Then calcite sample is scraped off with a scalpel and collected either directly in a pre-cleaned sample container (*left*) or onto a clean tray. Scraping is stopped as soon as paint becomes visible underlying the sample position (Photos: C. Hoffmann, J. Zilhão)

Summary and Conclusions

In cave environments, archaeologically relevant sections or artefacts can be found with stratigraphic relations to secondary calcite deposits which can be dated by U-series methods. State-of-the-art U-series techniques minimize sample sizes and thus allow selection of the most suitable calcite formations to provide many possibilities for employing this technique in archaeological contexts. The stratigraphic relations between calcite formation and archaeology need to be unambiguous in order to use U-series ages of calcite to constrain the age of archaeological finds and provide minimum or maximum ages.

Carbonates, Speleothem Climatic (U-Series)

David A. Richards*

School of Geographical Sciences, University of Bristol, Bristol, UK

Synonyms

Carbonates: calcite, aragonite

Speleothem: cave deposit, stalactite, stalagmite, flowstone

Climatic: proxy climate data

U-series: $^{230}\text{Th}/\text{U}$ dating, U-series disequilibrium

Definition

Carbonates. Strictly, a salt of the anion group CO_3^{2-} , but here refers specifically to calcium carbonates, generally associated with limestones (i.e., calcite and aragonite).

Speleothem. A secondary carbonate precipitate formed in a cave void by degassing of CO_2 from supersaturated waters. By far the most common speleothems used for the investigation of past climate are gravity-fed dripstones, such as stalagmites or flowstones formed in the vadose zone, as opposed to phreatic examples formed at or below the water table.

Uranium-series dating. Chronological tool based on the state of disequilibrium in the U-series decay chains. Generally refers to ^{238}U – ^{234}U – ^{230}Th and ^{235}U – ^{231}Pa methods but can also be applied to U–Pb methods.

Introduction

Secondary carbonate precipitates in caves (speleothems) provide an important archive of past environmental conditions (see extensive review in Fairchild and Baker 2012) that can be related directly to past climate and accurately dated by U-series (or U–Th–Pa and U–Pb disequilibrium) methods (Richards and Dorale 2003).

The presence of speleothem deposits is unambiguous evidence that conditions in the karst catchment at the time of formation were suitable for outgassing of carbonate-saturated water; that certain threshold conditions, such as permafrost (e.g., Vaks et al. 2013) or arid conditions (e.g., Wang et al. 2004), did not prevail for significant periods; or that cave passages were not flooded (by rising sea levels or water table, e.g., Richards et al. 1994). Thus, the presence or absence of calcite can be indicative of past climate. Also, successive growth layers in speleothems can preserve geochemical (or proxy) evidence of the state of past climate conditions, and a wide range of variables have been investigated at resolutions from submicron to cm scale, including Mg, Sr, Ba, and U elemental concentrations (e.g., Johnson et al. 2006), molecular organic matter (e.g., Blyth et al. 2008), stable isotopes of O, C (McDermott 2004), Mg (Galy et al. 2002), and Ca (Reynard et al. 2011) in the solid phase and also stable isotopes within fluid inclusions (e.g., Arienzo

*Email: david.richards@bristol.ac.uk

et al. 2013). Particularly important for both geochronology and climatic interpretation is the fact that most vadose speleothems comprise calcite, although not exclusively so, which is a dense, crystalline, stable mineral that is much less susceptible to postdepositional alteration than other climate archives, such as corals, sediments, and shells.

To successfully test models of past climate patterns in both the spatial and temporal domain, we need robust and accurate high-resolution evidence of leads, lags, or synchronous change in proxy climate signals in widely distributed archives. Increased attention on speleothems in the past decade (Henderson 2006) with a motivation to obtain ever higher precision ages on smaller subsamples has demanded constant reassessment of the basic assumptions of this dating technique, that is, accurate assessment of the state of initial conditions, closed-system behavior, and decay constants. Also, for most cases, the determination of axial growth history relies on a subsampling distribution that is less dense for dating than for the climate proxy of interest, which can be as high as sub-annual. For this reason, interpolation and extrapolation methods become just as important, in terms of age precision, as the age determinations themselves.

Initial Conditions

Uranium-series geochronology relies on the extreme fractionation in the hydrosphere of the parent U isotopes (^{238}U , ^{235}U , and ^{234}U) from their long-lived daughters ^{231}Pa and ^{230}Th . Uranium is highly mobile in the meteoric environment as either the uranyl ion or stable carbonate complexes, while the daughter products are readily hydrolyzed and either precipitated or adsorbed on detrital particulates (inorganic or organic), clay minerals, or Fe-oxyhydroxides. Because of these very distinct chemical behaviors in aqueous solutions, precipitation of calcite and other carbonate minerals such as aragonite will incorporate a state of disequilibrium in the ^{238}U and ^{235}U decay chains. With time, the system will evolve toward secular equilibrium (when $^{238}\text{U} \cdot \lambda_{238\text{U}} = ^{234}\text{U} \cdot \lambda_{234\text{U}} = ^{230}\text{Th} \cdot \lambda_{230\text{Th}}$; $^{235}\text{U} \cdot \lambda_{235\text{U}} = ^{231}\text{Pa} \cdot \lambda_{231\text{Pa}}$). With achievable precision for U and Th isotope ratios of sub-permil (<1 ‰) using state-of-the-art multi-collector mass spectrometers, finite ages >500 ka are now routinely possible; however, the maximum possible finite age is dependent on the amount of ^{234}U excess present at time of formation. While ages approaching ~0.8 Ma are possible with current technology, researchers are more likely to turn to alternative techniques including electron spin resonance, paleomagnetism, or U–Pb methods for material of this age and older.

Critical for the U–Th–Pa disequilibrium suite of methods is the assumption of negligible or known concentration of daughter products at the time of formation. It is recognized that there is always a component of Th or Pa adsorbed on detrital clays or colloidal particles, and these can be trapped in the calcite. The extent of detrital, colloidal, or hydrogenous ^{230}Th contamination is estimated by determining the ^{232}Th concentration and correcting for a typical initial $^{230}\text{Th}/^{232}\text{Th}$ activity ratio. For many samples, where silicates and clays are the principal contaminant, a bulk Earth activity ratio of 0.8 ± 0.4 is commonly used. However, this assumption should be tested by using three-dimensional isochron techniques to derive the local initial $^{230}\text{Th}/^{232}\text{Th}$ ratio (Ludwig and Titterton 1994). In numerous settings, radiogenic activity ratio values have been derived, as much as 10–100 times greater than bulk Earth (see Beck et al. 2001; Meckler et al. 2012).

A wide range of U concentrations, perhaps five orders of magnitude, has been observed in groundwaters, and this is reflected in the range of concentrations in secondary carbonate minerals, including speleothems. In general, aragonitic speleothems have higher U concentrations, by virtue of the higher partition coefficient, but calcite speleothems with concentrations $>100 \mu\text{g g}^{-1}$ have

been analyzed. Not surprisingly, higher U concentrations enable smaller sample sizes for the same effective precision. Indeed, researchers are now turning to laser ablation methods, especially in higher-concentration materials, to take advantage of the improved spatial resolution of analysis.

Closed-System Behavior

Speleothems comprise a wide variety of forms and mineralogical compositions; indeed, some samples exhibit repeated shifts in mineralogy associated with changing hydrological and/or climatological conditions. Many subsamples are not suitable for age determination because they exhibit, in section, zones of recrystallization or dissolution fronts. Not all samples provide primary, dense, crystalline calcite or aragonite throughout the growth axis, so the analyst must be careful when selecting specific horizons to date. Occasionally, primary aragonite may be recrystallized to a more stable form of calcite. If this occurs rapidly, the apparent age may be useful (e.g., Frisia et al. 2006). It is expected that material closest to hiatuses in growth might be susceptible to postdepositional alteration, yet this is often the most important calcite because it constrains the timing of initiation or cessation of continuous growth. Also, because sample sizes routinely used for multi-collector ICP-MS measurements are small (<30 mg for material with U concentrations of 100 ng g^{-1}), zones of alteration can easily bias the apparent age. For this reason, dense sampling and duplicate analyses from cogenetic horizons are expected to ensure closed-system behavior of U, Th, and Pa and provide the most accurate determination of the growth histories.

Decay Constants

Uranium-series dating relies on accurate determination of the decay constants involved and is ultimately limited, in terms of precision, by the uncertainties associated with these values. Different strategies have been used to determine these values, the most fundamental of which are direct decay counting or ingrowth. However, a recent update to the decay constants for ^{234}U and ^{230}Th relied on a different strategy (Cheng et al. 2013) that measured the U–Th isotopic ratios in numerous materials that were assumed to be at secular equilibrium and calibrated those measurements against an accurately determined gravimetric standard derived from U and Th metals of known purity. The suite of samples used included speleothems from the Alps, Australia, and South Dakota with ages ranging from 2 to 26 Ma based on U–Pb dating methods and also on vein and mega-crystalline calcite assumed to be much older. Using these improved values for decay constants, age uncertainties of 5–10 ka are achievable for materials older than 500 ka if U concentrations are >1 ppm. This degree of precision is sufficient to test the phasing relationships between records of stable isotopic composition (specifically, $\delta^{18}\text{O}$) in speleothem climate-proxy records and calculations of insolation forcing in the middle Pleistocene (Cheng et al. 2013; see Fig. 1).

Measurement Techniques

Alpha decay counting is still utilized in a few laboratories, but by far the most commonly used platform for analysis is mass spectrometry because of the reduced sample sizes and greater achievable precision. Ionization methods include thermal or inductively coupled plasma (with solution or laser introduction), and a combination of Faraday and ion counters is used for collection

Fig. 1 Sanbao $\delta^{18}\text{O}$ time series, based on the U–Th age–distance relationship using newly determined half-lives (Cheng et al. 2013). The climate-proxy data broadly matches the ~ 23 ka cycles in the summer insolation curve (60° N June, Berger, and Loutre 1991). Routine uncertainties of $< \pm 5$ ka are required to test the phasing of insolation forcing and climate response. Also, the good agreement illustrated is a strong support for the accuracy of the recent determinations of ^{234}U and ^{230}Th half-lives

in static or peak jumping mode, depending on ion beam intensity and required precision. Ionization and transmission efficiency are such that U and Th analysis can be conducted on speleothem subsamples < 50 mg (based on a typical U concentration of 300 ng g^{-1}). U and Th are separated from the carbonate matrix using extraction chromatography or ion-exchange methods prior to mass spectrometric analysis. Age uncertainty is a function of a multitude of parameters including sample size, age, U concentration, beam stability, decay constant uncertainty, and blank contribution.

Laser ablation techniques offer some distinct advantages over solution introduction protocols (see Eggins et al. 2005), although age precisions cannot be matched. If U concentrations are suitable, subsample resolution can be significantly reduced, such that individual domains of $< 100 \mu\text{m}$ can be analyzed. Also, sample preparation is more straightforward (no sample digestion or chemical purification). High-resolution maps of Sr, Ba, Mg, and U based on laser ablation can also reveal the internal architecture of samples, or growth layers, where none were visible petrographically

(Drysdale et al. 2012). These can then guide micro-milling of samples at the submillimeter scale for subsequent high-precision U-series solution work.

Constructing Growth Histories

Chronologies of past climate based on speleothems rely, for the most part, on multiple ages for subsamples that are strategically selected from along the growth axis (see Fig. 1). Subsampling density for the climate proxy of interest is generally at a much greater resolution than that used for dating, and thus, interpolation is required to estimate the age for each lamination formed along the axis. A variety of statistical strategies are employed, including linear interpolation, automatic smoothing splines, Monte Carlo simulation, and Bayesian methodology (for discussion, see Scholz et al. 2012). There is no standard method, and each has advantages and disadvantages with respect to outliers, treatment of hiatuses, and rapid changes in growth rates. Subsamples close to hiatuses are the most susceptible to alteration or contamination because they may have been exposed for extended periods of time; however, they are often the most important because they define the timing of thresholds in local hydrological or climate regime (arid/humid; submergence/emergence). Robust ages have been obtained for submillimeter wafers from former surfaces of flowstones and stalagmites deposited in underwater caves, where the calcite would have been submerged for many thousands of years (see Fig. 2). In spite of the potential problems, many robust chronologies have been developed for terrestrial stalagmite climate-proxy records that match or improve upon the resolutions of records determined from ice and ocean sediment cores, for example.

Fig. 2 Hiatus in speleothem flowstone sequence (GB-89-25-5A) collected from 18 m below present sea level in a Bahamas cave (Sagittarius; see Richards et al. 1994). The upper surface of calcite that grew during Marine Isotope 6 (MIS 6; penultimate glaciation >140 ka) was exposed to seawater, freshwater, and air in this inland blue hole prior to reinitiation of growth at ~80 ka. In spite of this, crystal terminations remain well preserved (see *arrow*) and U–Th results show no sign of age inversion (Scale bar, 1 mm width)

Comparison with Other Dating Methods

Ideally, to determine the accuracy of or improve confidence in the constructed growth histories of speleothem climate-proxy records, results determined by U–Th methods should be compared with other dating techniques for the same material. In practice, this is difficult because of the much greater precisions achievable using U-series methods. Radiocarbon methods would be useful in this regard for ages <50 ka (e.g., Hoffmann et al. 2010), but the precisions of ^{14}C dates in carbonates are not comparable because of the variability in dead carbon fraction correction that must be accommodated. Having said this, U–Th dated records (corals and speleothems) play a significant role in calibration of the atmospheric radiocarbon curves, particularly beyond the limit of overlapping tree-ring records (~15 ka). Additional dating methods that can be applied to speleothems include paleomagnetism, electron spin resonance, and Pb-210. Note that U–Pb dating methods can be applied to speleothems and are also included in the suite of disequilibrium methods (see Woodhead et al. 2006).

Conclusions

Uranium-series dating has provided excellent chronological constraints for high-resolution climate, sea level, and permafrost records preserved in secondary carbonates, especially speleothems. These have been compared directly with other climate-proxy records from ice cores, ocean cores, and lake sediments, for example, to test our understanding of the dynamics of past states of the Earth system. Mass spectrometric methods provide sufficient sensitivity to give uncertainties to the nearest year for historical archives and, perhaps, a few thousand years for ages up to ~500 ka. The technique can be applied for as long as a state of radioactive disequilibrium can be distinguished using high-precision analytical techniques on closed-system material and can be extended to include U–Pb methods, which have no effective age limit, if material has relatively high U and low Pb concentrations.

Carbonates, Pedogenic (U-Series)

Warren D. Sharp*

Berkeley Geochronology Center, Berkeley, CA, USA

Definition

Pedogenic carbonate: Secondary material consisting of authigenic carbonate and/or silica formed in the shallow vadose zone as part of soil development, typically in arid to semiarid climates.

Geochronological Significance

Pedogenic carbonate, if less than about 0.5 Myr old, dense, and relatively pure, is amenable to uranium-series dating. Such dates can provide useful estimates of the depositional age of the host rock and a time axis for paleoclimate proxy records contained in the carbonate itself.

Origin of Pedogenic Carbonate

Pedogenic carbonate (the term “carbonate” is used here for brevity, but silica is commonly also present either as a dispersed phase or in discrete layers) generally forms in regions with less than 750–1,000 mm annual precipitation, is common in a wide range of climates over more than half of the Earth’s land surface, and generally accumulates most markedly within soil profiles at depths of 0.3–2.0 m (Birkeland 1984). The primary sources of calcium ions (Ca^{2+}) for pedogenic carbonate are detrital carbonate or Ca-bearing silicates present in the parent material, wind-deposited carbonate-bearing dust, and Ca ions in rainwater (Machette 1985; Capo and Chadwick 1999). The latter two sources are sufficient for pedogenic carbonate formation in carbonate-poor parent materials. The requisite carbonate ions (CO_3^{2-}) form in the soil from a complex mixture of atmospheric CO_2 , plant-respired CO_2 , and carbon released by decomposing organic matter (Cerling 1999). The relative contributions of these sources vary with local conditions as revealed by carbon isotope studies (Amundson et al. 1994). During pedogenesis, Ca-bearing minerals are leached from the upper part of the soil profile along with trace amounts of uranium and other elements. At greater depths, typically concentrated between 0.5 and 2 m below the surface, pedogenic carbonate precipitation is caused by increasing ion strength resulting from evaporation, transpiration or freezing, degassing of CO_2 from the soil water, or changing solubility of CaCO_3 as solutions move along temperature gradients in soils (Birkeland 1984). In gravelly soils where substantial pore space may initially surround the sedimentary clasts, carbonate dissolved in the soil solutions is generally precipitated as the consequence of evapotranspiration. In soils as old as a hundred thousand years or more, up to six stages of pedogenic carbonate development have been described (Gile et al. 1966; Machette 1985).

Carbonate-rich clast coatings that begin to form on the bottoms of clasts in the earliest stages of carbonate accumulation in gravelly soils can consist of dense, pure, laminated carbonate that may be

*Email: wsharp@bgc.org

highly suitable for uranium-series (hereafter, U-series) dating (e.g., Ludwig and Paces 2002; Sharp et al. 2003). Datable thicknesses of such clast coatings (0.5 mm or less) may accumulate in as little as a few hundred years after host deposition. Accordingly, U-series dating of early formed pedogenic carbonate clast coatings can provide useful estimates for the age of gravelly alluvium deposits, which may be otherwise difficult to date.

U-Series Dating Applied to Pedogenic Carbonate

The basis for U-series dating using the $^{230}\text{Th}/\text{U}$ system is derived from the relation among ^{230}Th , ^{234}U and ^{238}U , all nuclides of the ^{238}U decay series. ^{230}Th (half-life 75.69 kyr) is the alpha-decay product of ^{234}U (half-life 245.25 kyr), which in turn forms by alpha decay of ^{238}U (half-life 4.4683 Gyr) through two short-lived intermediate daughter isotopes (Jaffey et al. 1971; Cheng et al. 2000). A closed uranium-bearing system will evolve toward a state of secular equilibrium in which the number of decays per unit time (the activity) of each nuclide in the decay series becomes equal. Newly formed pedogenic carbonate usually contains ppm levels of uranium and is depleted in ^{230}Th relative to secular equilibrium because uranium is immensely more soluble than thorium in oxygenated, infiltrating surface waters and soil waters. The initial concentration of ^{234}U in pedogenic carbonate generally exceeds the value obtained under secular equilibrium conditions because ^{234}U is enriched in soil waters by two processes: (1) ejection from particles by recoil upon its formation by alpha decay from ^{238}U and (2) enhanced solubility relative to ^{238}U because ^{234}U is located in lattice sites damaged by alpha decay. Accordingly, U-series dating using the $^{230}\text{Th}/\text{U}$ system relies on the ingrowth of ^{230}Th and the decay of ^{234}U toward secular equilibrium in a closed system (Ivanovich et al. 1992). Carefully selected, dense pedogenic carbonate has been shown to remain closed with respect to the $^{230}\text{Th}/\text{U}$ system for up to >500 kyr (Ludwig and Paces 2002).

The U-series method is sensitive to the presence of initial ^{230}Th , which will result in anomalously old apparent ages if left uncorrected. Mineralogically pure carbonate precipitated from oxygenated soil waters is likely to have negligible initial Th contents due to its extremely low solubility relative to U. This inference is supported by high $^{230}\text{Th}/^{232}\text{Th}$ activity ratios – that is, the ratio of uranogenic ^{230}Th to common ^{232}Th (the abundant Th isotope, with half-life ~14 Gyr) – observed in some visibly pure pedogenic carbonate samples (e.g., Sharp et al. 2003). These high $^{230}\text{Th}/^{232}\text{Th}$ activity ratios must reflect in situ decay of uranium in initially thorium-poor material (rather than incorporation of extraneous ^{230}Th) because coherent microstratigraphic relations are preserved among subsamples with widely varying $^{230}\text{Th}/^{232}\text{Th}$ ratios. Nonetheless, most pedogenic carbonate contains some ^{232}Th , probably reflecting contamination of the authigenic carbonate cements by fine-grained detritus, implying the presence of detrital ^{230}Th , ^{234}U , and ^{238}U . This detrital component must be subtracted from the measured concentrations to obtain the composition of the pure authigenic component, which has age significance.

U-series dating of pedogenic carbonate was pioneered by Ku et al. (1979), who used 5–8 g samples from the inner 2–3 mm of pedogenic carbonate rinds developed in soils on Pleistocene gravels of the arid Vidal Valley, California. Samples were leached with 1N HCL and both leachates and insoluble residues were analyzed using decay counting by alpha spectrometry. Correction for detrital U and Th isotopes was made using the residue analyses, which had U-Th isotopic ratios close to secular equilibrium and an average atomic $^{232}\text{Th}/^{238}\text{U}$ of 4 – similar to average upper continental crust (Taylor and McLennan 1985). More recently, carefully selected, milligram-size portions of pedogenic carbonate rinds that were totally dissolved and analyzed by mass spectrometry have been shown to be highly suitable for U-series dating (e.g., Ludwig and Paces 2002; Sharp et al. 2003).

Most such samples have sufficiently high $^{230}\text{Th}/^{232}\text{Th}$ activity ratios that correction for initial isotopes can be made using a model detritus composition (Ludwig and Paces 2002). This “single sample, single date” approach precludes meaningless $^{230}\text{Th}/\text{U}$ ages that can sometimes result from chemical fractionation of Th from U during laboratory processing by leach-residue techniques (e.g., Bischoff and Fitzpatrick 1991). Furthermore, the greatly reduced sample size of the latter approach helps to minimize averaging of long ($>10^5$ years), and sometimes visibly discontinuous, depositional histories of individual rinds and allows ages to be tested against microstratigraphic relations.

Highly sensitive analyses of U and Th in carbonates by ICP-MS (inductively coupled mass spectrometry; e.g., Shen et al. 2012) now make it possible to precisely analyze samples of pedogenic carbonate of sub-milligram size. Such analytical improvements, along with laser ablation ICP-MS analyses of carbonates (Hellstrom et al. 2010), facilitate studies of texturally complex, slowly formed pedogenic carbonate microstratigraphic sequences (e.g., Brock and Buck 2005). Where pure pedogenic silica is present, its higher U concentrations (>50 ppm) make analyses by SIMS (secondary ion mass spectrometry; i.e., ion probe) feasible, allowing dating at a spatial resolution of $\sim 30\text{ }\mu\text{m}$, albeit at relatively low precision (age uncertainties of $\pm 10\text{--}20\%$; Maher et al. 2007).

Examples of Application of U-Series Dating to Pedogenic Carbonate

U-series dating of pedogenic carbonate has been used to date landforms offset by faults, thereby establishing the timing and rate of fault motions in Nevada (Ludwig and Paces 2002), Tibet (Blisniuk and Sharp 2003; Gold et al. 2011), and along the San Andreas Fault system in southern California (Fletcher et al. 2010, 2011). Nuriel et al. (2012) studied and dated calcite veins and striations associated with the Dead Sea fault in Israel, thereby constraining the timing of mineralization and related deformation on the fault. Dating of Late Quaternary alluvial fans using U-series on pedogenic carbonate coordinated with ^{10}Be exposure dating has shown that the two techniques provide consistent dates. Combining results from both methods provides enhanced reliability relative to dates determined using a single technique (e.g., Behr et al. 2010; Blisniuk et al. 2012). U-series dating of pedogenic carbonate has been applied to landforms of climatic and geomorphic significance; for example, dates on glaciofluvial terraces in Wyoming help to constrain the timing of the penultimate glaciation in the Rocky Mountains (Sharp et al. 2003). U-series on pedogenic carbonate has been applied to calcic soils in Spain to quantify ages of landforms hosting such soils characterized by advanced stages of pedogenic carbonate development including the formation of calcretes (Candy et al. 2004, 2005).

Summary

Pedogenic carbonate ($\pm$ silica) is widely developed in soils formed in arid to semiarid climates. U-series dating of dense, relatively pure pedogenic carbonate that commonly forms in coarse clastic deposits such as alluvial gravels can provide reliable ages for Middle and Late Quaternary calcic soils and useful estimates of the ages of host deposits and landforms.

Definition

Uranium-series (U-series) isotopes are radionuclides that compose the ^{238}U and ^{235}U decay chains. Measurements of U-series isotopes in soils and river sediments can be used to infer timescales of chemical weathering and derive quantitative estimates of soil age and production rates as well as sediment transport rates through catchments.

Historical Material

U-series isotopes in geological materials have received significant interest since the 1960s (Adams et al. 1959; Pliler and Adams 1962; Cherdyntsev et al. 1964; Rosholt et al. 1966; Syromyatnikov et al. 1967; Hansen and Stout 1968; Scott 1968; Syromyatnikov and Ivanova 1968; Cherdyntsev 1969; Titayeva and Veksler 1977) or even earlier, when investigations were mostly supported by governmental programs motivated by the development of raw materials for nuclear weapons and power (Adams et al. 1959). The first studies were interested with the mobility of actinides in weathering profiles (Pliler and Adams 1962; Rosholt et al. 1966; Hansen and Stout 1968; Hansen and Huntington 1969; Moreira-Nordemann 1977, 1980), while others were investigating the radioactive disequilibrium associated with uranium ore deposits (Cherdyntsev et al. 1964; Syromyatnikov et al. 1967; Lively et al. 1979), in groundwater (Osmond and Cowart 1976, 1982; Cowart and Osmond 1977; Krishnaswami et al. 1982; Osmond et al. 1983) or in streams and estuaries (Scott 1968; Martin et al. 1978; Mangini et al. 1979). Early studies in nuclear physics examined the mechanisms for U-series isotope fractionation (e.g., Linhard and Scharff 1961; Harvey 1962). Later work would explore how these processes could account for radioactive disequilibrium in geological materials with a focus on recoil and preferential leaching effects (Kigoshi 1971; Fleischer and Raabe 1978a, b; Fleischer 1980, 1982a, b, 1983; Sheng and Kuroda 1984; Hussain and Lal 1986; Dran et al. 1988; Adloff and Roessler 1991). Despite a large body of early work on U-series isotope fractionation during chemical weathering, the 1980s and 1990s saw a decrease in interest for this application. However, the topic has regained interest since the late 1990s and early 2000s, in part thanks to improved chemical separation methods (Horwitz et al. 1993; Chabaux et al. 1994; Horwitz 1996; Bourdon et al. 1999) and the development of plasma source

Fig. 1 Uranium-238 decay chain. Each nuclide half-life is shown under its name and expressed in years (yr), days (d), hours (hr), or minutes (min). Two types of radioactive decay occur in the chain: α (decay energy shown under the symbol) and β

mass spectrometry allowing the precise measurement of low abundance U-series isotopes (e.g., Turner et al. 2001).

Essential Concepts and Applications

Uranium-238 (^{238}U) decays through a series of radioactive products to ^{206}Pb as the final, stable isotopic product (Fig. 1). The ^{238}U decay chain is composed of a series of daughter-parent systems where each daughter nuclide is the result of alpha or beta disintegration of the parent nuclide. Although “uranium-series” refer to both ^{238}U and ^{235}U decay chains, most studies focus on the decay products in the ^{238}U decay series, in particular three isotopes: ^{238}U , the parent nuclide of the decay series; ^{234}U , which is produced after alpha decay of ^{238}U into ^{234}Th followed by rapid decays to ^{234}Pa (by beta emission of ^{234}Th with a half-life of 24.1 days) and ^{234}U (by beta emission of ^{234}Pa with a half-life of 6.67 h); and ^{230}Th , produced by alpha decay of ^{234}U with a half-life of 2.46×10^5 a.

For any geological system that remains closed to mass exchange for more than a million years, all radioactive systems in the decay chain are in *secular equilibrium*, i.e., the activity of the daughter nuclide equals that of the parent. The *activity* of a nuclide is its rate of decay, i.e., the product between its abundance and its decay constant. Results are generally expressed in terms of daughter-to-parent activity ratios, for instance, $(^{234}\text{U}/^{238}\text{U})$ and $(^{230}\text{Th}/^{238}\text{U})$, with the use of parentheses indicating activities. Thus, if a system is in secular equilibrium, these ratios are equal to unity.

A variety of geological processes induce fractionation between U-series isotopes, termed *radioactive disequilibrium*, in which case the activity ratio deviates from unity. Once a disequilibrium is produced, the parent-daughter system will tend to return to secular equilibrium via radioactive decay, over a timescale that is about five times the half-life of the daughter nuclide (for instance, 1.2 Ma for ^{238}U - ^{234}U , 375 ka for ^{234}U - ^{230}Th). Thus, the value of the activity ratio in a geological sample is a function of (i) the behavior of isotopes during geological processes and (ii) the time elapsed since fractionation for a discrete process or the rate of fractionation for a continuous process.

Mechanisms of U-series Disequilibrium

Uranium can be found in two stable oxidation states, 4 and 6, while the only stable oxidation state for thorium is tetravalent. At low oxygen fugacity (i.e., reducing conditions as it is common in the Earth’s interior), uranium is tetravalent and has properties similar to thorium, although differences exist which yield ^{230}Th - ^{238}U disequilibrium in magmas (Harmon and Rosholt 1982; Bourdon et al. 2003; Lundstrom 2003; Turner et al. 2003b; Dosseto et al. 2010). Under oxidizing conditions (as it is commonly the case at the Earth’s surface), U is present in its hexavalent state and forms the uranyl ion UO_2^{2+} . This ion can form stable carbonyl complexes, which accounts for uranium’s solubility in natural waters. In contrast, thorium is relatively insoluble at pH values typical of surface waters (5–8), and it is soluble only in the presence of organic acids at low pH (<3), via binding to organic colloids (Langmuir and Herman 1980; Viers et al. 1997). As a consequence of these chemical behaviors, solutes (e.g., groundwater, soil pore water, and stream water) are generally enriched in U relative to Th and are characterized by $(^{230}\text{Th}/^{238}\text{U})$ activity ratios less than 1. *Weathering products* (hereby restricted to *solid* weathering products, i.e., weathered rocks, soils, stream sediments) are generally enriched in Th relative to U and show $(^{230}\text{Th}/^{238}\text{U})$ activity ratios greater than 1 (Syromyatnikov and Ivanova 1968; Titayeva and Veksler 1977; Latham and Schwarcz 1987).

Although ^{234}U and ^{238}U theoretically have the same chemical behavior, as illustrated by the absence of significant fractionation in igneous rocks, fractionation between these two isotopes occurs at the Earth’s surface, resulting in an enrichment of ^{234}U in natural waters and a depletion in weathered rocks, soils, and sediments (Syromyatnikov and Ivanova 1968; Titayeva and Veksler 1977; Latham and Schwarcz 1987). This fractionation occurs as a consequence of two processes: (i) Direct recoil of ^{234}Th out of the mineral grain during alpha decay of ^{238}U and subsequent beta decays into its granddaughter ^{234}U (Fig. 1; Kigoshi 1971). This occurs because when ^{238}U decays

Fig. 2 Schematic representation of various scenarios of alpha decay. In (a), case (a1) occurs when ^{234}Th (black dot) is directly recoiled out of the source mineral (red circle). In case (a2), the direction of recoil from ^{238}U (gray dot) is such that ^{234}Th is embedded further into the source mineral. In case (a3), ^{234}Th is embedded in an adjacent mineral (blue circle). In all cases, ^{234}Th then decays rapidly into ^{234}U . In (b), a fluid fills in the pore space. In case (b1), the ^{234}Th is directly recoiled into the fluid which readily transports the subsequently formed ^{234}U . In case (b2), mineral dissolution (light red area) exposes a recoil track such that the embedded ^{234}U can be leached out of the track. In case (b3), the recoil track in the adjacent mineral is exposed to the fluid and the embedded ^{234}U leached away

into ^{234}Th , the daughter is displaced by 15–35 nm (the *recoil length*) in most minerals (Hashimoto et al. 1985). If this occurs within a recoil length from the mineral surface, a fraction of ^{234}Th can be lost to the surrounding medium (air or water; Fig. 2 case (a1)). (ii) Preferential leaching of ^{234}U embedded in recoil tracks (Fleischer 1980, 1982b). The fraction of recoiled ^{234}Th that is not directly ejected into the surrounding medium is embedded in recoil tracks either deeper the source mineral (Fig. 2 case (a2)) or into adjacent minerals (Fig. 2 case (a3)) especially when the pore space is filled with air (Sun and Furbish 1995). When a solution fills the pore space, the ^{234}U produced by decay is leached out of the exposed recoil tracks in adjacent minerals (Fig. 2 case (b3)) (Fleischer 1980; Andersen et al. 2009) or from newly exposed recoil tracks as a result of dissolution of the source mineral (Fig. 2 case (b2)). Complete leaching of embedded nuclides occurs over a timescale as short as 200 years (Fleischer 1980).

Initially, it was proposed that by determining the fraction of ^{234}Th directly recoiled out of minerals, one could quantify the supply rate of ^{234}U to the solution leaching these minerals (Kigoshi 1971). However, it was later postulated that preferential leaching of embedded ^{234}U is another important mechanism for the delivery of ^{234}U to solutions (Fleischer 1980). It is important to note that although differentiating both mechanisms is important to accurately study the enrichment of solutions in ^{234}U over ^{238}U , when studying the complementary depletion in ^{234}U in residual solids (as it is the case below), such differentiation is not necessary. Indeed, assessments of recoiled ^{234}Th

can overestimate the actual amount of ^{234}U lost to the solution if a significant proportion is embedded into adjacent grains; however, it is exactly because these embedded nuclides are subsequently leached from recoil tracks that eventually all recoiled ^{234}Th end up being lost from the minerals (whether directly recoiled in the water or embedded to another grain and later leached).

As mentioned above, radioactive disequilibrium is generally reported as the ratio of daughter-to-parent activity, e.g., ($^{234}\text{U}/^{238}\text{U}$). The activity ratios used to report U-Th disequilibrium in the literature vary: some studies report ($^{230}\text{Th}/^{234}\text{U}$), while others use ($^{230}\text{Th}/^{238}\text{U}$). Since ^{230}Th is the produce of ^{234}U decay, it would seem more sensible to report ($^{230}\text{Th}/^{234}\text{U}$) ratios. However, if the aim is to study the U-Th disequilibrium imparted by the difference in mobility of U and Th during mineral dissolution, this ratio may not be appropriate: ^{234}U is sensitive not only to U mobilization during dissolution but also to direct recoil and preferential leaching of ^{234}U embedded in recoil tracks. ^{230}Th is also sensitive to these two processes, but because of the high reactivity of Th with particle surfaces, it is highly likely that the ^{230}Th released by recoil or preferential leaching will rapidly re-adsorb on mineral grains. As a consequence, the ($^{230}\text{Th}/^{238}\text{U}$) activity ratio may be a more appropriate measure of the U-Th disequilibrium that occurs during mineral dissolution.

Occurrence of U-series Nuclides in Weathering Products

Weathering products can be simplified as the mixture of four components: (i) primary minerals (i.e., mineral phases from the parent rock), (ii) secondary minerals produced during incongruent dissolution of primary minerals, (iii) secondary minerals produced by precipitation from soil pore water, and (iv) organic matter. Our understanding of the occurrence of U-series disequilibrium is bound to the distribution of U in these components.

As reviewed in Chabaux et al. (2003), uranium can be sorbed onto mineral surfaces with a sorption efficiency ranked as follows: Fe oxides and silica gels > clays and micas > opals (Ames et al. 1983a). For Fe oxides, the sorption efficiency is ordered as follows: amorphous Fe oxyhydroxides > goethite > hematite (Ames et al. 1983a, c; Hsi and Langmuir 1985; Manceau et al. 1992; Waite et al. 1994). For clays, U sorption efficiency is in the following order: montmorillonite > illite > kaolinite (Borovec 1981; Ames et al. 1983a; Shirvington 1983). U can also be sorbed on micas, mostly on muscovite, with a low sorption efficiency for biotite and phlogopite (Ames et al. 1983b). Near-neutral pH conditions tend to favor U sorption, while in acidic conditions, U sorption is enhanced by the presence of humic acids (Lenhart and Honeyman 1999). It has been shown that in some cases, organic acids can control the U budget of weathering products (Plater et al. 1992; Porcelli et al. 1997; Andersson et al. 1998; Dequincey et al. 2002; Chabaux et al. 2003; Vigier et al. 2005; Dosseto et al. 2006a, b). Plater et al. (1992) showed that for bed load sediments from the Witham River in the UK, the organic fraction accounts for 2–12 wt% of the total U budget, while amorphous and crystalline Fe-Mn oxyhydroxides represent 10–20 wt%. They found that resistate minerals, i.e., primary minerals, concentrate 62–85 wt% of the U in the sediments.

In primary minerals, U is mostly found in accessory phases with zircon, xenotime, or monazite exhibiting concentrations as high as several 1,000s of ppm, while ilmenite and magnetite have U concentrations between a few ppm and several 10s of ppm, and apatite between 5 and 150 ppm (Adams et al. 1959). Major minerals like quartz or feldspars contain sub-ppm to ppm levels of U, most likely in liquid inclusions or submicroscopic inclusions of accessory minerals (Adams et al. 1959). Other major minerals like micas or amphiboles can contain up to 10s of ppm of U. Interstitial U, i.e., at grain boundaries, along cleavages, and in microfractures, is another significant pool of uranium in igneous parent rocks (Tieh and Ledger 1981; Guthrie and Kleeman 1986). Guthrie and Kleeman (1986) showed that during the early stages of granite weathering,

Fig. 3 Schematic representation of the role of the different components of weathering products to their U-series isotope composition. U-poor minerals (e.g., quartz) do not contribute to the radioactive disequilibrium of soils or sediments because of their low U concentration. U-rich minerals that weather readily (e.g., monazite) do not contribute to the radioactive disequilibrium of soils or sediments because they are entirely dissolved and their entire ^{238}U , ^{234}U , and ^{230}Th isotope budget is transferred to the soil-forming solution. Insoluble U-rich minerals (e.g., zircon) do not contribute to radioactive disequilibrium because they are highly resistant to weathering. However, these minerals can contribute to radioactive disequilibrium if (i) they are highly metamict, which favors release of ^{238}U and its decay products, and (ii) they implant ^{234}U and ^{230}Th to adjacent minerals as a result of decay. U-rich primary minerals that weather, but survive weathering (e.g., muscovite or apatite), as well as secondary minerals derived from the incongruent dissolution of these primary minerals provide the dominant control on the U-series isotope composition of soils or sediments. In addition, authigenic phases (as secondary minerals precipitated from soil pore water) and organic matter inherit the U-series isotope composition of the solution from which they formed and can also contribute to the U-series isotope composition of the soil or sediments

“background” U (i.e., contained in quartz and feldspars) is redistributed to the interstitial pool, and a net loss of U occurs via (i) decrease of the interstitial U pool and (ii) dissolution of accessory minerals. While the model abundance of these accessory minerals decreases, their U concentration remains constant.

As shown below, U-series disequilibrium has been used in weathering products to determine the time elapsed since conversion of the parent rock into soils and sediments. In this respect, it is important to note that the behavior of primary minerals during weathering is as important as their U content: to impart radioactive disequilibrium to the weathering product, a mineral must not only (i) contain a significant amount of U but must also (ii) actively dissolve yet (iii) survive chemical weathering. On the one hand, for a U-rich mineral like zircon, because it is highly resistant to chemical weathering, it is likely that no significant loss of nuclides occur via dissolution (Fig. 3). However, it has been shown that intense metamictization can favor zircon weatherability (Balan et al. 2001). Note also that recoil can implant significant amounts of ^{234}U and ^{230}Th to adjacent minerals that may actively dissolve and this can result in a net loss of these nuclides. On the other hand, a U-rich mineral that readily dissolves and is consumed early during weathering will have no contribution to the $(^{234}\text{U}/^{238}\text{U})$ and $(^{230}\text{Th}/^{238}\text{U})$ ratios of the weathering product since all its U-series nuclides will have been lost to the solution (Fig. 3). Thus, the U-series isotope composition of primary minerals and their products is controlled by the U-rich minerals that actively dissolve but

survive the weathering process (Fig. 3). This was recently confirmed by a study of soil profiles in southeastern Australia which found a correlation between the soil residence time inferred from U-series isotopes and the soil muscovite content (Suresh et al. 2011, 2013).

Models of U-series Disequilibrium in Weathering Products

The time-sensitive property of U-series isotopes offers the perspective of being able to determine time constraints on weathering processes. Early studies investigated the qualitative potential of mechanisms to account for observed U-series isotope compositions in soils (e.g., Rosholt et al. 1966; Rosholt 1982). Latham and Schwarcz (1987) and Scott et al. (1992) later developed quantitative models that would describe the evolution of nuclide abundances in weathering products.

In Latham and Schwarcz (1987), a uranium-leach model was proposed to account for ($^{234}\text{U}/^{238}\text{U}$) ≤ 1 and ($^{230}\text{Th}/^{238}\text{U}$) > 1 in weathered granitic rocks. In this model, the abundance of a daughter nuclide, d , in the solid (rock, soil, or sediment) varies with time as a function of the amount of nuclides gained by radioactive decay of the parent, p , and the amount lost by their own decay and via dissolution:

$$\frac{dN_d}{dt} = \lambda_p \cdot N_p - \lambda_d \cdot N_d - w_d \cdot N_d \quad (1)$$

where N_p and N_d are the number of atoms of the parent and daughter nuclides, respectively; λ_p and λ_d are the decay constants for the parent and daughter nuclides, respectively (in a^{-1}); and w_d is a coefficient that represents the combined loss of the daughter nuclide during mineral dissolution and as a result of recoil when applicable (in a^{-1}). For ^{238}U , the first two terms on the right-hand side are absent because there is no parent, and ^{238}U decay can be neglected over the timescales considered (< 1 Ma).

Scott et al. (1992) proposed a similar weathering model that also explicitly accounts for the loss via recoil of a daughter nuclide produced by α decay.

$$\frac{dN_d}{dt} = (1 - f_d) \lambda_p \cdot N_p - \lambda_d \cdot N_d - w'_d \cdot N_d \quad (2)$$

where f_d is the fraction of daughter nuclide lost by recoil. In this formulation, w'_d is a coefficient that accounts for the loss of daughter nuclide via mineral dissolution only, i.e., if $f_d > 0$, $w'_d < w_d$. Note that for non-radiogenic nuclides (e.g., ^{238}U) or nuclides produced by β decay (e.g., ^{231}Pa), $w' = w$. While ^{234}U is produced by β decay from ^{234}Pa , it is lost by α recoil of ^{234}Th which rapidly decays into ^{234}Pa (half-life, $T_{234\text{Th}} = 24.1$ days), which rapidly decays into ^{234}U ($T_{234\text{Pa}} = 6.09$ h).

It has been proposed that in silt-sized sediments ^{234}U - ^{238}U fractionation occurs mainly via recoil and loss of ^{234}U to the surrounding medium (Maher et al. 2004; DePaolo et al. 2006). In this case, it is assumed that $w'_d = w'_g$ and Eq. (2) can be rearranged to express the ($^{234}\text{U}/^{238}\text{U}$) of the sediment as a function of time:

$$\left(\frac{^{234}\text{U}}{^{238}\text{U}} \right) = \left(\frac{^{234}\text{U}}{^{238}\text{U}} \right)_0 \cdot e^{-\lambda_4 t} + (1 - f_4) \left(1 - e^{-\lambda_4 T_{\text{comm}}} \right) \quad (3)$$

where ($^{234}\text{U}/^{238}\text{U}$)₀ is the initial activity ratio. T_{comm} is termed the comminution age and represents the amount of time needed for the activity ratio to evolve from its initial value (generally the source rock in secular equilibrium) to the observed value in the sediment. Note that because this approach

neglects the effect of chemical weathering (mineral dissolution) on U-series isotope fractionation, it is not discussed further in this contribution. The reader is referred to DePaolo et al. (2012) for a recent review.

Dequincey et al. (1999, 2002) proposed a model that allows not only for the loss of nuclide via mineral dissolution but also for its gain via precipitation of secondary minerals or dust deposition. For instance, the evolution of the abundance of a radiogenic nuclide in the solid is predicted by the equation:

$$\frac{dN_d}{dt} = \lambda_p \cdot N_p - \lambda_d \cdot N_d + \frac{F_d}{\lambda_d} - w_d \cdot N_d \quad (4)$$

where F_d is the activity input of the daughter nuclide per time unit (in atoms/a²). Note that here, recoil is not explicitly accounted for and is lumped into the dissolution coefficient, as in Latham and Schwarcz (1987).

Dosseto et al. (2008b) later modified this expression and introduced an input coefficient, Γ (in a⁻¹), such that input and dissolution coefficients could be directly compared.

$$\frac{dN_d}{dt} = \lambda_p \cdot N_p - \lambda_d \cdot N_d + \Gamma_d N_{d,i} - w_d \cdot N_d \quad (5)$$

The input coefficient Γ_d reflects how fast the initial concentration $N_{d,i}$ is increased by nuclide addition. Thus, the term $\Gamma_d N_{d,i}$ represents the flux of added nuclides (in atoms/g/a). Note that the model is sensitive to the initial isotopic ratios but not to the initial isotopic abundances (i.e., the initial U concentration, $N_{d,i}$, does not impact calculated activity ratios, but the initial activity ratios obviously do).

In order to better understand the evolution of each nuclide's abundance in the solid according to these models, processes that affect the mobility of each nuclide are reviewed below.

Mobility of ²³⁸U:

- Loss during mineral dissolution, releasing ²³⁸U to the solution (coefficient w_8). The ability of ²³⁸U to stay in solution then depends of the redox conditions, as explained above: in reducing conditions, tetravalent ²³⁸U has low solubility and will precipitate out of the solution, while in oxidizing conditions (typical of near-surface environments where mineral dissolution by weathering takes place), ²³⁸U will form the uranyl ion ²³⁸UO₂²⁺ which readily complexes with the carbonate ion to create a very stable and highly soluble species.
- Sorption from soil pore water onto mineral surfaces (coefficient Γ_8). It has been shown that uranium can be easily adsorbed on micas, clays, iron oxyhydroxides, and organic matter (Ames et al. 1983a, b, c; Chabaux et al. 2003), with a sorption capacity ranking as follows: hydrous Fe oxides > well-crystallized goethite >> montmorillonite > kaolinite (Szalay 1964; Manceau et al. 1992). Because sorption is enhanced by greater surface areas, this process has been invoked to account for the increasing radionuclide concentrations with decreasing grain size in soils (Megumi and Mamuro 1977).
- Precipitation of authigenic phases (coefficient Γ_8). The formation of carbonates and Fe-Mn oxyhydroxides can scavenge significant amounts of U from solution where U will be either adsorbed onto surfaces (see above) or incorporated into the crystal structure by isomorphic substitution (see review in Chabaux et al. 2003). When considering bulk soils or stream

sediments, the ^{238}U in these secondary phases can represent a significant proportion of the ^{238}U budget (e.g., Plater et al. 1992).

- Dust deposition (coefficient Γ_8). Gain of ^{238}U can also occur via deposition of mineral aerosols. Pett-Ridge et al. (2007) attributed U enrichments up to 531 % in Hawaiian soils older than 150 ka by dust deposition. Pelt et al. (2013) showed that dust deposition can account for up to 25 % of the U and Th budget of basaltic soils in Cameroon. Note that these are extreme scenarios because the parent material (basalt) has a low U content. The contributions from dust to the soil U budget would be less significant in granitic and sedimentary environments. Nevertheless, gain of ^{238}U via dust deposition is accounted for in the model by the parameter Γ_8 .

It is important to note that the numerical models only account for the gain of ^{238}U without differentiating between the different processes of sorption, precipitation, or dust deposition that contribute to that gain.

Mobility of ^{234}U :

- Loss during mineral dissolution (coefficient w_4). Congruent dissolution will release ^{234}U at the same rate as ^{238}U (not taking into account the preferential leaching mentioned below). In this case, no fractionation between these isotopes is expected, i.e., $w_4 = w_8$.
- Direct recoil of ^{234}Th and subsequent decay into ^{234}U contributes to enhance ^{234}U mobility compared to ^{238}U . The fraction ^{234}U lost by recoil in Scott et al.'s model is $1 - f_4$.
- Preferential leaching of ^{234}U embedded in recoil tracks. Tracks can provide pathways for migrating solutions to reach ^{234}U , thereby enhancing the mobility of ^{234}U compared to undecayed ^{238}U , i.e., $w_4 > w_8$.
- Preferential oxidation of ^{234}U compared to ^{238}U . Computer simulations of the recoiled ^{234}Th motion have shown that in minerals with a low U content, there is a high probability for ^{234}U to be found in the vicinity of oxygen atoms or radicals, making it more prone to oxidation to the hexavalent state resulting in preferential mobilization compared to tetravalent ^{238}U (Adloff and Roessler 1991). This will also contribute to a coefficient w_4 greater than w_8 .
- Sorption of ^{234}U on mineral phases (coefficient Γ_4). Although untested, it is believed that no fractionation between ^{234}U and ^{238}U occurs during this process. Thus, the adsorbed U will record the ($^{234}\text{U}/^{238}\text{U}$) ratio of the solution (i.e., Γ_4/Γ_8), which in most cases will be greater than 1. This relation is supported by measurements of ($^{234}\text{U}/^{238}\text{U}$) ratios in the exchangeable fraction leached from organic matter, carbonates, and crystalline Fe-Mn oxides that were bound to river sediments: all leachates showed values within analytical error of 1.3 (Plater et al. 1992).
- Precipitation of authigenic phases (coefficient Γ_4). As with ^{238}U , ^{234}U can be added to the bulk soil or stream sediment during the precipitation of secondary phases. Because no fractionation between ^{234}U and ^{238}U is believed to occur during secondary mineral precipitation, U in the precipitated phases will record the ($^{234}\text{U}/^{238}\text{U}$) ratio of the solution (in most cases greater than 1), which will define values of Γ_4/Γ_8 .
- Dust deposition (coefficient Γ_4). Similarly to ^{238}U , gain of ^{234}U can occur via the deposition of mineral aerosol. If this is a substantive process for U gain, the Γ_4/Γ_8 ratio represents the ($^{234}\text{U}/^{238}\text{U}$) activity ratio of the dust component.

Considering the processes described above, if sorbed U and authigenic phases can be removed by sequential leaching, we should observe ($^{234}\text{U}/^{238}\text{U}$) activity ratios <1 in weathering products. However, this is not always the case (Lee et al. 2010). A ($^{234}\text{U}/^{238}\text{U}$) >1 could be explained by the Sheng-Kuroda effect (Sheng and Kuroda 1986a, b). In this case, U-poor residual minerals can be

enriched in ^{234}U by implantation from U-rich minerals, which are subsequently removed by dissolution. Note that this process excludes zircon as a source for ^{234}U implantation as it is highly resilient to weathering.

Mobility of ^{230}Th :

- Loss during mineral dissolution (coefficient w_0). As ^{230}Th is produced by alpha decay of ^{234}U , it will be located in recoil tracks. Thus, as the mineral dissolves, recoil tracks will be exposed to migrating solutions allowing release of ^{230}Th . However, Th is highly insoluble, and any Th released to the solution is likely to precipitate back and/or be adsorbed on residual minerals. For these reasons, in most studies, it is assumed that $w_0 \ll w_4$ or w_8 . Nevertheless, significant ^{230}Th solubilization can occur in the presence of organic acids and colloids and/or at low pH (Langmuir and Herman 1980; Viers et al. 1997; Chabaux et al. 2003; Dosseto et al. 2006a, b). For instance, sediments from organic-rich rivers of the Amazon basin are characterized by $(^{230}\text{Th}/^{238}\text{U}) < 1$ (Dosseto et al. 2006a).
- Direct recoil of ^{230}Th during decay of ^{234}U . If decay of ^{234}U occurs within a few tens of nm of the mineral surface, ^{230}Th can be recoiled out of the mineral into the surrounding medium (air or water). The fraction of ^{230}Th lost by recoil is $1 - f_0$. However, as explained above, because of Th low solubility and its high reactivity for mineral surfaces (especially Fe-Mn oxyhydroxides), it is likely that ^{230}Th will be rapidly re-adsorbed onto mineral surfaces.
- Sorption of ^{230}Th from the solution onto minerals or incorporation into secondary minerals (coefficient Γ_0). Th can sorb onto organic matter, clays, and Fe-Mn oxyhydroxides (Chabaux et al. 2003), resulting in a gain of ^{230}Th . Based on $(^{230}\text{Th}/^{238}\text{U})$ and $(^{230}\text{Th}/^{234}\text{U})$ activity ratios measured during sequential leaching experiments of river sediments (Plater et al. 1992), it appears that U has a higher affinity for organic matter than Th (thus, Γ_8 or $\Gamma_4 > \Gamma_0$), while the opposite is observed for Fe-Mn oxides ($\Gamma_0 > \Gamma_8$ or Γ_4).
- Dust deposition (coefficient Γ_0). Gain of ^{230}Th can also occur via deposition of mineral aerosols. If this is a substantive process for the gain of U and Th isotopes, then the Γ_0/Γ_8 ratio reflects the $(^{230}\text{Th}/^{238}\text{U})$ activity ratio of the dust component (expected to be greater than 1).

Hence, based on the processes described above, $(^{230}\text{Th}/^{238}\text{U})$ ratios $>$ or < 1 can be observed in weathering products. Because $(^{230}\text{Th}/^{238}\text{U}) > 1$ are more commonly observed, it is likely that conditions where ^{230}Th is insoluble, or where any ^{230}Th lost via recoil is adsorbed onto Fe-Mn oxides, generally prevail.

A corollary from these observations is that at low dissolution rates, and where sorbed nuclides and secondary minerals have been removed, recoil of ^{230}Th should become important and $(^{230}\text{Th}/^{238}\text{U}) < 1$ should be expected in solids. This is similar to what has been proposed to explain $(^{234}\text{U}/^{238}\text{U})$ in waters from New Zealand (Robinson et al. 2004), where loss of ^{234}U is enhanced in situations where physical weathering (comminution) dominates over chemical weathering, thus favoring recoiled ^{234}U over the bulk loss of U.

The concepts and models presented above are used to describe how $(^{234}\text{U}/^{238}\text{U})$ and $(^{230}\text{Th}/^{238}\text{U})$ ratios evolve from initial to observed sets of values over a period of time. The initial $(^{234}\text{U}/^{238}\text{U})$ and $(^{230}\text{Th}/^{238}\text{U})$ are generally taken as those of the parent rock and assumed to represent secular equilibrium (i.e., all U-series activity ratios are equal to 1). Alternatively, when modeling regolith compositions in a weathering profile, initial ratios can be those of a deeper regolith sample. The amount of time required to evolve from initial to observed isotopic compositions represents the *duration of weathering*. In a weathering profile, this can be equivalent to the age of the weathering front, termed *weathering age*, i.e., the time elapsed since the weathering front was at a given depth

(Dosseto et al. 2008b, 2012). In river sediments, this is equivalent to the *residence time of sediments in the catchment*, i.e., the time spent by sediments in the catchment since production from the bedrock, integrating storage in weathering profiles and transport in the river (Chabaux et al. 2008; Dosseto et al. 2008a; Vigier and Bourdon 2011).

The set of parameters that best describe the observed ($^{234}\text{U}/^{238}\text{U}$) and ($^{230}\text{Th}/^{238}\text{U}$) ratios is sought for, generally by inverse modeling. The resulting parameters derived from the models are the duration of weathering and the set of coefficients for each nuclide (depending on the models: f_i , w_i , and/or Γ_i , where i is the nuclide considered).

To solve these models, several important assumptions are required:

1. The coefficients for nuclide loss, w , and gain, Γ , are constant over the duration of weathering. This assumption is commonly made in studies that model chemical weathering (e.g., Chamberlain et al. 2005; Ferrier and Kirchner 2008) and laboratory experiments that suggest constant w values for a given mineral (White and Brantley 2003).
2. In Scott et al.'s (1992) model, the fraction of recoiled nuclides (coefficient f) is constant over the duration of weathering.
3. Nuclide loss and gain operate on similar timescales.
4. Because of the large number of unknowns, several samples are required, and it is assumed that their activity ratios differ only as a result of different durations of weathering. Hence, each coefficient for each nuclide is assumed to be constant across samples.

These assumptions are difficult to verify because (1) conditions for mineral dissolution and precipitation are variable with time, especially over the timescales typically modeled (10^3 – 10^6 years). It is generally assumed that any actual variations will average out over such long timescales. (2) The fraction of recoiled nuclide is dependent on the surface properties of the material, which may vary with time (e.g., as the result of mineral dissolution). (3) The onset of nuclide loss (weathering) could take place significantly earlier than nuclide gain (e.g., illuviation). Nevertheless, even in the early stages of weathering, secondary minerals that contain significant amounts of U are observed (Guthrie and Kleeman 1986; Pelt et al. 2008). (4) Constant nuclide gain and loss coefficients between samples are difficult to verify because conditions of mineral dissolution and precipitation can be variable even over small length scales. Despite these strong caveats, previous studies have yielded unprecedented constraints on rates of soil formation and sediment transport (see Chabaux et al. 2008; Dosseto et al. 2008a; Vigier and Bourdon 2011 for recent reviews).

Current Investigations, Controversies, and Gaps in Knowledge

This section presents a review of studies using U-series isotopes to constrain timescales of chemical weathering in weathering profiles, rinds, and soil chronosequences. For a review of applications to fluvial sediments, the reader is referred to the reviews by Dosseto et al. (2008a) and DePaolo et al. (2012).

Weathering Profiles

When discussing weathering profiles, we must first define a few terms. Here, the *soil* is defined as the top part of the weathering profile, which is mobile as it creeps downhill (colluvial transport). Soil production occurs by physical and chemical weathering of the underlying saprolite or bedrock, often with living organisms playing a preponderant role. The *saprolite* is defined as weathered material

Fig. 4 Conceptual definitions of the *weathering age* and the *sapolite/regolith production rate*. If one considers the downward propagation of the weathering front into bedrock (*lower dashed line*), the weathering age, τ_{sap} , of a given sapolite sample (*red dot*) is the amount of time required for the weathering front to migrate over the distance h_{sap} , which is the height of the sample above the current weathering front. The sapolite or regolith production rate ϵ_{sap} (in mm/ka), averaged over the distance h_{sap} , can then be calculated by dividing h_{sap} (in mm) by τ_{sap} (in ka) (Modified from Dosseto et al. (2008b))

that still retains some structural aspects of the bedrock. It is produced at the *weathering front* by physical and chemical weathering of the bedrock. The *regolith* is the ensemble of sapolite and soil, which together constitutes the *weathering profile*. Thus, sapolite production, regolith production, and weathering front advance refer to the same process.

The development of weathering profiles is the result of a complex interaction between tectonics, climatic, and biotic processes. The thickness and nature of these profiles are an expression of landscape evolution in response to these various mechanisms. The topsoil is of particular importance because it is the basic resource required for sustaining nearly all biological ecosystems including agriculture and human civilizations. Despite this importance, little is known on how fast weathering profiles develop. In contrast, their rate of denudation is well constrained, even at millennial timescales (using cosmogenic isotopes; Brown et al. 1995, 1998). Cosmogenic isotopes can also be used to determine soil production rates (Heimsath et al. 1997; Larsen et al. 2014); however, this requires the assumption that the soil thickness is in steady state, which is seldom verifiable. This approach, by definition, renders it impossible to evaluate soil evolution, i.e., imbalances between production and denudation. Indeed, even if soil thickness has reached a steady state, how was it achieved? The soil must have been thickening before reaching steady state. Furthermore, soil production is only one aspect of the development of a weathering profile, with production of sapolite or regolith being the other, even more important aspect. It has been proposed that cosmogenic isotopes could also be used to infer sapolite production rates (Dixon et al. 2009); however, this suggestion also requires the assumption that the entire weathering profile thickness is in steady state, which is not easily tested.

Fig. 5 Conceptual definitions of the *soil weathering age* and *production rate*. If one considers a given soil sample (yellow dot), the soil weathering age, τ_{soil} , is the amount of time required for the soil-saprolite boundary (dashed line) to migrate downward over the distance h . The distance h represents the height of the soil sample above the current soil-saprolite boundary. Two cases are considered: in case 1, bioturbation is neglected, and the soil production rate ϵ_1 , averaged over the distance h , is the ratio of h over τ_{soil} . In case 2, bioturbation is considered, and the soil production rate ϵ_2 , averaged over the entire soil thickness H , is the ratio of H over τ_{soil} . In the latter case, the soil thickness must be in steady state in order to obtain a meaningful production rate (Modified from Dosseto et al. (2008b))

U-series isotopes offer an alternative to quantify soil and saprolite production rates. Using the model of Dequincey et al. (2002), it is possible to model the amount of time that elapsed to produce the observed U-series isotope composition since departure from secular equilibrium. This is equivalent to the time elapsed since the onset of chemical weathering and is termed *weathering age* (Fig. 4). By using the weathering age of a given saprolite sample in the profile and its height above the weathering front (i.e., the difference between its depth and the depth of the weathering front), we can infer an average saprolite (or regolith) production rate. This represents the average rate at which the weathering front has propagated between the two depths considered (Fig. 4). Similarly, considering a soil sample and using the composition of the underlying saprolite as the initial conditions, we can use the time required to evolve from the U-series isotope composition of the saprolite to that of the soil sample and the height of the soil sample above the soil-saprolite boundary to infer an average soil production rate (Fig. 5).

This approach has been applied to weathering profiles developed over granitic lithologies in tectonically passive, tropical/equatorial regions of south America (Mathieu et al. 1995) and western Africa (Boulad et al. 1977; Dequincey et al. 1999, 2002). In Cameroon, Boulad et al. (1977) estimated regolith production rates of 70 mm/ka (Fig. 6 and Table 2). In Burkina Faso, while no regolith production rate was estimated, Dequincey et al. (2002) determined weathering ages of ~400–500 ka. In the Amazon, Mathieu et al. (1995) calculated that it took ~300 ka to develop 15 m

Table 1 Parameters used for U-series isotope models

Parameter	Description	Units
N_8, N_4, N_0	Concentrations of ^{238}U , ^{234}U , and ^{230}Th , respectively	Atoms g^{-1}
$\lambda_8, \lambda_4, \lambda_0$	Decay constants for ^{238}U , ^{234}U , and ^{230}Th , respectively	a^{-1}
w_8, w_4, w_0	Dissolution coefficients for ^{238}U , ^{234}U , and ^{230}Th , respectively	a^{-1}
$\Gamma_8, \Gamma_4, \Gamma_0$	Gain coefficients for ^{238}U , ^{234}U , and ^{230}Th , respectively	a^{-1}
f_4, f_0	Fraction of recoiled ^{234}Th (and thus ^{234}U) and ^{230}Th , respectively	Unitless

Fig. 6 Compilation of U-series-isotope-derived regolith (closed *rectangles*) and soil (*open rectangles*) production rates (in mm/ka)

of regolith in the Amazon. This implies an average regolith production rate of 50 mm/ka (Table 2). These production rates are surprisingly high considering that (i) erosion rates in these areas are most likely <10 mm/ka and (ii) weathering rates are expected to be slow because the weathering front is several tens of meters deep and likely to be isolated from meteoric waters (Gaillardet et al. 1995, 1997, 1999). However, it is important to note that regolith production rates inferred from U-series isotopes are averaged over a timescale that represents the weathering age. Thus while modern weathering rates are most likely slow, they were probably much higher in the past when the weathering front was closer to the surface and subject to higher rainfall and temperatures.

A U-series isotope study was also conducted in Puerto Rico (Chabaux et al. 2013), where the weathering profile is also developed over a granitic parent rock under tropical conditions, but erosion rates are much higher than in western Africa or Brazil (43 ± 15 mm/ka (Brown et al. 1995); 33 ± 8 mm/ka (Riebe et al. 2003)). Calculated regolith production rates were 45 ± 12 mm/ka (Chabaux et al. 2013) (Table 2). This implies that, at the scale of the weathering profile, the loss of regolith is largely balanced by its production from the bedrock. A recent U-series study of stream sediments in the same area shows that a balance between rates of regolith production and erosion is also true at the catchment scale (Dosseto et al. 2014). These results are in agreement with previous work (White et al. 1998; Riebe et al. 2003; Turner et al. 2003a; Pett-Ridge et al. 2009a, b; Ferrier et al. 2010). Furthermore, similar regolith production rates over granitic parent rock in

Table 2 Compilation of regolith and soil production rates from U-series isotope studies

Location	Parent rock	Regolith (or saprolite) production rate (mm/ka)	Soil production rate (mm/ka)	Reference
<i>Weathering profiles</i>				
Cameroon	Granite	70	n/d	Boulad et al. (1977)
Burkina Faso	Granodiorite	30–40	n/d	Dequincey et al. (2002)
Amazon (Brazil)	Granite	50	n/d	Mathieu et al. (1995)
Icacos (Puerto Rico)	Granodiorite	45 ± 12	n/d	Chabaux et al. (2013)
Bisley (Puerto Rico)	Volcaniclastic sedimentary rock	334 ± 46	n/d	Dosseto et al. (2012)
Nunnock (Australia)	Granodiorite	4–46	12–77	Dosseto et al. (2008b)
Frogs Hollow (Australia)	Granite	n/d	10–24	Suresh et al. (2013)
Shale Hills (PA, USA)	Shale	n/d	17–50	Ma et al. (2010, 2013)
<i>Weathering rinds</i>		Rind formation rate (mm/ka)		
Costa Rica	Basalt	0.5 ± 0.2		Pelt et al. (2008)
Guadeloupe	Basalt	0.18–0.24		Ma et al. (2012)
Icacos (Puerto Rico)	Granodiorite	52 ± 13		Chabaux et al. (2013)

different areas suggest that production is relatively insensitive to erosion rates and is mostly controlled by the composition of the parent rock and/or climatic conditions.

Dosseto et al. (2012) suggested that the composition of the parent rock is a more important control on regolith production rates than climatic conditions, because they calculated production rates of 334 ± 46 mm/ka for a weathering profile developed over a volcaniclastic sedimentary rock in the same region (and thus very similar climatic conditions) as the granitic profile of Chabaux et al. (2013) (Fig. 6 and Table 2). These rates are faster than those for the granitic profile by a factor of ~ 4 .

Studies have also been conducted in temperate regions for weathering profiles developed over granitic lithologies in southeastern Australia (Dosseto et al. 2008b; Suresh et al. 2013) and shale in northeastern USA (Ma et al. 2010, 2012). In southeastern Australia, the region studied is characterized by a retreating escarpment separating a coastal plain to the east from highland plateaus (elevation ~ 900 m) to the west. Weathering profiles were studied in two different geomorphic contexts: on the escarpment (Dosseto et al. 2008b) and on the plateau (Suresh et al. 2013). Sampling strategies differed between the two studies in that Dosseto et al. (2008b) sampled profiles across the hillslope, while Suresh et al. (2013) sampled profiles on ridgetops so that colluvial transport could be neglected.

On the escarpment, saprolite weathering ages ranged from 0.55 to 6.2 Ma. Values increase downhill with distance from the ridge. These estimates represent the amount of time required to develop ~ 25 m of saprolite and result in saprolite production rates ranging between 4 and 46 mm/ka (Dosseto et al. 2008b) (Table 2). These values are similar to local estimates of denudation rates

(9–68 mm/ka; Heimsath et al. 2000), thus demonstrating that the entire weathering profile is in steady state. This suggests that, over the 0.55–6.2 Ma of saprolite development, an equilibrium has been reached between erosion and the conversion of granitic bedrock into saprolite. Similarly, soil weathering ages range from 6 to 38 ka representing the amount of time needed to develop ~0.5–1 m of soil from the underlying saprolite. Soil production rates calculated from U-series range from 12 to 77 mm/ka (Table 2). Here again, it is similar to denudation rates and demonstrates that the soil thickness is in steady state too. Thus, at this site, the three major interfaces that constitute the weathering profile (atmosphere-soil, soil-saprolite, and saprolite-rock) are progressing downward at similar rates. These results are surprising as the escarpment is the most dynamic part of the landscape in this region.

On the plateau, calculated soil weathering ages are up to 30 ka. This represents the amount of time required to develop 30–60 cm of soil from the saprolite. Soil production rates show a much narrower range than at the escarpment, between 10 and 24 mm/ka (Suresh et al. 2013) (Table 2). Here too, production rates are similar to denudation rates inferred from cosmogenic isotopes, effectively demonstrating that soil thickness has also reached a steady state.

At the Susquehanna/Shale Hills Critical Zone Observatory in northeastern USA, Ma et al. (2010, 2013) quantified soil weathering ages and production rates from pits along two opposing hillslopes, developed over a Palaeozoic shale. On the north-facing hillslope, soil weathering ages vary between 7 and 40 ka, representing the amount of time to develop 30–70 cm of soil. This amounts to soil production rates of 17–45 mm/ka (Ma et al. 2010) (Table 2). On the south-facing hillslope, soil weathering ages vary between 12 and 16 ka (to develop 60–80 cm of soil). Inferred soil production rates are 40–50 mm/ka (Ma et al. 2013) (Table 2). These rates are similar to the range observed in granitic environments. This suggests that the composition of the parent rock has little effect on the rate of soil production. However, in the case of Shale Hills, the soil is directly developed over the parent rock, while in granitic environments it is developed over a saprolite. It is thus difficult to use results from the Shale Hills site to assess the role of parent rock composition since pedogenetic processes are quite different from those related to weathering profiles developed over granitic or volcanoclastic sedimentary parent rock.

Soil Chronosequences

Soil chronosequences are defined as a group of soils that differ in age but have similar parent materials and have formed under similar conditions of climate, vegetation, and geomorphic position (Jenny 1941). They are particularly useful for U-series isotopic studies if the soil's maximum weathering age is known as they can then be used to calibrate the U-series isotope weathering models.

Pett-Ridge et al. (2007) have studied a chronosequence of soils developed in Hawaiian tephras with ages ranging from 0.3 to 4,100 ka. They showed that the U budget of the soil is largely dominated by dust deposition at older sites and that Fe oxides are the main mineral phases carrying U in these soils. Pelt et al. (2013) reached similar conclusions on the role of dust deposition on the U budget of soils in a study of Holocene basaltic flows in Cameroon. These results are a consequence of rapid dissolution of primary phases in basaltic parental material under wet conditions (average annual rainfall: 2,500 mm/a). By 20 ka, they are completely exhausted (Crews et al. 1995). In basaltic parent material, U is mostly contained in the groundmass which dissolves very readily, leaving the soil U budget easily dominated by dust deposition and Fe oxides. Where U is contained in primary minerals that are more resistant to chemical weathering (e.g., biotite and apatite in granitic rocks, illite in sedimentary rocks), the importance of dust deposition and the role of solution-derived secondary phases would be lessened.

The U-series isotope composition of soils developed along a chronosequence has been modeled in a recent study by Keech et al. (2013). The parent material is composed of glacial outwash sediments with deposition ages ranging from 40 ka to 3 Ma. For each soil profile, they averaged the U-series isotope composition of samples collected at different depths and attempted to use the model described in Eq. (1) to reproduce the average activity ratios, knowing the maximum weathering age of each soil profile (i.e., the deposition age). In doing so, they assumed that the known age of the parent material represents an average weathering age for the profile. While it is unclear whether an average activity ratio for a given soil profile has any significance in terms of pedogenic processes, the average weathering age of a soil profile should be a value between 0 and the age of the parent material. The authors used the model described by Eq. (1) but could not reproduce the observed average values for ($^{234}\text{U}/^{238}\text{U}$) and ($^{230}\text{Th}/^{238}\text{U}$), which showed a decrease with increasing age. To explain this discrepancy, the authors proposed a two-stage model where labile U is mobilized first, followed by the mobilization of U in crystal lattices during mineral dissolution. This two-stage model assumes that the parent material was in secular equilibrium prior to soil formation. However, in this case, the parent material is an unconsolidated sediment and is likely to have already undergone significant weathering. This pre-deposition weathering episode would have imparted a disequilibrium to the parent material which would have decayed away only over >300 ka (assuming closed system, which is unlikely during the deposition of an alluvial sediment). Therefore, the greater disequilibrium observed in younger soils may simply be the result of pre-deposition radioactive disequilibria (with ^{234}U and ^{230}Th excesses over ^{238}U) which had not yet decayed away. Thus, there is no need for a two-stage model. Without knowing the U-series isotopic composition of the parent material (which was not sampled), it is not possible to derive reliable time information from this work.

Andersen et al. (2013) have studied the U-series isotopic compositions of soils from a chronosequence formed by glacier retreat in Scotland. The parent material is composed of alluvial sediments deposited in fluvial terraces with ages between 0.1 and 13 ka. At this location, the authors observed that, on average, the ($^{234}\text{U}/^{238}\text{U}$) activity ratio decreased with increasing deposition age, starting with values >1 , similarly to what was observed in Keech et al. (2013), but ($^{230}\text{Th}/^{238}\text{U}$) increased with deposition age, from values initially <1 . The model described in Eq. (1) was used to determine ^{238}U dissolution coefficients for 5.6-ka- and 13-ka-old soils, assuming that the soil weathering age was the same as the deposition age. However, here too the parent material was assumed to be in secular equilibrium. This is unlikely to be the case because soils were developed on fluvial sediments, which were unlikely to be at secular equilibrium at the onset of soil formation (as observed in all fluvial sediments; see the review in Dosseto et al. (2008a)). The decrease in ($^{234}\text{U}/^{238}\text{U}$) with soil age could reflect loss of ^{234}U via recoil or more likely (as pointed out by the authors) via preferential leaching. The initial ($^{230}\text{Th}/^{238}\text{U}$) <1 in the parent material could be explained as the sediment is likely to be derived from organic-rich hillslopes. The presence of organic acids is known to mobilize Th (Porcelli et al. 1997, 2001; Viers et al. 1997; Andersson et al. 1998; Chabaux et al. 2003), and organic-rich soil horizons can exhibit ($^{230}\text{Th}/^{238}\text{U}$) <1 (Dosseto et al. 2008b; Ma et al. 2010; Chabaux et al. 2013; Suresh et al. 2013). The increase in ($^{230}\text{Th}/^{238}\text{U}$) could be explained by the subsequent loss of U during soil development.

While the study of soil chronosequences is an exciting endeavor with a great potential to improve our understanding of soil processes and the use of U-series isotopes, the different aspects of U-series models need to be carefully considered. For instance, initial conditions (i.e., the composition of the parent material) must be adequately assessed in order to apply the appropriate model parameters.

Weathering Rinds

In the early stages of weathering, the parent rock can sometimes develop rinds of weathered material. The measurement of U-series isotopes on a depth profile across the pristine core and the outer weathering rinds can be used to infer how fast the weathering front propagates into the rock. As shown above, it is expected that U is lost preferentially compared to Th and ^{234}U preferentially to ^{238}U , so increasing ($^{230}\text{Th}/^{238}\text{U}$) and decreasing ($^{234}\text{U}/^{238}\text{U}$) activity ratios, respectively, should develop with time. However, in a study of weathering rinds developed on a basaltic clast from a 125-ka-old alluvial terrace in Costa Rica, Pelt et al. (2008) observed the opposite with ($^{230}\text{Th}/^{238}\text{U}$) < 1 and ($^{234}\text{U}/^{238}\text{U}$) > 1 in the most extensively weathered parts of the rinds. This was interpreted as the result of (i) the conservative behavior of Th and (ii) external input of U from soil solutions having ($^{234}\text{U}/^{238}\text{U}$) > 1 , with minimal loss of U during weathering. The input of U was modeled, resulting in a rind formation rate of 0.5 ± 0.2 mm/ka (Table 2). In another study, Ma et al. (2012) also found ($^{230}\text{Th}/^{238}\text{U}$) < 1 and ($^{234}\text{U}/^{238}\text{U}$) > 1 in weathering rinds from a basaltic clast from Guadeloupe Island. They inferred a rind formation rate of 0.18–0.24 mm/ka (Table 2). These rates are three orders of magnitude lower than what has been inferred considering the scale of the weathering-profile development for basaltic lithologies (Dosseto et al. 2012). As explained in Navarre-Sitchler and Brantley (2007), this apparent discrepancy stems from the fractal nature of the weathering advance rate, its value being largely controlled by the length scale over which it is measured. This is a consequence of the variable spatial resolutions used to measure the surface area of the weathering front (from the 10^{-3} m scale when studying weathering rinds to the meter scale when investigating weathering profiles). Navarre-Sitchler and Brantley (2007) showed that it is possible to compare weathering advance rates across length scales by calculating the roughness of the weathering front at each length scale, using the fractal dimension characteristic of the weathering advance rate (for instance, ~ 2.3 for basaltic weathering).

In a weathering profile developed over a granitic corestone in Puerto Rico, Chabaux et al. (2013) also quantified the rate at which weathering-rind formation advances into the corestone and estimated a value of 52 ± 13 mm/ka. Interestingly, this is similar to the saprolite production rate inferred in the same profile (Table 2). This can be explained by the small length scales of weathering-rind development studied by Pelt et al. (2008) and Ma et al. (2012) measured in millimeters, compared to the weathering rinds studied by Chabaux et al. (2013), which cover a length scale similar to that of the weathering profile developed above them.

Implications for Landscape Evolution

A compilation of calculated regolith and soil production rates, similar to the one shown in Dosseto et al. (2012), allows us to make several observations concerning the development of weathering profiles (Fig. 6). Note that these observations need to be considered with caution, given the small number of studies published so far. However, they hint at some aspects of landscape evolution that are worth investigating.

It has been known for a long time that different rocks weather at different rates, depending on the susceptibility to dissolution of the minerals that compose them. This is illustrated on Fig. 6, where in Puerto Rico, regolith production over a volcanoclastic sedimentary rock occurs at a rate more than six times faster than over granodiorite. However, parent material composition does not appear to play a strong role for soil production: soils over a shale are produced at about the same rate as those produced over a granitic rock (Fig. 6). This may imply that soil production is mostly driven by physical weathering, via the mechanical action of plants and animals, rather than by chemical weathering.

The role of climate (runoff, temperature) on regolith production is not clear from results shown in Fig. 6: granitic profiles seem to develop at similar rates across a range of climatic conditions. While it is possible that regolith production rates that are lower than expected in Africa and the Amazon may be the consequence of thick weathering profiles shielding the weathering front from meteoric waters, profiles in Puerto Rico and southeastern Australia have similar thicknesses and production rates despite very different climatic conditions.

Erosion rates in lowlands of western Africa and the Amazon are expected to be <10 mm/ka (Gaillardet et al. 1997; Wittmann et al. 2010). In contrast, Larsen (2012) has estimated long-term hillslope erosion rates in the Rio Icacos basin of Puerto Rico to be ~ 75 mm/ka, mostly driven by landslides. Despite about an order of magnitude difference in erosion rates, regolith production rates for these granitic profiles are relatively similar. They exceed erosion rates in tropical lowlands, while they are similar to or lower than erosion rates in Puerto Rico. This could suggest a decoupling between the surface (where erosion occurs) and the weathering front. The advance rate of the weathering front seems to be most sensitive to the composition of the parent material, showing similar values for granitic profiles across a range of climatic conditions and erosion rates.

Gaps in Knowledge

The models described above are intended to track the U-series isotope composition of minerals derived from the parent rock, whether they are residual primary minerals or secondary minerals formed during incongruent dissolution of primary minerals. Existing studies have focused on bulk material (regolith, soil, sediments). As explained above, the regolith is a complex mixture of primary minerals (derived from the parent rock), secondary minerals precipitated from soil pore water (e.g., carbonates and Fe-Mn oxyhydroxides), allochthonous minerals (via dust deposition), and organic matter (Fig. 3). Each of these phases is likely to have its own U-series isotope composition. Thus, the application of the U-series models is complicated by the contribution of each of these components to the isotopic composition of the bulk sample. Future works should investigate techniques to remove these phases either physically (e.g., mineral separation; (Menozzi and Dosseto 2013; Rihs et al. 2013)) or chemically (e.g., sequential extraction; (Schultz et al. 1998; Blanco et al. 2004; Martin et al. submitted)). Until then, we will still be relying on whichever phases control the U budget of the samples. If the U budget is controlled by only a single primary phase or a secondary phase derived from primary minerals, the models may provide reliable results. If the U budget is controlled by more than one primary phase or secondary phase derived from primary minerals, there might be some noise in the data that make the models less straightforward to apply. If controlled by a mixture of primary and associated secondary minerals, as well as solution-derived secondary minerals, allochthonous minerals, or organic matter, it is likely that the models will yield less than straightforward information. Finally, if the U budget of the samples is controlled by solute-derived secondary minerals, allochthonous minerals, or organic matter, the models will provide meaningless information in terms of weathering age, as defined above. Thus, the future of this technique depends on our ability to understand the U-series contributions from the various components involved and how they impact the overall compositions from which the models are developed.

Conclusions

U-series isotopes in weathering products (weathering rinds, regolith, sediments) allow us to place time constraints on weathering processes. These then can be used to determine the rate of formation of weathering profiles (*regolith production rates*). Results from available studies, when combined

with other tools like cosmogenic isotopes, provide unprecedented insights on the development of weathering profiles and landscape evolution. Results from these studies show that climate seems to have a secondary role on regolith production rates. Instead, the primary control on regolith production appears to be the composition of the parent material. Under tropical climates, for instance, regolith can be produced ~ 6 times faster over a volcanoclastic sedimentary rock than over a granodiorite parent. Conversely, soil production seems to be relatively insensitive to the parent material composition: under temperate climates, soil is produced at the same rates over shale and granodiorite. Finally, regolith production rates are similar for sites that show a range of erosion rates. This suggests a decoupling between the land surface and the weathering front. In this case, the topography of the weathering front would be determined by the lithology, while the surface topography is determined by denudation in response to climatic and tectonic conditions.

Several studies have emphasized the role of dust deposition on weathering profile development and in particular on the uranium budget of the soil. While this is taken into account in existing models of U-series isotopic evolution, further work is needed to improve the robustness of the information derived from these models. In order to achieve this objective, innovative chemical and/or physical protocols for sample preparation are important avenues to explore.

Finally, soil chronosequences represent fascinating natural laboratories to test the application of U-series isotope methods and to further improve the quality of information that U-series models provide. However, these studies need to be carefully undertaken, with a full understanding of the assumptions required by each different model.

With these considerations in mind, it is clear that, combined with other geochronological and geochemical techniques, U-series isotopes supply us with an ability to better understand the evolution of the Earth's surface. As summarized in this entry, more than 10 years of studies on the topic illustrate the unique prospects that this technique offers.

[Denudation](#)

Definition

Exhumation is the vertical upward movement of a rock particle toward the Earth's surface.

Introduction

Exhumation is the vertical upward movement of a rock particle toward the Earth's surface or, more generally, the vertical upward component of a rock-particle path with respect to the Earth's surface. The opposite vertical movement (downward with respect to the Earth's surface) is called burial. Exhumation rate is the vertical upward component of the velocity at which rocks move with respect to the Earth's surface.

Exhumation, Denudation, and Erosion

Usage of the term exhumation with respect to the similar terms erosion and denudation is not rigorously defined. “► [Erosion](#)” is often used to refer to the *physical processes* that remove material from the Earth's surface, whereas denudation and exhumation are commonly used in reference to the movement of rocks with respect to the Earth's surface and are therefore *geometrical quantities*. However, the term erosion is also used in the latter context when referring to relatively short (historical to millennial) timescales. In contrast, exhumation or denudation refers to longer (geological) timescales and/or larger (regional) spatial scales. The distinction between exhumation and denudation is even more subtle: in one usage (Ring et al. [1999](#)), exhumation refers to the upward movement of rocks with respect to a reference frame fixed to the Earth's surface, whereas denudation refers to the downward movement of the Earth's surface with respect to a reference frame fixed to the rock. In another usage (Summerfield and Brown [1998](#)), the term exhumation is reserved for rocks or surfaces that have previously been buried, whereas denudation is the more general term (i.e., a granite can only be denuded, not exhumed, unless it was denuded in a previous cycle and subsequently reburied; a sedimentary rock or erosion surface can be buried and subsequently exhumed). Most workers, however, consider exhumation and denudation to be synonyms and use the two terms interchangeably.

Fig. 1 Schematic depiction illustrating exhumation of rocks by different mechanisms: erosion (erosional exhumation), normal faulting, ductile thinning, exhumation in subduction channel (collectively known as tectonic exhumation). *Top panels* show initial situation, *bottom panels* show situation after exhumation of rock particle (black dot). Double arrows show depth of rock particle below surface before and after exhumation. Shaded regions represent the crust; other arrows indicate tectonic movements

Mechanisms of Exhumation

Exhumation of rocks can be caused by various mechanisms (Fig. 1): (1) erosion, by removing rocks from the Earth's surface, diminishes the vertical distance between the underlying rocks and the surface (erosional exhumation); (2) rocks in the footwalls of normal faults will be exhumed by extensional faulting; (3) a less generally inferred mechanism is ductile stretching of the crust, which will lead to pure-shear extension and thinning, thereby diminishing the vertical distance between the surface and a rock sample; (4) continental rocks that are brought to great depths by subduction can be subsequently buoyantly exhumed in a subduction channel, by replacing denser surrounding mantle rocks. The latter three mechanisms collectively contribute to tectonic exhumation. The most generally inferred exhumation mechanism is erosional exhumation. Tectonic exhumation by normal faulting is an efficient mechanism in metamorphic core complexes, which are exhumed along extensional detachments that can accumulate several tens of kilometers of extension. Buoyant exhumation of deep rocks is limited to subduction settings, while exhumation by ductile stretching of the crust is rarely invoked. The opposite mechanisms will lead to burial of rocks: sedimentary burial beneath an accumulating pile of sediments, tectonic burial in the footwall of a thrust fault, burial by ductile pure-shear shortening and thickening, and deep burial in subduction zones.

Measuring Exhumation

There is no direct way of measuring the amounts or rates of erosional exhumation. The amount of tectonic exhumation by normal faulting or ductile extension and thinning can, in theory, be quantified using structural or tectonic markers such as extensional fault offsets or strain markers. In practice, however, these are rarely sufficiently preserved to allow such reconstruction. If rocks have been buried sufficiently deeply to be metamorphosed, metamorphic pressure-temperature estimates allow quantifying the amount of exhumation; such measures are commonly used to quantify buoyant exhumation of rocks in subduction settings, for instance. The most generally

employed techniques for quantifying the amount and rates of exhumation on geological timescales rely on ► **Thermochronology** data. Different thermochronometers (including (U-Th)/He in apatite, titanite, and zircon; fission tracks in apatite, titanite, and zircon; K-Ar or ^{40}Ar - ^{39}Ar in K-feldspar, mica, and hornblende) are characterized by different closure temperatures (varying from $\sim 70^\circ\text{C}$ for the apatite (U-Th)/He system to $\sim 500^\circ\text{C}$ for the hornblende ^{40}Ar - ^{39}Ar system). Determining the ages of any subset of these different systems in an exhumed rock sample will provide information on whether that sample was buried deeply enough to have experienced sufficiently high temperatures to reset a specific thermochronometric system (allowing a minimum amount of exhumation to be established) and when the sample last cooled through the closure temperature while being exhumed toward the surface (allowing an exhumation rate to be estimated). All of these methods provide a measure of cooling (rate) in a thermal reference frame, however; converting this to an exhumation (rate) in a spatial reference frame requires estimating (or guessing) the geothermal gradient at the time of cooling through the closure temperature. Additional constraints on exhumation rates and pathways can be obtained by combining samples with a known spatial relationship to each other, for instance, by using their age-elevation relationship. Note that exhumation refers to the vertical upward component of motion of a rock particle with respect to the surface. Because both temperature and pressure gradients are (close to) vertical in the Earth's crust, metamorphic pressure-temperature estimates combined with thermochronology yield estimates of exhumation. However, in many orogens, particle paths have large horizontal components as well. Therefore, cumulative amounts of surface erosion may be very much larger than the total amount of exhumation (Batt and Brandon 2002).

On much shorter (millennial) timescales and smaller (metric) spatial scales, in situ produced terrestrial cosmogenic nuclide dating also allows quantification of erosion/denudation rates.

Uplift Versus Exhumation

Confusion remains widespread between the terms and concepts of uplift versus exhumation, even though the difference between these has been made clear more than 20 years ago (England and Molnar 1990). While exhumation refers to the vertical upward movement of rocks with respect to the Earth's surface, uplift refers to vertical upward movement of rocks (rock uplift) or the Earth's surface (surface uplift) with respect to an external reference frame such as sea level (Fig. 2). The above-cited techniques are not able to determine either surface or rock uplift, which require a measure of paleo-elevation with respect to a distinct datum, such as sea level. The three measures are not totally independent, however: by definition, rock uplift is the sum of surface uplift and exhumation.

Summary

Exhumation is the vertical upward movement of a rock particle toward the Earth's surface. Although subtle differences exist in meaning, most workers consider the terms exhumation and denudation as synonyms; both are geometrical quantities representing a diminution of overburden above a rock particle. Different mechanisms can lead to exhumation of rocks; these are classified as erosional exhumation or tectonic exhumation. The most common method to quantify and date exhumation is

Fig. 2 Schematic depiction showing relationships between rock uplift (u_r), surface uplift (u_s), and erosion/exhumation (e). *Shaded rectangles* represent rock columns; *open rectangle* represents eroded material; *black dot* indicates exhumed rock particle. Note that thermochronological or thermobarometric methods record the amount of exhumation, not (either rock or surface) uplift

by thermochronology; if the exhumed rocks were previously buried sufficiently deeply to be metamorphosed, petrologic pressure-temperature estimates can also be used to quantify the amount of exhumation. Exhumation and uplift are different quantities and no direct measure of (either surface or rock) uplift currently exists.

Introduction and Definition of Brittle Fault Dating

Dating of deformation revolutionized our understanding of crustal evolution by inserting the element of time and rate into strain and regional geology. Middle and deep crustal faults (>10–15 km depth) deform in a temperature regime that promotes growth of various mineral phases containing radiogenic elements, which allow direct and indirect dating of deep fault zones (e.g., van der Pluijm et al. 1994). On the other hand, shallow crustal faulting occurs in the brittle regime, where growth of suitable phases for dating is much more limited. The exception is the K-bearing mineral illite, which is widespread and can be used for dating with K-Ar and Ar-Ar methods in a range of settings, from diagenesis to deformation (Kelley 2002). K-Ar dating has been successful in many areas (e.g., Clauer et al. 1997, 2012; Zwingmann et al. 2010), while others focus on Ar-Ar dating (e.g., Haines and van der Pluijm 2008; Yun et al. 2010). This entry describes the use of Ar-Ar chronology to date brittle faults, including the mineralogic characterization of samples, Ar-Ar systematics and clay dating, and an example application. Application of illite age analysis (IAA) to fault dating has the following benefits: very small sample volumes can be analyzed, potassium and argon are measured simultaneously, and it has high precision. Regardless of the dating approach, separation of grain-size fractions and characterization and quantification of illite are key to reliable ages, requiring the integration of quantitative X-ray analysis.

Illite Characterization and Quantification

Illite-bearing samples of fault rock, herein called clay gouge (Vrolijk and van der Pluijm 1999), are separated into multiple size fractions. Crushed rock is placed in an ultrasonic bath for deflocculation and separated into size fractions using centrifuge settling following Stoke's law. A sample of fault rock is separated into three or four size fractions, in the range of <2.0 to <0.02 μm; samples containing feldspar may require <0.5 μm as the upper size limit to avoid contamination. To characterize bulk mineralogy, oriented clay slurry mounts are analyzed with X-ray diffractometer (XRD) by scanning from 2° to 50° 2Θ (Cu Kα) of both air-dried and glycolated samples (Moore and Reynolds 1997). If carbonate minerals obscure peaks required for quantification of illite polytypes, size fractions of gouges are treated with a weak (~1 N) acetic acid solution after separating material for use in ⁴⁰Ar-³⁹Ar dating. A separate aliquot is used to limit any effects of acid treatment on Ar and K retention.

*Email: vdpluijm@umich.edu

To determine the crystallite size and diagenetic grade of gouge, oriented slurry samples of each size fraction are scanned from 2° to $20^\circ 2\Theta$ using an X-ray diffractometer. If appropriate, the percent illite in illite-smectite (%I in I-S) is determined using the method of Środoń (1980) and diffraction patterns are modeled using the program NEWMOD[©] (Reynolds and Reynolds 1996). Illite crystallinity (IC), which reflects the thickness distribution of illite crystallites, is determined by measuring the full width at half maximum (FWHM) of the 001 illite peak in $^\circ 2\Theta$ (Kübler 1968), calibrated by Warr and Rice's (1994) method and standards. Crystallite thickness is calculated using the Scherrer equation (Drits et al. 1997).

Illite age analysis requires quantifying the percentages of the two main polytypes of illite: the higher temperature (detrital) $2M_1$ polytype and the lower temperature (authigenic) $1M/1M_d$ polytype. Standard-oriented X-ray mounts tend to obscure peaks that have non-(00l) indices, so randomized powder mounts are made using an end-packer device (after Moore and Reynolds 1997). Illite polytypes are quantified by matching natural XRD patterns with synthetic XRD patterns created using WILDFIRE[©] software (Reynolds 1993). The program allows different properties for $2M_1$ and $1M/1M_d$ illite and varying parameters such as randomness, crystallite size, hydration state, percentage cis- and trans-vacant interlayers, and smectite interlayers. We use a spreadsheet program to match measured XRD patterns to the synthetic XRD patterns, as illustrated in Fig. 1. Typical precision for illite polytype quantification is 2–3 %.

^{40}Ar - ^{39}Ar Chronology of Clays

The K-Ar dating technique is based upon the assumption that radiogenic ^{40}Ar (i.e., $^{40}\text{Ar}^*$) produced by the beta-decay of ^{40}K is quantitatively retained within a mineral structure. Given this assumption, the $^{40}\text{Ar}^*/^{40}\text{K}$ ratio is effectively a measure of the time since a mineral became closed to Ar loss. The ^{40}Ar - ^{39}Ar technique extends the K-Ar method by using the fast neutron reaction $^{39}\text{K}(\text{n,p})^{39}\text{Ar}$ to produce ^{39}Ar , which is a proxy for ^{40}K , and therefore, the $^{40}\text{Ar}^*/^{39}\text{Ar}$ ratio is used as a measure of the age of mineral. However, unlike the decay reaction that produces $^{40}\text{Ar}^*$, the reaction that forms ^{39}Ar is highly energetic and it causes the resulting nucleus to recoil an average distance of 162 nm within silicate minerals (Turner and Cadogan 1974; Onstott et al. 1995). For most minerals that are dated using the ^{40}Ar - ^{39}Ar method, this recoil distance is considered to be insignificant relative to the average grain size, but in the case of fine-grained clay particles, the average thickness of a grain might be much less than the average recoil distance. This means that ^{39}Ar recoil effects can dominate argon systematics for clay-sized particles, and an approach for collecting any ^{39}Ar lost due to recoil is needed in order to use the ^{40}Ar - ^{39}Ar technique to date clays.

Seidemann (1976) first described a vacuum encapsulation technique, where a sample is placed within an evacuated fused silica capsule. After neutron irradiation, the capsule was cracked open within a vacuum system and the released argon isotopes were analyzed using an attached noble gas mass spectrometer. Subsequently, the technique has been used in several laboratories (e.g., Hess and Lippolt 1986; Foland et al. 1992; Smith et al. 1993), but the most extensive use of the method has been at the University of Michigan.

Smith et al (1993) noted that the quantity of ^{39}Ar released during neutron irradiation, called the recoil gas fraction, was less than anticipated purely from geometrical considerations due to the sample grain size. They attributed the difference to efficient reimplantation of ^{39}Ar between neighboring grains and postulated that the dominant control on the retention of ^{39}Ar during neutron irradiation was the depth of penetration of the recoiled nucleus. In effect, ^{39}Ar retention depends on where the recoiled nucleus stops and does not depend strongly upon grain size or the recoiled

Fig. 1 XRD patterns (*black curve*) for six mixtures of Owl Creek muscovite ($2M_1$) and IMt-1 illite ($1M_d$) and the best-matched models (*gray lines*). Note that for $2M_1$ -rich mixtures, the best matches are obtained from $2M_1$ -specific peaks, while for $1M_d$ -rich mixtures, the best matches fit the entire pattern between 21° and 36° 2θ (From Haines and van der Pluijm 2008)

distance. This point was further supported by the observation that the retained fraction of ^{37}Ar was virtually identical to that for ^{39}Ar despite ^{37}Ar having over twice the expected recoil distance compared to ^{39}Ar (Onstott et al. 1995). Dong et al. (1995) confirmed these observations and observed that the fraction of ^{39}Ar released due to recoil from illite was correlated with the crystallinity index as derived from XRD analysis, with well-crystallized illite having extremely low loss of ^{39}Ar , regardless of grain size. This suggested that the amount of Ar loss due to recoil depends mostly on the nm-scale structural state of illite.

Total Gas Ages and Retention Ages of Illite

Dong et al. (1995) postulated that the retention of ^{39}Ar is controlled by the density of dislocations, defects, and exposed mica surfaces within illite crystal packets. It has long been suggested that Ar can only diffuse along the interlayer regions between the structurally strong 2:1 unit sheets that comprise micaceous minerals (e.g., Hames and Bowring 1994; Kramar et al. 2003). Therefore, it is likely that an Ar atom that arrives within a bounded interlayer will be retained. Given an average illite packet thickness of n 2:1 structural units, there are a total of $2n$ surfaces on these n sheets. Two adjacent 2:1 structural units comprise an interlayer region, and there should be $2n - 2$ internal surfaces and 2 exposed surfaces. Dong et al. (1995) suggested that in this case, the fraction of non-retentive sites is $2/2n = 1/n$.

The ages calculated from both the ^{39}Ar ejected due to recoil and the Ar retained within the sample in the Dong et al. (1995) study (called **total gas ages**) were often too young when compared with other geological constraints. Specifically, well-crystallized epizonal-grade illite was found to give much older ages than lower-grade diagenetic illite within the same sedimentary basin, indicating that the lower-grade, poorly crystallized illite had already lost a significant fraction of its radiogenic ^{40}Ar . Dong et al. (1995, 1997) found that ages calculated without the recoil gas fraction, meaning ages calculated only from Ar that was retained within the sample, gave geologically reasonable values; these were called **retention ages**. This was further confirmed for hydrothermally produced clay minerals by Hall et al. (1997, 2000). These retention ages assume that there is K within both retained interlayer sites as well as in exposed sites in defects, dislocations, and exposed surfaces. K residing in these non-retentive sites will contribute to the total ^{39}Ar inventory; however, any ^{40}Ar produced at these sites will not have been retained over geological time. In effect, the Ar retention ages correct for the loss of radiogenic ^{40}Ar by ignoring any Ar from non-retentive sites.

Subsequently, Dong et al. (2000) found that total gas ages gave stratigraphically correct ages for smectite-rich illite-smectite (I/S), and van der Pluijm et al. (2001, 2006) found that the total gas age model yielded reliable ages for authigenic I/S formed during shallow fault motion. This indicates that in weakly crystallized I/S, defect sites are almost entirely composed of K-poor smectitic layers. Thus, total gas ages and retention ages represent end-member models that are linked to the crystal structure of illite, with total gas ages assuming there is no K in non-retentive sites and with retention ages assuming that non-retentive sites have K concentrations equal to that in internal, retentive interlayer sites.

Illite Age Analysis: Example

The Sierra Mazatán fault is part of a Cordilleran metamorphic core complex in Sonora, Mexico, that separates mid-crustal Paleocene granites and minor gneisses in the footwall from Cretaceous metavolcanics and unmetamorphosed Tertiary sedimentary rocks in the hanging wall (Wong and Gans 2003). XRD pattern matching of size fractions from the fault shows that gouge compositions range from 84 % to 18 % 2M_1 illite and that compositions are positively correlated with grain-size fraction (Haines and van der Pluijm 2008). The corresponding Ar degassing spectra and total gas and retention ages for four samples of coarse to very fine material are shown in Fig. 2.

The retention ages vary nonsystematically, from 19.6 to 20.2 Ma, while the total gas ages are younger and vary systematically with decreasing grain size (18.0–15.5 Ma). Illite crystallinity measurements, recording a small average illite crystallite size, indicate that total gas ages should be used for the dating of these samples, which result in systematically younger ages as the

Fig. 2 Ar degassing spectra for four size fractions of the Mazatán fault, showing total gas ages and retention ages for each, as well as Ca/K and Cl/K ratios (Modified from Haines and van der Pluijm 2008)

percentage of detrital 2M_1 illite decreases and authigenic $1\text{M}/1\text{M}_d$ illite increases in finer-grained samples. Plotting age versus % 2M_1 illite for each size fraction and using York regression (Mahon 1996) produces a lower intercept, representing 100 % authigenic illite, of 14.8 ± 0.2 Ma and an upper intercept, representing 100 % mica in the granitic footwall, of 18.7 ± 0.7 Ma (Fig. 3). The extrapolated authigenic illite age supports well-known field constraints on faulting and the upper intercept age matches feldspar cooling ages from these samples (Wong and Gans 2003). The use of

Fig. 3 Illite age analysis plot for gouge from the Sierra Mazatán detachment. Numbers in *bold* are the extrapolated ages for the authigenic (14.8 Ma) and host illite population (18.7 Ma) mixed in the gouge. Percentage host rock illite ($2M_1$) is plotted against the function $(e^{\lambda t} - 1)$ because it is proportional to $^{40}\text{Ar}^* - ^{40}\text{K}$, which in turn is a linear function of the proportion of authigenic and detrital grains. λ is the total decay constant for ^{40}K and t is the apparent age (Reprocessed data from Haines and van der Pluijm 2008)

four size fractions significantly improves the statistics of the age determination over using the minimum of three size fractions, with an age error that is mostly defined by the error in clay quantification and not Ar ages of each size fraction.

Summary and Progress

Illite age analysis combines quantitative X-ray analysis of clay separates with encapsulated sample ^{40}Ar - ^{39}Ar dating. Both illite in illite-smectite (I in I/S) and illite polytype methods offer robust, internally consistent approaches to dating of upper crustal deformation structures that involve the (trans)formation of illitic phases, which is common in natural rocks. It has been reliably applied to shallow faults in multiple regional settings that include reverse, normal, and strike-slip systems and was recently extended to include the dating of fold systems (Fitz-Diaz and van der Pluijm 2013).

Definition

The use of U-series geochronology applied to fault-related calcite for dating brittle fault activity.

Introduction

Absolute time constraints on fault activity are an essential part of many plate tectonic and paleoseismic studies, and their potential interpretation in terms of fault seismicity and seismic hazards is well recognized (e.g., Grant et al. 1999; Hee-Kwon and Schwarcz 1995). The introduction of paleoseismological exploratory trenching studies offered the opportunity to determine the number and timing of large paleo-earthquakes and their estimated magnitude and recurrence intervals (e.g., Clark et al. 1972; Sieh 1984). Other studies provided important paleoseismic records recovered in laminated sediments (Ken-Tor et al. 2001; Marco et al. 1996) and damaged speleothems (Kagan et al. 2005; Plan et al. 2010). However, most paleoseismological studies use indirect methods for dating fault movement based on the geochronology of material collected from the displaced or damaged stratigraphic section and not from the fault zone itself. In addition, most paleoseismological dating studies are based on ^{14}C and optically stimulated luminescence (OSL) dating methods, which are both limited to relatively young events [≤ 50 ka for ^{14}C (Ramsey et al. 2012) and ≤ 100 ka for OSL (Huntley et al. 1985)]. U-series dating of fault-related calcite precipitates is therefore an important source of information of both processes occurring in the fault zone during seismic events and of paleoseismic events occurring further back in the geological history.

The use of U-series method for dating fault activity implies temporal association among faulting, fluid circulation, and precipitation processes in the fault zone. For example, calcite dissolution and reprecipitation are common processes in fault zones within host-rock carbonates due to enhanced fluid infiltration processes in the fractured damage zone. In this setting, the formation of secondary calcite may occur during (syn-tectonic), or following (post-tectonic), a faulting event. While U-series ages of syn-tectonic calcite provide constraint on the timing of seismically active period, ages of post-tectonic calcite can be used to constrain the timing of inter-seismic period and/or provide a minimal age for the timing of the deformation event. Identifying syn-tectonic from post-tectonic precipitates therefore represents a fundamental step toward accurate interpretation of the

*Email: perach@stanford.edu

U-series age results. Making these interpretations requires a combination of structural, isotopic-geochemical, and geochronological approaches.

Fault-Related Calcite Precipitates in Brittle Fault Zones

Fault-related structures are formed during brittle deformation events and are commonly used as kinematic indicators for strain orientation (Boullier et al. 2004; De Paola et al. 2008) and sense of displacement (Petit 1987). Tension gashes, fault breccias, dilation veins, striation marks, and injection veins are examples for fault-related structures that are potential sites for calcite precipitation (Fig. 1). Calcite precipitated in these fault-related features is a good candidate for the implementation of U-series geochronology for dating fault activity; however, further microstructural and

Fig. 1 Fault-related calcite precipitates. (a) Tension gash filled with calcite from the Dead Sea fault zone (DSFZ), Southern Israel (Nuriel et al. 2011); (b) calcite-cemented breccia; (c) calcite-filled dilation vein from the DSFZ, Northern Israel (Nuriel et al. 2012a); (d) calcite coating striation marks from the DSFZ, Northern Israel (Nuriel et al. 2012b); and (e) calcite injection vein from the Pamukkale geothermal fields (Uysal et al. 2009). All fault-related calcite are secondary phases within limestone host rock

Fig. 2 Microstructures of fault-related calcite. **(a)** Polished slab of a hand specimen taken perpendicular to fault plane and grooves showing the occurrences of syn-tectonic calcite (within striation and breccia) and post-tectonic calcite (coating layer), **(b)** close-up of calcite striation (location is shown in **a**) showing characteristic morphology of syn-tectonic calcite (calcite twins with euhedral crystals and radial growth texture) and post-tectonic calcite (crack-seal texture). Sample is from the DSFZ, Northern Israel (Nuriel et al. 2012b)

isotopic-geochemical characterization is needed in order to determine the temporal association between calcite precipitation and faulting (e.g., syn- or post-tectonic).

Microstructures of Fault-Related Calcite Precipitates

Microstructural studies of fault-related precipitates provide important information on the progressive development of a structure, on temporal changes in precipitation conditions and on growth mechanisms. In particular, the size of displacement along fault asperities will result in the occurrence of either syn-tectonic or post-tectonic precipitates (Gratier and Gamond 1990). Large displacement is associated with a cataclastic-seismic event and the formation of large cavities (several mm in size). These open cavities can be filled with syn-tectonic calcite, characterized with morphologies including twining, euhedral crystals, and radial growth texture (Fig. 2a, b). In contrast, small displacement is associated with aseismic slip, involving dissolution and sealing of successive microcracks (μm in size) by crack-seal mechanism (Ramsay 1980). Calcite that precipitated by crack-seal mechanism should be considered as post-tectonic (Gratier and Gamond 1990) and is characterized with fibrous crystals (Fig. 2b) and surface-parallel arrays of detached overgrowths containing fluid inclusions (Cox and Etheridge 1983; Uysal et al. 2011).

Geochemistry of Fault-Related Calcite Precipitates

The geochemistry of fault-related calcite precipitates can provide important information on the fluids that are responsible for their formation (e.g., Pili et al. 2002). The type and source of fluids and their transport mechanism and residence time in the system can also help determine the time relation between faulting, precipitation, and fluid circulation. Common analytes used to determine fluid

Fig. 3 Geochemistry of fault-related calcite precipitates and host-rock samples from the Dead Sea fault zone (DSFZ), Northern Israel (Modified after Nuriel et al. 2012b). (a) $\delta^{13}\text{C}$ versus $\delta^{18}\text{O}$ with values given in per mil (‰) relative to Vienna Pee Dee Belemnite (V-PDB) carbonate standard and Vienna Standard Mean Ocean Water (V-SMOW) standard, (b) $^{87}\text{Sr}/^{86}\text{Sr}$ versus $1/\text{Sr}$ concentration (ppm) plot, and (c) chondrite-normalized REE patterns of the different types of calcite precipitates relative to their host rock. Calcite types are marked with different symbols (Chondrite values from Haskin et al. (1971))

source and transportation mechanisms include stable isotopes ($\delta^{18}\text{O}$ vs. $\delta^{13}\text{C}$; Fig. 3a), strontium isotopes ($^{87}\text{Sr}/^{86}\text{Sr}$; Fig. 3b), and rare earth element (REE) concentrations (Fig. 3c). Based on these and other parameters, various fluid sources and transportation mechanisms have been proposed for the formation of fault-related calcite precipitates in different tectonic settings, including: (1) earthquake-mobilized fluids (Uysal et al. 2007; 2011), (2) pressurized solutions (Gratier et al. 2002; Nuriel et al. 2012b), (3) meteoric water interacting with host-rock carbonates to various degrees (Labaume et al. 2004; Nuriel et al. 2011; 2012a; Verhaert et al. 2004; 2003), and (4) a mixing of several sources (Boles and Grivetti 2000; Verhaert et al. 2009). In addition, the geochemical-isotopic signature of syn-tectonic and post-tectonic calcite precipitates from the same site (or same sample) can be very different and can reflect differences in the formation mechanisms (see example in Fig. 3).

U-Series Dating of Fault-Related Calcite Precipitates

The U-series dating technique is based on the fact that the ^{238}U decay chain has two intermediate radiogenic and radioactive daughters (^{234}U and ^{230}Th). Both have geologically short half-lives ($\sim 10^5$ years), meaning that the method is appropriate only for dating processes that occurred in the

Fig. 4 U-series ages of fault-related calcite from the Dead Sea fault zone, Northern Israel (modified after Nuriel et al. 2012b). U-series ages, in ka, are shown for syn-tectonic (*squares*) and post-tectonic (*triangles*) calcite from different samples (sample names are denoted at the left-side axes). *Solid vertical lines* indicate well-defined (high-robustness) deformation events characterized by coeval development of syn-tectonic precipitates. Post-tectonic calcite is interpreted to form following deformation events during inter-seismic periods. *Dashed vertical lines* indicate moderately defined (low-robustness) deformation events based on single-sample age. Symbols are larger than 2σ age errors

last ~500,000 years (Edwards et al. 1987). Basic assumptions that apply to the U-series dating method include two main points (e.g., Ivanovich and Harmon 1992; van Calsteren and Thomas 2006): (1) daughter nuclides (i.e., ^{230}Th) were not present in the sample at the time of precipitation, and (2) the sample must be a closed system to post-formation migration or addition of any of the radionuclides (i.e., ^{234}U , ^{230}Th). Thus, changes in U/Th isotopic abundance in the system occur only by radioactive decay and growth processes. The first assumption can be validated by the presence of ^{232}Th (Kaufman and Broecker 1965; Ku and Liang 1983), the more common of the two Th isotopes that behaves like a stable isotope due to its long half-life. According to the Kaufman-Broecker concept, if measured $^{230}\text{Th}/^{232}\text{Th}$ activity ratios are low (<20), it is likely that non-authigenic ^{230}Th is also present (i.e., initial ^{230}Th present at the time the calcite was formed rather than forming subsequently by in situ decay of ^{234}U or ^{238}U), and a correction procedure is needed. However, if $^{230}\text{Th}/^{232}\text{Th}$ activity ratios are high (>20), the correction for initial ^{230}Th is negligible. The second assumption is, however, much harder to validate, particularly in syn-tectonic calcite. Unlike dating of corals and speleothems, which commonly exhibit measured activity ratios ($^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{238}\text{U}$) predicted by U-series isotope evolution in material formed by progressive deposition (continuous growth, see Ku 1965), syn-tectonic precipitates form episodically during different precipitation events and may result in complex patterns of physical growth. As such, it can be much more difficult to evaluate whether U-series isotopes remained closed to secondary mobility. One way to help evaluate resulting ages is to assume closed system behavior and compare ages calculated for syn-tectonic and associated post-tectonic precipitates, which formed continuously during the inter-seismic period from the same site and preferably from the same sample. Dating post-tectonic and syn-tectonic precipitates from the same site may also provide a more complete history for fault activity that includes both the active (seismic) and inactive (inter-seismic) periods. An example for such a record from the Dead Sea fault zone in Northern Israel is shown in Fig. 4.

Conclusion

Microstructural, geochemical, and isotopic signatures of syn-tectonic and post-tectonic calcite precipitated in brittle fault zones reflect different formation mechanisms and temporal relations to faulting events. Therefore, assessment of these features is important for making accurate

interpretations of U-series ages of fault-related calcite. Resulting ages have been used to directly determine the timing of faulting events in many recent studies (Boles et al. 2004; Flotté et al. 2001; Nuriel et al. 2009, 2011, 2012a, b; Uysal et al. 2007; Verhaert et al. 2003, 2004). In addition, U-series ages of both syn-tectonic and post-tectonic calcite precipitates from the same site can shed light on seismic and inter-seismic fault activity.

Definition

Dating hydrothermal events related to the formation of ore deposits by the Rb–Sr dating method

Historical Background

Dating of a hydrothermal event related to ore formation was conducted initially by dating the granite that was regarded as the heat source for the hydrothermal activity and assuming that ore deposition occurred contemporaneously with emplacement of the granite. Indirect dating of alteration minerals such as sericite using K–Ar, Ar–Ar, and Rb–Sr methods was also attempted. Results from these studies, however, have been problematic because of (1) complex associations between ore and alteration minerals and (2) possible multiple hydrothermal events, which can reset chronological information. Gangue minerals can be used as more direct targets of dating. Shepherd and Darbyshire (1981) obtained the Rb–Sr age of 392 ± 5 Myr from fluid inclusions in quartz from the Carrock Fell tungsten vein deposits, northern England. However, the cause of the large variable Rb–Sr ratios observed in their fluid inclusion samples remains uncertain, which suggests mixing of different stages of ore-forming fluids. These problems strongly demand direct dating of ore minerals.

Rb–Sr Dating of Sphalerite from Mississippi Valley-Type Ore Deposit

Most long-lived radioactive nuclides, aside from Re, do not enter into metal sulfides, which makes direct dating of ore deposits difficult. Sphalerite from Mississippi Valley-type (MVT) ore deposits was the first example of successful dating of a sulfide mineral by Rb–Sr method. Mississippi Valley-type deposits are carbonate-hosted lead–zinc deposits. These deposits are regarded as the product of large-scale fluid movements in the upper crust. However, they are formed from warm basinal brines and are not hydrothermal deposits in the strict sense. Direct dating of an ore mineral, sphalerite, was attempted by Nakai et al. (1990) and Nakai et al. (1993). In those analyses, sphalerite samples were crushed and leached in purified water to separate fluid inclusions, which represent solutions trapped at the time of ore-mineral formation. Sphalerite solid residues contain Rb and Sr of 0.05–0.5 and 0.3–2 ppm, respectively, with variable $^{87}\text{Rb}/^{86}\text{Sr}$ of 0.2–2. Water from fluid inclusions trapped in these same grains, however, contains high Sr with low and limited $^{87}\text{Rb}/^{86}\text{Sr}$ of 0.05–0.26. Figure 1 shows a Rb–Sr isochron plot of sphalerite residues and their fluid inclusions from Coy Mine, Mascot–Jefferson City district, eastern Tennessee, United States. The Rb–Sr isochron of sphalerite solid residues yields an age of 377 ± 29 Ma. The isochron was regressed on data for solid residues without using fluid inclusion data. The point for C15, which was more deformed than the other samples, was not considered in the age calculation. The resulting age ruled out any genetic

Fig. 1 Rb–Sr isochron of sphalerites from Coy Mine, Mascot–Jefferson City district, east Tennessee (Data were taken from Nakai et al. (1990)). Data for sphalerite residues are shown as *filled circles*, whereas data for fluid inclusions are shown as *open squares*. The isochron was fitted to data for sphalerite residues analyzed after removing solutions contained in fluid inclusions, excluding data from C15 (see text)

connection between mineralization and the Alleghenian orogeny (330–250 Ma). Combining the Rb–Sr age of sphalerites from the Immel Mine, it was concluded that MVT deposits in the eastern United States were formed by brine migration triggered by the earlier Acadian orogeny (380–350 Ma). Sphalerites from Pine Point district, Canada (Nakai et al. 1993); from the West Hayden ore body, Wisconsin, in the Upper Mississippi Valley district (Brannon et al. 1992); from the Polaris Mine in the Canadian Arctic Archipelago (Christensen et al. 1995a); and from Blendevalle, Western Australia (Christensen et al. 1995b), were dated using this method.

Nakai et al. (1993) reported that sphalerites from Daniel’s Harbour Mine, Newfoundland, Canada, and from Monte Cristo Mine, Arkansas, United States, showed no isochron. The samples used for dating might be mixtures of sphalerites from different stages of ore deposition. Nakai et al. (1993) reported that minute amounts of inherited silicate inclusions might have disturbed the Rb–Sr isotopic system in sphalerites from the Monte Cristo Mine because the samples contained very low Sr.

Validity of Rb–Sr Isochron Age

The observed variable Rb–Sr ratios in sphalerite residues engender some doubt about whether the Rb–Sr correlations were formed by mixing of sphalerite and (1) a high Rb–Sr phase, such as a silicate mineral, or (2) a low Rb–Sr phase, such as a fluid inclusion.

Nakai et al. (1993) analyzed Rb and Sr isotopes in K-feldspars from unmineralized carbonate rocks in the Immel Mine. Their results showed that K-feldspar data plotted above an isochron formed by sphalerite. They concluded that mixing between K-feldspar and other components with low Rb–Sr ratio could not have formed the observed sphalerite isochron.

Fig. 2 Plot of $^{87}\text{Sr}/^{86}\text{Sr}$ versus reciprocal Sr concentration ($1/[\text{Sr}]$) for sphalerites from Coy Mine, Tennessee (Data are from Nakai et al. (1990)). Symbols are the same as those in Fig. 1. Sphalerite residues do not form a *straight line*, ruling out the possibility that Rb–Sr isochron was formed by variable degrees of mixing with fluid inclusions

Regarding the possible influence of fluid inclusions, Pettke and Diamond (1996) examined the relation between $^{87}\text{Sr}/^{86}\text{Sr}$ and reciprocal of Sr concentration for samples showing Rb–Sr isochrons. Figure 2 presents data for sphalerites from the Coy Mine using data from Nakai et al. (1990). Pettke and Diamond found that this type of plot shows no correlation indicative of mixing in the observed isochrons except for the sphalerites from the West Hayden ore body reported by Brannon et al. (1992). It can be concluded that Rb–Sr isochrons were not mixing lines between sphalerite residues and low Rb–Sr fluid inclusions except in this case. In addition, Christensen et al. (1995b) showed that Rb–Sr ratio in sphalerite residues from the Canning Basin was not controlled by Sr concentration negating the influence of fluid inclusions. They concluded that Rb incorporation into sulfide minerals during precipitation might be controlled kinetically.

Apart from MVT deposits, Shneider et al. (2007) compared Rb–Sr and Re–Os ages of ore-stage Zn–Cu–Ge sulfides, including sphalerite from the Kipushi base metal deposit, Democratic Republic of Congo. They respectively obtained concordant Rb–Sr and Re–Os ages of 451.1 ± 6.0 and 450.5 ± 3.4 Ma. The concordant ages further clarified the geological significance of direct Rb–Sr dating of sphalerites.

Rb–Sr Dating of Pyrite and Other Minerals

Apart from sphalerite, some other sulfide minerals have been found to be suitable for Rb–Sr dating. Tretbar et al. (2000) reported that Galkhaite $[(\text{Cs},\text{Tl})(\text{Hg},\text{Cu},\text{Zn})_6(\text{As},\text{Sb})_4\text{S}_{12}]$ from sedimentary-rock-hosted disseminated gold deposits known as Carlin-type gold deposits in Nevada formed a Rb–Sr isochron. The mineral shows high and variable $^{87}\text{Rb}/^{86}\text{Sr}$ ratios from 3,000 to 23,000. Pyrite has also been found to be a suitable mineral for Rb–Sr dating. Yang and Zhou (2001) dated pyrites from Linglong gold deposit, Jiaodong Peninsula, China. Yang and Zhou (2001) analyzed three sets of pure pyrite grains from three hand specimens of $6 \times 6 \times 9$ cm assuming that subsamples

from a single hand specimen are more likely to have a uniform initial Sr isotope composition. The three isochrons show concordant ages of 122 ± 11 , 122.7 ± 3.3 , and 123.0 ± 4.2 Ma. Wei et al. (2003) also applied Rb–Sr dating to pyrite from the Liaodong gold province, China.

Summary and Conclusions

Rb–Sr dating of sulfide minerals has been confirmed as a robust method for dating hydrothermal events. Because sulfide minerals contain only trace amounts of Rb and Sr, careful treatment of analyses is necessary. Combining Rb–Sr dating with other geochronometers such as Re–Os dating of sulfide minerals and Sm–Nd dating of scheelites is expected to shed light on details of ore formation processes of hydrothermal deposits.

Definition

Nucleocosmochronology. Use of radiogenic isotope ratios for determining ages of nucleosynthesis and other fractionations occurring in the galaxy and stars.

Introduction

Stars reflect the ongoing evolution of the galaxy as nuclidic abundances of metals (elements from carbon up in terms of proton number) are formed from the fusion reactions transforming light elements in to heavy. At the Fe abundance peak, fusion no longer releases energy, and elements heavier than iron are the result of two reaction pathways involving the addition of neutrons. The s-process involves the *slow* addition of neutrons, where slow indicates that the chances of beta decay is more likely than the chance of adding another neutron. The s-process therefore keeps the nucleosynthetic pathway close to the stable nuclides we see around us. The s-process stops at ^{209}Bi , this being the heaviest stable nuclide. The site of the s-process is likely dominated by asymptotic giant branch (AGB) stars, also known as red giants, that are burning He into heavier nuclides releasing abundant neutrons in the process.

The r-process denotes *rapid* addition of neutrons, so that many neutrons are added before a nuclide has a chance to decay. In the r-process, neutrons are added to quasi-stabilize nuclides far off the pathway of stability; once the neutron source is extinguished, the nuclides beta decay back to the canonical stable nuclides. The r-process therefore leads to much heavier nuclides being formed as the neutrons in the nucleus decay to protons. Uranium and thorium isotopes are therefore formed in this way. The astrophysical site of the r-process is likely to be supernova explosions resulting from core collapse as the density in the stellar core cannot resist gravitational contraction forming abundant neutrons in the process. These explosions take place over time periods of a few seconds with secondary nucleosynthesis (related to decay) on the order of months to years depending on the nuclide.

In terms of galactic chemical evolution, it is widely held that massive star formation was more prevalent in the early solar system, and hence r-process contributions are dominated by early galaxy supernovae explosions.

*Email: trevor.ireland@anu.edu.au

Chronological Implication

It follows that nucleosynthesis itself could be dated if the initial abundances were known and the products could be measured. Theoretical models of r-process nucleosynthesis can be used to establish the abundances of uranium and thorium isotopes originating from that source. A classic case is that of the $^{235}\text{U}/^{238}\text{U}$ of our solar system first related in detail in the classic study of Willy Fowler and Fred Hoyle. The benefit of simply using uranium is that there is no inherent fractionation between the isotopes because of chemical processing. The isotope ratio is taken to simply reflect the decay of ^{235}U (half-life of 700 Myr) relative to ^{238}U (half-life of 4.4 Gyr). The r-process production (P) ratio $^{235}\text{U}/^{238}\text{U}$ is based on the contributions of not only $A = 235$ and $A = 238$ but also their respective α -decay progenitors up to $A = 255$ where spontaneous fission alone occurs; P235/P238 can be affected by details in r-process nucleosynthesis models. Fowler and Hoyle (1960) used a P235/P238U ratio of 1.65 in their calculations. The present day $^{235}\text{U}/^{238}\text{U}$ of our solar system is 0.00725, and the initial $^{235}\text{U}/^{238}\text{U}$ of the solar system is therefore 0.320 for the age of the solar system of 4.567 Gyr (Amelin et al. 2010). It follows then that

$$N^{235}/N^{238} = P^{235}/P^{238} e^{-(\lambda_{235}-\lambda_{238})t}$$

and the time t to evolve from a primitive r-process contribution to the time of the formation of our solar system is 2.0 billion years.

The Th/U ratio can also be used as a chronometer because of the difference in half-lives of ^{238}U and ^{232}Th . Here the calculation will also be affected by the potential for chemical fractionation of Th from U, which for the purposes of this calculation will be ignored. For the present Earth, the Th/U abundance is 3.6, and therefore 2.3 for the early solar system (Anders and Grevesse 1989). The r-process production ratio is around 1.7. Following a similar formalism to that above for uranium, the decay time is 2.8 billion years. Thus, the actinide abundances in the early solar system can be accommodated by injection of nucleosynthetic material that has been allowed to decay for 2–3 billion years.

However, the actinide abundances are being maintained in an equilibrium state balancing the nuclear decay with augmentation from new stellar explosions. Such a scenario is now supported additionally by the presence of short-lived radionuclides, many with half-lives less than 10 Myr such as the r-process nuclide ^{182}Hf . In accounting for this ongoing production and decay, Fowler and Hoyle derived an age of 15 (+5/–3) Gyr for the age of the galaxy, a remarkably prescient prediction.

Chronology from Stellar Abundances

For dating stellar systems other than our own, the ability to perform this kind of analysis is severely limited by our ability to measure the abundances of the nuclides in optical spectra. Isotopic analysis of heavy nuclides such as uranium is not possible. In fact detection of uranium is very difficult because of the coincidence of a CN (cyanide) line with U(II). Thorium is more promising to reflect age. The Th/Eu ratio can be used as a proxy for age because Eu is predominantly r-process and is a stable nuclide. The Th/Eu abundance will fall with time at a known rate because of the decay of ^{232}Th . As an example, the Th/Eu of the star CS 22892–052 is 0.219, well below the r-process ratio of 0.463, consistent with a simple radioactive decay age of 15.2 ± 3.7 Gyr.

These calculations assume simple single-stage decay models. Such a scenario is unlikely with a variety of stellar inputs likely making up the galactic abundances in any region of the galaxy.

Presolar grains are recovered from primitive meteorites, and these grains are believed to have condensed around stars that were extant before our solar system formed. Most of these appear to be derived from AGB stars with characteristic isotopic compositions from that source. Within single grains, U and Th are observed reflecting the ongoing r-process history of our galaxy.

Conclusion

The abundances of the radiogenic elements U and Th reflect ongoing processing in the galaxy. The abundances of these nuclides reflect billions of years of decay coupled with ongoing augmentation from supernovae.

Uranium–Lead, Extraterrestrial, Planetary Materials

Alexander Nemchin*

Department of Applied Geology, Curtin University of Technology, Perth, WA, Australia

Definition

From a broad perspective, extraterrestrial planetary materials comprise samples representing several identifiable planetary bodies in the solar system. The source planetary bodies can be identified with a high degree of confidence. Under a narrower definition used here, only samples originating from Moon and Mars are discussed.

Introduction

Extraterrestrial planetary materials available for study are restricted to a number of meteorite groups recovered mostly from deserts and Antarctic ice deposits on Earth, where meteorites are easily visible due to the significant contrast with the surrounding environment. These groups comprise several types of achondrites representing relatively small objects in the asteroid belt, SNC (Shergotty-Nakhla-Chassigny) meteorites believed to be originating from Mars and lunar meteorites. In addition, lunar materials have been made available by the Apollo and Luna missions that delivered around 380 kg of samples from nine locations on the near side of the Moon.

Many of the available samples contain U-bearing accessory minerals, such as zircon, zirconolite, tranquillityite, baddeleyite, apatite, and merrillite, allowing determination of U–Pb ages with the uncertainties of few million years. However, the relatively small abundance of these minerals in the samples, as well as the commonly restricted size of the samples, resulted in a limited number of analyses obtained prior to the advent of wide application of microanalytical techniques such as SIMS (secondary ion mass spectrometry) and LA ICPMS (laser ablation inductively coupled plasma mass spectrometry). Attempts to analyze U–Pb system in the whole rock samples or multigrain mineral separates using dissolution and chemical separation produced large errors due to the uncertainties associated with the unknown isotope composition of the non-radiogenic Pb component (i.e., Pb that is not formed from the in situ U decay) present in the samples. Nevertheless, recent application of intense leaching prior to dissolution of the samples helps to circumvent the problem and remove this non-radiogenic component, which often consists of a complex mixture of Pb incorporated into the samples during their formation or alteration or as contamination during the laboratory processing. Although leaching artificially separates Pb from U thereby reducing applicability of the system to ^{207}Pb – ^{206}Pb only, it does allow levels of accuracy and precision compatible with those obtained in the analysis of accessory minerals.

Development of analytical protocols combined with the improved understanding of behavior of U–Pb system in rocks and minerals resulted in an accelerated buildup of the chronological database of planetary materials during the last decade. This buildup helps to get a glimpse of geological

*Email: a.nemchin@curtin.edu.au

processes operating in the solar system from its early evolutionary stages when magma differentiation and meteoritic bombardment influenced development of small bodies in the asteroid belt, Moon, and Mars to the very recent basaltic magmatism on Mars.

Although meteorites originating in the asteroid belt can be considered to represent early stages of planetary evolution and therefore treated as planetary materials, they are excluded from the discussion in this section, which concentrates on describing U–Pb systems in the rocks and minerals from the relatively large planetary bodies, Moon and Mars, each showing a prolonged history of magmatic evolution and differentiation.

U–Pb Ages of Lunar Samples

Two unique features of the Earth's Moon extend applicability of U–Pb system to the dating of materials that are often impossible to date in other terrestrial and extraterrestrial samples. The first one is the initial depletion of the Moon in Pb, which is attributed to the relative volatility of this element and its profound loss during the formation of the Moon. This loss results in a generally very high U/Pb observed in the majority of lunar materials, reducing influence of the initial Pb corrections required for the age calculations. This also makes it possible to extract coherent age information from usually difficult mineral phases such as apatite and even from volcanic and impact glasses, often showing very low U concentrations of 1–200 parts per billion (ppb). The second is a substantial enrichment of near side of the Moon in the incompatible elements, which stems from the final stages of crystallization of a global magma ocean on the Moon that formed a KREEP reservoir (for high concentration of K, rare earth elements (REE), and P). This results in an unusually high abundance of U-bearing minerals, including zircon in many lunar rocks, even those that are mafic in composition, which do not commonly host these minerals in non-lunar materials.

The contribution of U–Pb methods to the lunar chronology has to be viewed in the context of modern understanding of lunar history, which comprises several major stages following each other. This understanding was established utilizing a combination of different chronological, petrological, and geochemical techniques and suggests formation of the Moon as a result of a Giant Impact, which led to the lunar magma ocean that has determined initial differentiation of the planetary body and its subsequent magmatic evolution. Early plutonic magmatism was followed by extensive formation of mare basalts, which mostly subsided by about 3.0 Ga, with only few younger ages recorded in the available sample collection. In addition, the Moon as an airless body with very limited recent internal activity preserved evidence of meteoritic bombardment throughout its history. In particular, lunar exploration during the post-Apollo era has established the presence of a spike in the flux of impactors around 3.9 Ga, named the terminal lunar cataclysm.

Zircon is particularly abundant in the rocks of Mg and alkali suites formed as a result of a widespread plutonic magmatism on the Moon, which followed crystallization of the lunar magma ocean. These rocks range in composition from dunite and troctolite to gabbro-norite and anorthosite and probably formed as a result of differentiation of mafic magma inside the lunar crust by the processes similar to differentiation of layered intrusions on Earth. Some more felsic differentiates such as quartz-monzodiorite and granite are also present but substantially less common on the Moon. U–Pb dating of zircon from these rocks collected from several Apollo landing sites indicates multiple spikes of plutonic activity on the Moon between about 4.37 and 3.90 Ga (Meyer et al. 1996; Nemchin et al. 2008).

In addition to tracing the magmatic history of the Moon, lunar zircon grains often contain multiple features indicative of impacts. These features include planar deformation features (PDFs) and twins developed along specific directions in the crystals as well as deformed, recrystallized or amorphous domains present in the grains. Some of these internal structures are large enough to be dated using modern microanalytical methods and allow constraining ages of impacts. Importantly, the zircon U–Pb system is extremely stable even under very harsh conditions compared to the other radiogenic systems. As a result, unlike other systems that often record a substantial spike in the flux of impactors at about 3.9 Ga, zircon preserves a memory of much older impacts. At least two such impacts at about 4.35 and 4.20 Ga have been recognized based on the recent studies of lunar zircon (e.g., Pidgeon et al. 2007; Grange et al. 2009; Nemchin et al. 2009a).

Lunar phosphates represented by apatite and merrillite are common in both mare basalts and plutonic rocks. However, only in the latter do they appear to contain enough U to provide high quality age constraints. The earlier mentioned Pb depletion of the Moon makes lunar phosphates a much better target than similar minerals from other extraterrestrial and terrestrial materials. Nevertheless, only a limited number of U–Pb ages of lunar phosphates are published. These published results indicate a profound resetting of the system during the 3.9 Ga cataclysm (Grange et al. 2009; Nemchin et al. 2009b).

Rasmussen et al. (2008) demonstrated that at least some lunar basalts contain a suite of Zr minerals, such as zirconolite, tranquillityite, and baddeleyite. All these minerals also concentrate U in the quantities sufficient for a precise U–Pb dating. Although this initial work demonstrated the capability and opened the gateway for the investigation of ages of lunar basalts, only a few random studies of these minerals in lunar meteorites and Apollo breccia samples have been published during the following few years (e.g., Wang et al. 2012). A systematic study of U–Pb ages of accessory minerals in different types of lunar basalts from different landing sites remains one of the great opportunities for the future research.

In addition to mare basalts, late post-3.9 Ga basaltic volcanism on the Moon is represented by different types of volcanic glass beads accumulated in the lunar soils. These types are distinguished by their chemical compositions often indicating different source and depth of formation of parent melt in the lunar mantle. The glass beads are spherules varying in size from few microns to few millimeters and believed to be formed by lava fountaining into space, resulting in the dispersion of melt and formation of spherical droplets, which solidify and settle downwards accumulating in the lunar regolith. Nemchin et al. (2011, 2013) showed that some of these glasses contain a very small proportion of initial Pb and enough U to provide meaningful ages, opening yet another avenue to study lunar basaltic magmatism. The general spread of ages between about 3.8 and 3.0 Ga was constrained for both mare basalts and volcanic glasses following the sample returns by Apollo missions. However, development of new microanalytical methods opens an opportunity to investigate detailed distribution of ages of different types of basalts on the Moon with unprecedented temporal resolution utilizing advantages given by the U–Pb system, such as its general stability in many minerals even under severe conditions during secondary events and capability to test internal consistency using two independent decay schemes (i.e., ^{238}U to ^{206}Pb and ^{235}U to ^{207}Pb).

One major component of the lunar rock suite identified by the investigation of samples in the Apollo collection, which appears not to be suitable for U–Pb dating using a microanalytical approach, is a set of ferroan anorthosites (FAN) comprising the crust of the Moon. These anorthosites commonly contain just a few percent of mafic minerals and no U-bearing accessory phases restricting applicability of U–Pb dating methods. Multiple attempts to determine U–Pb ages of these rocks using whole rock samples and mineral separates were hindered by the presence of multiple non-radiogenic Pb components. However, recent study of a FAN sample from Apollo 16

landing site (Borg et al. 2011) utilized heavy leaching of the separates prior to their dissolution for analysis and was able to quantitatively remove these components, achieving precise age estimate of 4359.2 ± 2.4 Ma from the $^{207}\text{Pb}/^{204}\text{Pb}$ versus $^{206}\text{Pb}/^{204}\text{Pb}$ isochron. This age is similar to Sm–Nd age obtained from the same separates increasing confidence that it is a true age of the sample.

U–Pb Ages of Martian Samples

Martian samples are less abundant than lunar materials and restricted to basalts and mafic-ultramafic cumulates. Detailed imaging of the Martian surface by orbiters indicates significant difference in elevation and composition of northern and southern hemisphere. This dichotomy is also expressed in the substantial difference in the observed crater density and hence the age. The southern hemisphere called the southern highlands is heavily cratered and ancient. In contrast the lowlands of northern hemisphere show very few large craters and appear to be much younger. It is believed that majority of available Martian Shergotty-Nakhla-Chassigny (SNC) meteorites originate from this younger part of the planet.

Analysis of various isotope systems in whole rocks and mineral fractions of SNC meteorites resulted in a general agreement that nakhlites and chassignites are ~1.3 Ga old and shergottites are significantly younger in the order of a few hundred million years (e.g., Nyquist et al. 2001). However, U–Pb or rather Pb–Pb systematics of one SNC group, basaltic shergottites, became a subject of ongoing controversy. Most mineral isochrons obtained by different isotope techniques cluster around 180 and 330–475 Ma (Nyquist et al. 2001). However, in $^{207}\text{Pb}/^{204}\text{Pb}$ versus $^{206}\text{Pb}/^{204}\text{Pb}$ coordinates, data for a number of these samples form arrays, interpreted by Bouvier et al. (2005, 2008) as isochrons, defining ages close to 4.0–4.1 Ga. Consequently two conflicting interpretations of U–Pb system in basaltic shergottites have coexisted in the literature for almost a decade. One interpretation advocates a young time of formation for these rocks (e.g., Nyquist et al. 2001; Borg et al. 2005; Borg and Drake 2005) and explains unusually old Pb–Pb ages of shergottites as a feature inherited from the basaltic magma source that differentiated very early in Martian history. The other (Bouvier et al. 2005 and 2008) interprets these old ages as true ages of the rocks, finding additional evidence for this conclusion in the studies of cratering of Martian surface. These studies suggest a very small fraction of young terrains on Mars, creating a conflict if shergottites are young and present in a high proportion among the available Martian meteorites. Within this point of view, younger ages of basaltic shergottites obtained using other isotope systems reflect resetting of these systems during the impacts, probably those that ejected meteorites from Mars and set them on the collision course with Earth.

Several studies attempted to resolve this controversy by U–Pb dating of baddeleyite often present in shergottites and formed during the magmatic crystallization of the rocks. Zhou et al. (2013) reported $^{206}\text{Pb}/^{238}\text{U}$ age of 182.7 ± 6.9 Ma for baddeleyite from the Zagami meteorite, while Moser et al. (2013) investigated baddeleyite crystals overgrown by the submicron zircon grains from meteorite NWA5298. This zircon was interpreted as forming as a result of reaction between baddeleyite and high-Si fluid or melt generated during the impact that launched this meteorite into the space. The $^{206}\text{Pb}/^{238}\text{U}$ ages of baddeleyite grains investigated in this study spread between 227 ± 18 and 22 ± 2 Ma, giving both time of baddeleyite crystallization, estimated as 187 ± 33 Ma on the basis of the least disturbed grains, and an upper limit for the impact event given by the youngest baddeleyite analysis (Moser et al. 2013). Consequently, published results of U–Pb baddeleyite dating appear to support the young age of basaltic shergottites.

One of two samples that are different from the main population of rocks in the Martian meteorite collection is orthopyroxenite ALH84001. The sample is composed of 96 % orthopyroxene, a composition unusually uniform for Martian meteorites (Mittlefehldt 1994), and some minor chromite, plagioclase, and phosphate. In addition carbonates with strong compositional zoning are found along the fractures and cataclastic areas. Difference of this sample from all other known Martian meteorites is also supported by the consistently ancient age obtained from all isotope systems (Nyquist et al. 2001). Even Rb–Sr and K–Ar (^{39}Ar – ^{40}Ar) systems, which are most prone to resetting, show ages that are not younger than 3.9 Ga. Although, the silicate constituents of ALH84001 are not possible to date using U–Pb system, Borg et al. (1999) utilized compositional variability of carbonates in these samples to obtain a 4.04 ± 0.1 Ga age from the $^{207}\text{Pb}/^{204}\text{Pb}$ – $^{206}\text{Pb}/^{204}\text{Pb}$ isochron. This is similar within the errors to the Rb–Sr age of 3.90 ± 0.04 Ga, supporting an ancient formation age of its carbonates.

The second set of samples distinct from SNC is represented by paired meteorites NWA7533 and NWA7034 recently identified as originating from Mars (Agee et al. 2013). Humayun et al. (2013) described these rocks as a regolith breccia formed as a result of impact or series of impacts that collected a variety of fragments of different origin near the Martian surface and fused them together with the interstitial impact melt. Mineral and chemical composition of the fragments and the samples suggest that these meteorites are the first available samples from southern hemisphere of Mars. This is supported by the age of zircon grains identified in these samples and associated with the group of leucocratic, K-feldspar-rich clasts. Humayun et al. (2013) reported results of U–Pb dating of these zircons. Several analyzed grains are concordant defining a crystallization age of zircon grains (and their host rocks) as $4,428 \pm 25$ Ma. Others fall on a discordia with the upper intercept age similar to that of concordant zircon and the lower intercept defining the time of resetting of U–Pb system in the most metamict grains as $1,712 \pm 85$ Ma.

Summary or Conclusions

Development of microanalytical methods of isotope analysis allowing in situ age determination in the small (few tens of micrometers) areas inside individual grains resulted in significant expansion of U–Pb age database of planetary materials, which include lunar and Martian samples. Combined with detailed imaging of the samples, these ages give unprecedented new information about the origin and evolution of the planets and have direct and indirect influence on the development of ideas and models for evolution of our own planet Earth. A variety of planetary materials of diverse composition and origin can be dated using U–Pb system, as U is concentrated in the quantities sufficient for analysis in a number of different minerals and glasses. Some of these materials, such as zircon in lunar breccias, have been extensively studied during the last decade, while capability of others remain mostly unexplored leaving a significant potential for the future research and new discoveries.

Early Life on Earth

David Wacey*

Centre for Microscopy Characterisation and Analysis, University of Western Australia, Crawley, Perth, Australia

Definitions

The most obvious signs of early life on Earth are in the form of *body fossils*. On the early Earth, only the most primitive of microorganisms lacking any hard parts would have been present, so only soft parts in the form of cells, sheaths, and perhaps associated secreted polymeric substances are likely to be found. Alternatively, signs of life may be in the form of *trace fossils*. These are nonbody remains that in the broadest sense indicate the activity of an organism (e.g., a microboring) or a community of organisms (e.g., a stromatolite or microbially induced sedimentary structure). A third way early life may be recognized is in the form of *chemical fossils*. These are traces of biological activity indicated by specific chemical signals left in rocks. Chemical fossils may be preserved in organic matter or in “biominerals” such as pyrite; they include isotopic variations in carbon, sulfur, nitrogen, or iron, distinctive ratios of elements, or molecular compounds that may be tied to a particular group of organisms.

Protocols for Identifying Early Life on Earth: Where to Look

This is not merely a case of looking at Earth’s oldest rocks. As well as being demonstrably of the correct age, such rocks must have been deposited in a setting that could viably host life and ideally should have undergone minimal postdepositional alteration. When these factors are taken into consideration, the search for Earth’s earliest life is focused on two main areas of the world: the Pilbara Craton of Western Australia and the Barberton greenstone belt of southern Africa, both containing sedimentary and volcanic rocks up to c. 3.5 billion years old (Ga [giga-annum]). In addition, parts of Greenland contain putative sedimentary rocks approaching 3.8 Ga, but these have been altered (metamorphosed) at higher temperatures and strain rates making the identification of life more difficult and controversial.

Protocols for Identifying Early Life on Earth: Establishing Antiquity

Proving that a putative life signature is of undoubted early Archean (i.e., >c. 3 Ga) age is a vital step in testing any claim for Earth’s earliest life. Hence, a number of antiquity criteria have been put forward that any life sign should satisfy. These include being able to demonstrate the age and provenance of the host rocks, that the candidate life sign is both physically embedded within the host rock (indigenous) and not introduced by later fluids (syngenetic), and that it has a composition (carbonaceous or non-hydrated mineral) and color (i.e., black to dark brown if carbonaceous)

*Email: david.wacey@uwa.edu.au

consistent with the deposition and alteration history of the host rock (see Wacey 2009, for detailed criteria).

Protocols for Identifying Early Life on Earth: Establishing Biogenicity

Criteria have also been put forward to minimize the possibility of interpreting a nonbiological structure as biological. Thus, candidate microfossils should exhibit the following: biological morphology that can be related to extant cells, sheaths, or waste products; more than a single step of biology-like processing, perhaps in the form of associated biominerals, geochemical fractionations of isotopes, specific organic compounds, or distinctive elemental ratios; a geological and evolutionary context that is plausible for life; abundance, ideally occurring in a multicomponent assemblage showing community behavior; kerogenous carbon composition or composed of microbially mediated minerals such as pyrite; a largely hollow nature and occupying a restricted biological morphospace; evidence for taphonomic degradation such as collapse of cells, folding of films, or fracturing; and dissimilarity from known potentially coexisting nonbiological organic bodies (e.g., self-organizing spherulitic structures).

Similarly, trace fossils such as microbial borings should exhibit the following: circular to elliptical cross sections and a restricted range of diameters; preferential exploitation of certain substrates or horizons; enrichments of biologically important elements, such as carbon and/or nitrogen enriched linings, or biomineral infillings; and preferred growth orientations. Stromatolites must also fulfill a set of criteria in an attempt to exclude abiotic mimics such as soft sediment deformation, later structural deformation, and chemical precipitation of stromatolite-like crusts (see Wacey 2009, for detailed criteria).

Protocols for Identifying Early Life on Earth: Techniques

Fulfilling the criteria outlined above requires the use of a wide range of techniques that permit investigation from the kilometer to nanometer scale. Geological mapping at scales from kilometers to meters, supported by mapping of petrographic thin sections (c. 30–100 μm -thick rock slices), is required to show that candidate life structures are truly syngenetic and ancient. This contextual and petrographic mapping is also the first stage in falsifying the null hypothesis of a nonbiological origin for a given object.

Obtaining evidence for a uniquely biological morphology requires in situ imaging and mapping of morphospace to distinguish the fields of biological and nonbiological morphology and to compare these with self-organizing structures. This is commonly undertaken under the optical microscope using petrographic thin sections but with recent technological advances may also extend to investigation using a scanning electron microscope (SEM), transmission electron microscope (TEM), lasers, or X-rays. One recent advance is the ability to extract site-specific ultrathin (c.100 nm) wafers from a petrographic thin section or rock chip using a focused ion beam (FIB), allowing the morphology of candidate life signs to be studied at nanometer-scale spatial resolution in the TEM. FIB combined with SEM also permits 3D modeling and reconstruction of candidate microfossils at nanometer-scale resolution. Laser Raman microspectroscopy and X-ray tomography also permit visualization of candidate microfossils in 3D albeit at poorer spatial resolution.

Finally, obtaining geochemical evidence for metabolic cycling requires micro- to nanoscale in situ mapping and analysis. Here, potential biological isotope fractionations can be detected using

Table 1 Summary of reported evidence for life in >3 Ga rocks in the Pilbara region of Western Australia

Age	Geological unit	Morphological evidence	Geochemical evidence	References
~3 Ga	Farrel Quartzite, Gorge Creek Group	Microfossils: spheroids, 2.5–80 µm in diameter; lens/spindle shapes up to 40 µm in length and 35 µm in width; threadlike filaments <1 µm diameter and up to 100 µm in length; potential carbonaceous biofilms (see Fig. 1j)	Bulk carbon isotopes: $\delta^{13}\text{C}$ c. –30 ‰ to –35 ‰ consistent with biology Laser Raman: fossils are made of carbon and carbon structure is consistent with age and biology Elemental mapping: C, N, and S found in microfossil walls	Sugitani et al. 2009
~3.24 Ga	Kangaroo Caves Formation, Sulfur Springs Group	Microfossils: solid pyritic filaments 0.5–2 µm in diameter and up to 300 µm in length, often intertwined and densely clustered (see Fig. 1h) Microfossils: filaments and tubes <1 µm wide, often bundled in packages 1–5 µm in diameter and up to 100 µm in length; aggregates of tiny spheres <50–100 nm in diameter	None Bulk carbon isotopes: $\delta^{13}\text{C}$ c. –27 ‰ to –34 ‰ consistent with biology	Rasmussen 2000 Duck et al. 2007
~3.35 Ga	Euro Basalt, Kelly Group	Trace fossils: microtubes 1–5 µm in diameter and up to 150 µm in length, often branched and segmented Microfossils: spheroids c. 8 µm in diameter; spheroids c. 21 µm in diameter sometimes enclosed by a potential sheath	Elemental mapping: possible enrichments of C and N within the microtubes None	Banerjee et al. 2007 Schopf and Packer 1987
~3.4 Ga	Strelley Pool Formation	Microfossils: carbonaceous spheroids (c. 5–25 µm in diameter), tubes (c. 7–20 µm in diameter), and rare cellular envelopes (up to 80 µm in diameter), associated with micron-sized pyrite. Spheroids often cluster and organize into chains. Microfossils colonize sand grains and some show taphonomic degradation (see Fig. 1f) Stromatolites: best examples are conical and columnar morphologies with trapped and reworked grains (see Fig. 1d) Microfossils: lenticular/spindle shapes (long axis c. 35–120 µm), large spheroids (up to c. 100 µm diameter), clusters of smaller spheroids, wrinkled and folded carbonaceous films, and threadlike filaments	In situ carbon isotopes: $\delta^{13}\text{C}$ –33 ‰ to –46 ‰ consistent with biology In situ sulfur isotopes: $\delta^{34}\text{S}$ range of 18 ‰ and $\Delta^{33}\text{S}$ of +1.43 ‰ to –1.65 ‰ indicating sulfur-processing metabolisms Elemental mapping: nitrogen enrichment in microfossil walls Laser Raman: carbon structure consistent with age and biology Elemental distributions: co-occurrence of C, N, and S in detrital carbonaceous grains; rare earth element enrichment in carbonate laminae relative to chert laminae is consistent with younger microbial carbonates Bulk carbon isotopes: $\delta^{13}\text{C}$ c. –31 ‰ to –37 ‰ consistent with biology Laser Raman: shows microfossils are carbonaceous and carbon has structure consistent with age and biology	Wacey et al., 2011a Allwood et al. 2006 Sugitani et al. 2010

(continued)

Early Life on Earth, Table 1 (continued)

Age	Geological unit	Morphological evidence	Geochemical evidence	References
		Trace fossils: microborings (channels and spherical to elliptical surface pits, with near constant diameter of 1–5 μm) often concentrated in clumps along one side of a detrital pyrite grain (see Fig. 1e)	Elemental mapping: C and N enrichments in some microborings Laser Raman: shows carbonaceous biofilms associated with some microborings; carbon has structure consistent with age and biology	Wacey et al., 2011b
		Possible trace fossils: microtubes containing a pyrite grain at their termination – known as ambient inclusion trails	In situ carbon isotopes: mean $\delta^{13}\text{C}$ of c. –26 ‰ from carbonaceous microtube linings Elemental mapping: enrichments in C, N, P, and S in some microtubes	Wacey et al. 2008
~3.45 Ga	Panorama Formation, Warrawoona Group	Microbial mat with microfossils: spheroids (<1 μm in diameter), often clustered or in chains; filaments (<1 μm diameter and up to 40 μm in length); occasional rod shapes; films interpreted as fossilized extracellular polymeric substances (see Fig. 1c)	Bulk carbon isotopes: $\delta^{13}\text{C}$ c. –26 ‰ to –30 ‰ consistent with biology Laser Raman: spectra indicate carbon with a structure consistent with age and biology	Westall et al. 2006b
~3.46 Ga	Apex Basalt, Warrawoona Group	Possible microfossils: filaments – eleven “species” varying in average diameter from 0.5–16.5 μm and 28–89 μm in length BUT: many are C-, J-, and L-shaped structures around spherulitic silica crystals; some follow ghost rhombic crystal outlines	Bulk carbon isotopes: $\delta^{13}\text{C}$ averages –27.7 ‰ consistent with biology Laser Raman: spectra show objects are made of carbon and structure consistent with biology BUT: carbon isotope and Raman signals are also consistent with abiotic carbonaceous artifacts; some may not be carbonaceous	Schopf 1993 Brasier et al. 2002
~3.49 Ga	Dresser Formation, Warrawoona Group	Microfossils: 3 types of filaments: (a) average 1 μm in diameter, some mutually interwoven and branched; (b) segmented, unbranched, average 8.7 μm in diameter; (c) non-segmented, tubular, average 12.6 μm in diameter Stromatolites: coniform, nodular, domical and wavy-laminated morphotypes (see Fig. 1a) Microfossils: entire “hollow cells” and fragments such as “cell walls” observed under the transmission electron microscope Possible biominerals: microscopic pyrite (no biological morphology) Methane in fluid inclusions: no biological morphology	Bulk and in situ carbon isotopes: $\delta^{13}\text{C}$ c. –30‰ to –42 ‰ consistent with biology None Bulk carbon isotopes: $\delta^{13}\text{C}$ c. –32 ‰ to –36 ‰ consistent with biology Bulk and in situ sulfur isotopes: $\delta^{34}\text{S}$ range of 22‰; $\Delta^{33}\text{S}$ of +6 ‰ to –1.2 ‰ consistent with sulfur-processing biological metabolisms Carbon isotopes: $\delta^{13}\text{C}$ –36 ‰ to –56 ‰ consistent with microbial methanogenesis	Ueno et al. 2001 Van Kranendonk et al. 2008 Glickson et al. 2008 Shen et al. 2009 Ueno et al. 2006

Table 2 Summary of reported evidence for life in >3 Ga rocks in the Barberton region of South Africa

Age	Geological unit	Morphological evidence	Geochemical evidence	References
~3.22 Ga	Moodies Group	Microbially induced sedimentary structures: wrinkle and roll-up structures; aligned grains in a matrix of carbonaceous laminae (see Fig. 1i)	Bulk carbon isotopes: $\delta^{13}\text{C}$ around -20‰ consistent with biology	Noffke et al. 2006
~3.25 Ga	Fig Tree Group	Stromatolites: laterally linked domes, pseudo-columns, and crinkly stratiform varieties	None	Byerly et al. 1986
		Putative microfossils: spheroidal 1–4 μm in diameter; possible internal contents; possible binary division	None	Knoll and Barghoorn 1977
~3.3–3.4 Ga	Kromberg Formation, Onverwacht Group	Microbial mat: carbonaceous laminations with portions “ripped up” and/or folded over; some filaments preserved (see Fig. 1g)	Bulk carbon isotopes: $\delta^{13}\text{C}$ of -25‰ to -35‰ consistent with biology	Tice and Lowe 2004
		Carbonaceous grains: possible eroded fragments of a microbial mat	Bulk carbon isotopes: $\delta^{13}\text{C}$ of -25‰ to -35‰ consistent with biology	Tice and Lowe 2004
		Putative microfossils: a selection of <2 μm spheroidal and rodlike morphologies, often clustered or paired	Bulk carbon isotopes: $\delta^{13}\text{C}$ of -27‰ consistent with biology	Westall et al. 2001
		Putative microfossils: tubular and solid carbonaceous and pyritic filaments up to 2.5 μm diameter and 200 μm long, plus large spindle shapes	None	Walsh 1992
~3.45 Ga	Hoogenoeg Formation, Onverwacht Group	Trace fossils: segmented microtubes ~ 4 μm in diameter and up to 200 μm in length (see Fig. 1b), plus clustered spheres	In situsulfur isotopes: $\delta^{34}\text{S}$ of -40‰ to -3‰ from pyrite in microtubes indicates sulfur-based metabolism	McLoughlin et al. 2012
			Bulk carbon isotopes (carbonate): $\delta^{13}\text{C}$ of -16‰ to $+4\text{‰}$	Furnes et al. 2004
		Putative microfossils: solid filaments up to 2.6 μm diameter and 200 μm long	None	Walsh and Lowe 1985
		Putative microfossils: sausage-shaped, up to 3.8 μm long and 1.1 μm wide	None	Westall et al. 2006a
		Putative microbial mat: crinkly carbonaceous laminations; some bundled, broken, or folded over; carbonaceous grains	None	Walsh 1992
		Microbial mat: comprising parallel and interwoven filaments; mat was flexible	Bulk carbon isotopes: $\delta^{13}\text{C}$ of -23‰ consistent with biology	Westall et al. 2006a

secondary ion mass spectrometry (SIMS); high sensitivity and high spatial resolution elemental mapping can be performed using NanoSIMS, TEM, or synchrotron. The structure of carbon or

more complex organic material can be investigated using laser Raman microspectroscopy, TEM, or synchrotron, and the oxidation and bonding states of some biologically important elements such as Fe and S can also be resolved using TEM or synchrotron (see Wacey 2009, 2012, for details on techniques).

Examples of Earth's Earliest Life

Reported examples of > 3 Ga life on Earth are summarized in Tables 1 and 2, plus Fig. 1.

Summary

Possible signs of life have been reported from eleven separate geological formations and from at least eight different lithologies in the Pilbara and Barberton regions, spanning almost the entire exposed 3–3.5 Ga stratigraphy. Evidence for life includes stromatolites, microfossils, trace fossils, biominerals, and isotopic signatures and comes from environments as diverse as a carbonate platform, sandy beach, and deep-sea hydrothermal black smoker. Putative life signals, in the form of isotopic signatures, have also been reported from rocks as old as c. 3.8 Ga in Greenland but these are particularly controversial.

Synonyms

CFC dating; Chlorofluorocarbon dating; SF₆ dating

Definition

Atmospheric environmental releases refer to the emission of stable, long-lived compounds of solely anthropogenic origin into the atmosphere and the use of the compounds to estimate dates of their incorporation into groundwater.

Introduction

The majority of environmental anthropogenic tracers that can be used to date groundwater were released to the atmosphere after 1940 (Fig. 1). Groundwater dating relates the measured concentration of these trace atmospheric gases to the reconstructed history of the trace gas concentration in the atmosphere. Three general types of tracers can be used to date groundwater: (1) halogenated tracers, including the chlorofluorocarbons and hydrochlorofluorocarbons (CFCs and HCFCs), the perfluorocarbons and hydrofluorocarbons (PFCs and HFCs), sulfur hexafluoride (SF₆), trifluoromethyl sulfur pentafluoride (SF₅CF₃), and nitrogen trifluoride (NF₃) (IAEA 2006); (2) anthropogenic radiogenic tracers introduced by atmospheric nuclear testing and reactor fuel reprocessing (³H, ¹⁴C, ³⁶Cl, and ⁸⁵Kr) (Cook and Herczeg 1999; Plummer 2005); and (3) event markers which include alkylbenzene sulfonate (ABS) and linear alkylbenzene sulfonate (LAS) surfactants, herbicides, pharmaceuticals, pesticides, and their degradation products (Plummer et al. 1993). A number of excellent reviews discussing groundwater ages and dating methods using environmental tracers have been published (Plummer et al. 1993; Cook et al. 1995; Plummer and Friedman 1999; Goode 1996; Höhener et al. 2003; Bethke and Johnson 2008; Darling et al. 2010; Newman et al. 2010). This section discusses the application of halogenated atmospheric tracers to groundwater dating.

CFCs were first synthesized in the late 1920s, and by the 1940s they became the replacements for ammonia, sulfur dioxide, and methyl chloride as refrigerants, which had been implicated in a series of accidents and deaths (Giunta 2006). CFC production, applications, and releases accelerated after World War II, with chlorofluorocarbons eventually comprising approximately half of the tropospheric chlorine burden (Schauffler et al. 1993). In developed countries, production of CFCs stopped, and releases slowed following ratification of the *Montreal Protocol on Substances that Deplete the Ozone Layer* treaty. Concentrations in the atmosphere are now in decline (WMO 2010). The CFCs have been replaced by hydrochlorofluorocarbons (HCFCs), which will also be phased out by 2030, and by hydrofluorocarbons (HFCs). These compounds have much shorter atmospheric

Fig. 1 Historic northern hemisphere background air concentrations of CFC-11, CFC-12, CFC-113, and SF₆ (<http://water.usgs.gov/lab>); global average ⁸⁵Kr activity per liter of air (Ahlsweide et al. 2009, 2013); northern hemisphere ³⁶Cl deposition rate (Bentley et al. 1986; Bentley et al. 1982; Althaus et al. 2009); ³H activity in Washington, DC, precipitation (IAEA/WMO 2006); and global average percent modern ¹⁴C in atmospheric CO₂ (Nydal and Lövseth 1983; Winger et al. 2005; Turnbull et al. 2007)

lifetimes and are less damaging to the ozone layer than the CFCs (WMO 2010). The concentration of perfluorocarbons (PFCs) (CF₄, C₂F₆), SF₆, and SF₅CF₃ are lower than CFCs, have atmospheric lifetimes of hundreds to thousands of years, and are potent greenhouse gases (IPCC 2007). PFC analysis in water is difficult and these compounds have not been routinely used in groundwater dating (Deeds et al. 2008; Deeds 2008). In contrast, analyses of CFCs, SF₆, and SF₅CF₃ are relatively easy by gas chromatography with an electron capture detector (GC-ECD) (Lovelock 1958, 1974; Thompson and Hayes 1979; Busenberg and Plummer 1992; Bullister and Weiss 1988; Hofer and Imboden 1998; Busenberg and Plummer 2000, 2008).

Dating young groundwater is important for evaluating groundwater resources. CFC dating was used to obtain the historical record of nitrate contamination in aquifers (Böhlke and Denver 1995; Katz et al. 2001; Lindsey et al. 2003; Böhlke et al. 1997; Johnston et al. 1998) and groundwater pollution histories and evaluation susceptibility of aquifers to contamination (Shapiro et al. 2004; Nelms et al. 2003; Plummer et al. 2008), to evaluate aquifer resources (Dunkle et al. 1993; Szabo et al. 1996; Plummer et al. 2000; Bauer et al. 2001; Burton et al. 2002; Lindsey et al. 2003; Cook et al. 2005; Gooddy et al. 2006; McMahon et al. 2011; Manning et al. 2012; Liu et al. 2013; von Rohden et al. 2010b), and to calibrate groundwater models (Reilly et al. 1994; Weissmann et al. 2002).

Groundwater Dating Theory

The concentrations of environmental tracers in groundwater are affected by transport processes. Dating based on concentrations of atmospheric gases in groundwater depends on the model used and model-dependent assumptions of mixing and transport in aquifers. For preliminary age interpretations, the piston-flow model is used (Fontes 1982; Zuber 1986). The piston-flow dating method uses

the measured tracer concentrations in water and their calculated partial pressures and subsequently compares them to known historical concentrations in the atmosphere. Several assumptions are implied by the piston-flow model: the tracers are in equilibrium with the gas at the water table during recharge (when the water reaches the water table), the tracer partial pressures at the water table are the same as the atmosphere (i.e., the unsaturated zone is less than 10 m thick), the recharge temperature and elevation are known, and the tracer concentrations in the aquifer were not significantly modified by adsorption, contamination, matrix diffusion, or biodegradation. The piston-flow model assumes that water moves as closed packets with no mixing or hydrodynamic dispersion (Fontes 1982). The concentration of several environmental tracers in groundwater can also be described by lumped-parameter mathematical models. These models use simplified aquifer geometries, flow, hydrodynamic dispersion, and mixing to describe tracer concentrations in the aquifer and borehole (Zuber 1986; Zuber and Rosanski 2007; Cook and Böhlke 1999; Gooddy et al. 2006; Eberts et al. 2012; Jurgens et al. 2012). However, groundwater samples are mixtures of packets of molecules each with a unique age and tracer concentration. This is an important distinction, as individual components have different aquifer residence times. Thus, a successful reactive transport flow model will calculate all the observed tracer concentrations in the groundwater. Tracer concentrations are best used to calibrate transport and flow models which can be used to determine the average residence time of the sample in the aquifer (Etcheverry and Perrochet 2000; Bethke and Johnson 2008; Newman, et al. 2010).

Uncertainty in age determination (disparities between tracers ranging from several to many years) can derive from many sources, including vadose zone thickness, recharge temperature, infiltration rate, dispersion, mixing, and bacterial activity (IAEA 2006). Corrections need to be applied to tracer concentration measurements if recharge is through thick unsaturated zones since the partial pressures at the water table can be significantly different from atmospheric concentrations due to diffusion through the vadose zone (Cook et al. 1995, 2006; Cook and Solomon 1997, Busenberg and Plummer 2000, 2008; Engesgaard et al. 2004). The recharge temperature may be different from the water temperature at the time of sampling, since recharge temperature is often within ± 1 °C of the mean annual air temperature of the recharge area (Collins 1925; Zuber et al. 1995; Stute and Schlosser 1993). Tracer concentrations will exceed the equilibrium concentration when there is a rapid rise in the water table, which causes trapped gas bubbles (excess air) to dissolve due to the increase in hydrostatic pressure and which requires correction of the dissolved tracer concentrations (Stute et al. 1995; Aeschbach-Hertig et al. 1999, 2000; Sun et al. 2010). The recharge temperature, excess air, and recharge elevation can be estimated from dissolved noble gas concentrations (Ne, Ar, Kr, and Xe) measured by mass spectrometry (Cook et al. 2006; Sun et al. 2010). In aerobic waters, the recharge temperature and excess air can be estimated by gas chromatography (GC) from the concentrations of N₂ and Ar alone (Heaton and Vogel 1981).

Relationships Between Age Tracers and Solubility

The equilibrium concentration of gases in water is described by Henry's Law (Eq. 1), which equates the aqueous concentration to the partial pressure (mole fraction) of gases above the water:

$$C_w = K_h(x_i) \quad (1)$$

where C_w is the molar concentration of the gas in water, K_h is the Henry's Law constant, and x_i is the partial pressure of the gas (Weiss 1970; Warner and Weiss 1985). The equilibrium concentration is

Table 1 Solubility coefficients to the Clarke-Glew-Weiss (Eq. 4) used for determining solubilities in water (Warner and Weiss 1985; Bu and Warner 1995; Bullister et al. 2002; Busenberg and Plummer 2008). Units are in mol L⁻¹ atm⁻¹

Compound	A	B	C	D	E	F	Ref.
CFC-11 (CCl ₃ F)	-134.1536	203.2156	56.2320	-0.144449	0.092952	-0.015997	(Bullister and Weiss 1988)
CFC-12 (CCl ₂ F ₂)	-122.3246	182.5306	50.5898	-0.145633	0.092509	-0.0156627	(Bullister and Weiss 1988)
CFC-113 (C ₂ Cl ₃ F ₃)	-134.243	203.898	54.9583	-0.02632	0.005874	–	(Bu and Warner 1995)
SF ₆	-80.0343	117.232	29.5817	0.0335183	-0.0373942	0.00774862	(Bullister et al. 2002)
SF ₅ CF ₃	-12.8108	23.9976	-3.9715	–	–	–	(Busenberg and Plummer 2008)

dependent on the atmospheric pressure and the solution temperature and salinity. The mole fraction of the gas above the solution is given by the equation:

$$x_i = \frac{m_i}{K_h(P - p_{H_2O})} \quad (2)$$

where x_i is the dry mole fraction of the i th tracer, m_i is the molar concentration, P is the atmospheric pressure, and p_{H_2O} is the vapor pressure of water, respectively. p_{H_2O} is given by the empirical equation:

$$p_{H_2O} = e^{(24.4543 - 67.4509 * (\frac{100}{T}) - 4.8489 \ln(\frac{T}{100}) - 0.000544 * S)} \quad (3)$$

where S is the salinity of the water in per mill and T is the temperature in degrees Kelvin (Weiss and Price 1980). The Clarke-Glew-Weiss equation (Eq. 4) is commonly used to parameterize the temperature- and salinity-dependent gas solubilities (Table 1) (Warner and Weiss 1985; Bu and Warner 1995; Bullister et al. 2002; Busenberg and Plummer 2008):

$$\ln K_h = A + B \times \left(\frac{100}{T}\right) + C \times \ln\left(\frac{T}{100}\right) + S \left(D + E \left(\frac{T}{100}\right) + F \left(\frac{T}{100}\right)^2 \right) \quad (4)$$

where A , B , C , D , E , and F are fit coefficients and T is the equilibrium (recharge) temperature in degrees Kelvin. The solubilities for atmospheric age tracers are shown in Fig. 2.

Historical Atmospheric Concentrations

Ascertaining the historical atmospheric concentrations of tracers is of critical importance to dating with environmental tracers. The historic concentrations of halocarbons have been measured and extensively studied because of their role in atmospheric chemistry and potent radiative forcing properties (IPCC 2007; WMO 2010; Montzka, et al. 2011; Garcia et al. 2012). Many halocarbons that are stable in groundwater systems are routinely measured in a network of ground stations around the world by the National Aeronautics and Space Administration (NASA)-funded Advanced Global Atmospheric Gases Experiment (AGAGE) and the National Oceanic and Atmospheric Administration Earth System Research Laboratory's (NOAA ESRL) Halocarbons and other Atmospheric

Fig. 2 The temperature-dependent solubility of commonly used environmental tracers in pure water

Trace Species Group (HATS) (AGAGE 2013; HATS 2013). These projects have been collecting archive samples and reporting in situ and flask measurements since 1978. The pre-1976 atmospheric concentrations have been reconstructed from production and release estimates (McCarthy et al. 1977; AFEAS 2013). Measurements are typically reported on calibration scales prepared by NOAA (HATS 2013) or Scripps Oceanographic Institute (AGAGE 2013). The majority of atmospheric tracers are produced and released in the northern hemisphere; consequently, there is an approximate 1-year lag in transport between hemispheres (Seinfeld and Pandis 1998). Local atmospheric sources can increase concentrations above background levels in the vicinity of the source, requiring knowledge of the local history in these instances in order to reliably interpret groundwater ages (Oster et al. 1996; Ho et al. 1998; Cook and Solomon 1997; Cook et al. 2006).

Analytical Methods

Purge-and-trap-based GC-ECD systems are usually used to quantify CFCs, SF₆, and SF₅CF₃ concentrations (Lovelock 1958, 1974; Thompson and Hayes 1979; Bullister and Weiss 1988; Busenberg and Plummer 1992, 2000, 2008; Hofer and Imboden 1998). To quantify the HCFCs, HFCs, and many PFCs, methods employing a GC with mass spectrometer detectors (GC-MS) are used, as these compounds have low response in ECDs (Sousa and Bialkowski 1997; Miller et al. 2008; Deeds 2008; Deeds et al. 2008).

Environmental releases of ultra-trace halocarbons may soon become useful in dating groundwater because of improved sampling procedures in the field. Several techniques are being developed that will allow the extraction of gases from very large volumes of water and enable the use of tracers that have atmospheric concentrations of only a few parts per quadrillion (1×10^{-15}) in dating studies (Johnson 1999; Probst et al. 2007; Loose et al. 2009; Ohta et al. 2009; Busenberg and Plummer 2008; Gardner and Solomon 2009; AGAGE 2013).

Fig. 3 Useful dating ranges of CFCs, SF₆, and their ratios

CFC-11, CFC-12, CFC-13, and CFC-113

CFC-11, CFC-12, and CFC-113 are commonly used in groundwater dating studies (Thompson and Hayes 1979; Busenberg and Plummer 1992; Ekwurzel et al. 1994; Solomon et al. 1996; Cook and Solomon 1997), as the other CFCs (CFC-114(a), CFC-115, and CFC-13), have low atmospheric concentrations and(or) are more difficult to detect (Busenberg and Plummer 2008). CFC-11 (CCl₃F) and CFC-12 (CCl₂F₂) were extensively used as safe refrigerants, nonflammable aerosol propellants, and blowing agents for foam plastics. Significant production of CFC-113 (C₂Cl₃F₃), a liquid degreaser and cleaning agent, started in the 1950s. CFC-13 (CClF₃) was primarily used as a very low-temperature refrigerant and has shown promise as a dating tool. CFCs are relatively inert with long atmospheric lifetimes (102, 45, and 85 years for CFC-12, CFC-11, and CFC-113, respectively). CFC-11 and, to a lesser degree, CFC-12 and CFC-113 are susceptible to degradation by methanogenic bacteria in aquifers (Lovley and Woodward 1992; Bauer et al. 2001; Sebol et al. 2007; Balsiger et al. 2005; Montzka and Reimann 2010). CFC atmospheric concentrations in the northern hemisphere peaked between 1990 and 2000 (CFC-12 peaked at 546 pptv in 2001, CFC-11 at 272 pptv in 1994, and CFC-113 at 85 pptv in 1996). Atmospheric concentrations are now slowly decreasing with the 2010 northern hemisphere concentrations of 529, 237, and 74 pptv, for CFC-12, CFC-11, and CFC-113, respectively (Montzka and Reimann 2010). This decrease in atmospheric concentrations can complicate piston-flow age interpretation of modern waters since there is not a unique age solution. This difficulty may be overcome by using CFC/CFC or CFC/SF₆ ratios or SF₆ concentration to qualify the apparent piston-flow age (Fig. 3) (Busenberg and Plummer 2000; IAEA 2006).

SF₆ and SF₅CF₃

Sulfur hexafluoride (SF₆) is an inert gas that has the highest known dielectric constant. The production of SF₆ began in the 1940s as part of the war effort; the high electrical insulating properties were crucial in the development of million volt x-ray tubes, radar, and the first atomic bombs (Preston 2003). Large-scale production began in 1953 with the introduction of SF₆-filled electrical switches and transformers (Ko et al. 1993; Maiss and Brenninkmeijer 1998; Busenberg and Plummer 2000). SF₆ has also been used extensively in oceanic tracer studies and as an inert blanketing gas in the melting and production of magnesium metal (Maiss et al. 1996; Wilson and Mackay 1996; Caplow et al. 2003; Hall et al. 2011; Smith et al. 2011). A natural atmospheric steady-state preindustrial background source of <0.05 pptv has been recognized and is thought to originate from silicate-rich igneous rocks, the mineral fluorite (CaF₂), some natural gases, and ancient groundwater (Maiss et al. 1996; Harnisch et al. 2000; Busenberg and Plummer 2000). These geologic sources can cause elevated levels of SF₆ in some aquifers above atmospheric equilibrium and complicate dating (Busenberg and Plummer 2000; Deeds et al. 2008; von Rohden et al. 2010a). SF₆ is an important dating tracer because, unlike CFCs, it is not known to be susceptible to microbial degradation and it has an estimated atmospheric lifetime between 800 and 3,200 years; thus, atmospheric concentrations are not expected to decrease in the foreseeable future (Ko et al. 1993; Levin et al. 2010).

SF₅CF₃ was first reported in the atmosphere by Sturges et al. (2000) and is entirely of anthropogenic origin. SF₅CF₃ does not have commercial applications and is believed to be a by-product of production of some fluorochemicals (Sturges et al. 2000; Santoro 2000; Erboy and Smethie 2012; Sturges et al. 2012). SF₅CF₃ has been used as a dating tool in groundwater studies (Busenberg and Plummer 2008) and as a tracer in hydrologic studies (Sturges et al. 2000; Ho et al. 2008; Busenberg and Plummer 2010). Samples of air from polar snowpack (“fern”) and archived air show that the atmospheric SF₅CF₃ concentration increased from <0.005 pptv in the 1960s to 0.158 pptv in 2008 after which the SF₅CF₃ concentration plateaued due to changes in fluorochemical production methods (Sturges et al. 2000, 2012; Busenberg and Plummer 2008).

Perfluoroalkanes (C_nF_{2n+2}) and Cyclic Perfluorocarbons

The most abundant PFC in the atmosphere is CF₄. Like SF₆, it has both natural and anthropogenic sources, with a preindustrial steady-state atmospheric concentration of 34 ± 1 pptv. After 1960, the concentration increased to the present concentration of ~80 pptv (AGAGE 2013; Simmonds et al. 2002; Mühle et al. 2010). The next most abundant PFC, C₂F₆, had a preindustrial background concentration of <0.3 and the concentration has increased to ~3.5 pptv as of 2010 (Worton et al. 2007; AGAGE 2013). CF₄ occurs naturally in fluorite minerals and granite (Harnisch et al. 1996, 2000) and is also present in significant concentrations in natural gas and in deep groundwater (Deeds 2008). CF₄ and C₂F₆ are produced at the graphite anodes during Al production (Roberts and Ramsey 2013). C₃ to C₈ perfluorocarbons have been detected in the atmosphere and their concentrations are increasing (Mühle et al. 2010; Ivy et al. 2012).

Perfluorocycloalkanes are very stable compounds and are increasing in the atmosphere (Straume et al. 1998; Watson et al. 2007) and have been successfully used to trace air masses and may be used in future groundwater studies (Watson et al. 2007). They cannot be easily analyzed by GC-ECD, and research into detection approaches using specialized GC mass spectrometry

(GC-MS) and negative chemical ionization mass spectroscopy (GC-NCI-MS) is ongoing (Galdiga and Greibrokk 1997; Simmonds et al. 2002; Miller et al. 2008).

Nitrogen Trifluoride

Prather and Hsu (2008) recognized the potent greenhouse gas NF_3 in the atmosphere, which has a lifetime of 740 years (Prather and Hsu 2008). NF_3 is extensively used in the electronics industry for equipment cleaning, for etching of microcircuits, and in the manufacture of flat-panel displays and thin-film photovoltaic cells (Weiss et al. 2008). The NF_3 concentrations have increased from about 0.02 pptv in 1978 at a rate of 11 % per year to 0.45 in 2008 (Weiss et al. 2008) and may have uses in future hydrologic investigations.

Summary

Anthropogenic atmospheric tracers have been extensively used in hydrologic tracer studies and in groundwater dating studies. CFCs and SF_6 were the most extensively used tracers; however, many other environmental tracers (SF_5CF_3 , CFC-13, PFCs, and HFCs) show potential as dating tools pending development of improved analytical methods. Dating of groundwater using the piston-flow model, lumped-parameter mathematical models, or reactive transport flow models requires the knowledge of recharge conditions (recharge temperature and pressure and vadose zone thickness) and aquifer properties that affect the dissolved tracer concentrations in the sample (adsorption, contamination, degradation).

Dendrochronology, Entomology

Barry Cooke*

Government of Canada, Northern Forestry Centre, Canadian Forest Service, Natural Resources Canada, Edmonton, AB, Canada

Definition

Dendroentomology, a subfield of dendrochronology, documents past occurrence of forest insect outbreaks, and provides an understanding of insect population dynamics, including duration of outbreaks, interval between outbreaks and spread. (Speer 2010)

Dendroentomology is the study of spatiotemporal patterns of herbivory caused by forest insects, based on inferences from (1) the analysis of annually resolved tree-ring data and (2) relatively robust species associations between forest insects and the host-tree tissues that they tend to prefer to consume. See also the definition in Text Box 1.

Introduction

As illustrated in Text Box 1, dendroentomology is related to dendrochronology – which is the use of annually resolved tree rings to date growth anomalies (narrow rings, frost rings, discolored rings, etc.) within woody samples (stems, roots, branches) and to cross-date such anomalies across samples. Dendroentomology is a subfield of dendroecology – which is the use of annually resolved tree rings to accurately date (Stokes and Smiley 1996), and to study, growth anomalies related to ecological factors (including site and species characteristics) that affect tree growth rates. It is distinct from, but not unrelated to, dendroclimatology – which is the use of annually resolved tree rings to date and to study growth anomalies related to climatic events of the past, especially as pertaining to positive and negative anomalies in temperature, precipitation, radiation, etc., which influence tree growth rates (Fritts 1976).

For foliage-grazing insects, such as the defoliating Lepidoptera (caterpillars) or Hymenoptera (sawflies), it is often possible to study negative growth anomalies in extant trees (or coarse woody debris) that are not attributable to climate and to attribute them to a foliage-grazing insect that does not kill its host tree. Because tree growth rings, when properly prepared, are annually resolved, it is often possible to date such impacts with relative accuracy, to the year in which the impact occurred.

Text Box 1 Definitions from Grissino-Mayer’s (2014) “Principles of Dendrochronology”

Henri Grissino-Mayer (2014) provides a definition of dendrochronology that is broadly inclusive:

Dendrochronology: The science that uses tree rings dated to their exact year of formation to analyze temporal and spatial patterns of processes in the physical and cultural sciences.

such that dendroentomology is considered as one of many subfields of dendrochronology:

Subfields of Dendrochronology

- **Dendroarchaeology:** Dating of Archaeological dwellings.
- **Dendroclimatology:** Developing a record of past climate.
- **Dendrogeomorphology:** Dating land movements such as landslides in the past.
- **Dendrohydrology:** Creating a record of past water availability and flooding.
- **Dendroglaciology:** Dating past movements of glaciers.
- **Dendrovolcanology:** Dating the past eruptions of volcanoes.
- **Dendrochemistry:** Using tree rings as a monitor of the chemical makeup of the soil.
- **Dendroecology:** Recording ecological processes such as tree-line movement, insect outbreaks, or movement of invasive tree species.
- **Dendropyrochronology:** Dating the past occurrence of forest fires.
- **Dendroentomology:** The use of tree rings to reconstruct past population levels of insects.
- **Dendromastecology:** The use of tree rings to reconstruct fruiting events in trees

Table 1 Tree-defoliating insects which have been a target of dendroentomological reconstruction of past outbreaks

Host-tree species	Defoliator insect species	Geographic region	Authority
Douglas fir	Western spruce budworm	USA	Swetnam and Lynch (1993)
Eastern larch	Larch sawfly	Canada	Jardon et al. (1994)
European larch	Larch budmoth	Switzerland	Weber (1997)
Ponderosa pine	Pandora moth	USA	Speer et al. (2001)
Trembling aspen	Forest tent caterpillar	Canada	Cooke and Roland (2007)
White spruce	Eastern spruce budworm	Canada	Boulanger et al. (2012)
Douglas fir	Western spruce budworm	Canada	Alfaro et al. (2014)

Applications

Some well-known examples of applications in dendroentomology are provided in Table 1.

For phloem-feeding, fungus-vectoring bark beetles (Coleoptera: Scolytidae), which tend to kill their hosts in order to successfully reproduce, herbivory is inferred not from negative anomalies in annual radial growth, but positive anomalies among surviving trees that did not experience lethal attack (Campbell et al. 2007).

The attributes of tree rings that are used to infer past entomological disturbances may include radial ring width, the ratio of latewood to earlywood, wood density, chemical profiles, and characteristic mis-colorations associated with altered wood chemistry and/or cell structure.

The reconstruction of herbivory events though time is necessarily an imprecise science, as (1) the association between insect species and tree species is typically not strictly one-to-one, but rather several-to-several, where there are several potential herbivore species that might grow to significant numbers on a given tree species, and (2) insect populations, when they rise, do not always grow to devastating levels, and light herbivory will be indistinguishable from background variations that are expected to result from numerous ancillary agents, especially moisture or temperature limitations occurring during the growing season.

Frequently, the study of neighboring tree species that are typically not defoliated by the target insect species of interest will be studied as a “control.” If this control species is not attacked by either the target insect or other insects and if, further, its responses to climatic fluctuations mirror those of the primary host-tree species that is attacked, then the two species will tend to share a common dendroclimatic signal that may be removed by subtraction, thus enhancing the target signal of interest to the dendroentomologist.

Uncertainty in the reconstruction of entomological history includes imprecision in dating accuracy and imprecision in impact calibration. Dating accuracy within a sample is limited by the fact that radial tree growth responses often lag a year and more behind the herbivory event. Dating accuracy across samples is limited by the fact that while climatic influences may be highly correlated across samples, entomological disturbances may or may not be as highly correlated. For example, a spreading epidemic will result in spatial and temporal lags in growth reductions occurring across samples. This hinders the otherwise straightforward procedure of accurately cross-dating samples by “wiggles matching” the high-frequency variations in ring attributes over time (Stokes and Smiley 1996).

Estimating the proportion of sample trees affected during an insect outbreak is sensitive to assumptions about the relationship between insect population density, defoliation levels, and the impact of defoliation on the ring attributes of interest, and in many cases these assumptions are not verified. Outbreak reconstructions therefore typically carry an unknown level of imprecision. A final, irreducible source of imprecision and bias is the fact that historical reconstructions tend to make use of living samples, which are the survivors of previous disturbance events. As the most intensely attacked trees are selectively removed from the extant population available for sampling, the result is an unstably biased reconstruction signal, with an unknown level of bias that grows over time with each disturbance event that removes trees from the sampling population (Cooke et al. 2003).

When insect populations are extremely high, the mortality that occurs, through the creation of gaps in the forest canopy, gives rise to the establishment of a new cohort of seedlings and saplings. Indeed, the mortality that may occur during heavy defoliation events leads to characteristic patterns of cohort development which may be used to supplement inferences about the impact of past outbreaks.

The reconstruction of past herbivory based on tree rings is aided by, but distinct from, the study of insect paleomacrofossils, which are fossilized remnants of insect body parts (e.g., heavily sclerotized mouthparts, head capsules, or wings) or frass (i.e., excrement), which are often taxonomically unique identifiers to the species level. A thick deposit of macrofossils of a particular insect species that is found in an ancient lake or bog may be carbon-dated (within a limited range of accuracy), thus providing corroborating evidence for inferences drawn from tree-ring analysis (Bhiry and Filion 1996; Simard et al. 2006; Brunelle et al. 2008).

Luminescence Dating of Shell-Rich Deposits

Robert Hendricks* and Alex Hodson

School Geography & Earth Sciences, McMaster University, Hamilton, ON, Canada

Synonyms

OSL of anthropological shell middens; OSL of shell mounds; OSL of geological layers rich in shells

Definition

Shell-Rich Deposits. Any stratum composed primarily of shells which consist of either aragonite or calcite biomineral. The remaining materials maybe a complex composition of siliciclastic or carbonate grains with or without carbonate cement.

Introduction to Shell-Rich Deposits and OSL

Although optically stimulated luminescence dating (OSL) and/or infrared stimulated luminescence dating (IRSL) is typically used in environments where the predominant clasts or grains consist of sand-size particles of quartz and feldspars, shell-rich deposits containing these grains can also be dated using this method. These shell-rich deposits can be either of marine or lacustrine origin, or artificial concentrations created by humans. This allows OSL to be used to answer chronologic questions pertaining to geologic processes and features and well as anthropological sites and events. Many studies traditionally obtain chronologic information from shell deposits using radiocarbon (^{14}C), $^{230}\text{Th}/^{234}\text{U}$, and amino acid racemization.

Geological shell deposits are formed when coastal processes concentrate the shells by either winnowing fines or depositing larger shells within a particular portion of the near-shore zone. Examples of these environments include shell lags created as the result of sea-level transgressions and regressions as well as chenier plains formed from tidal action (Rosendahl et al. 2007; Masselink et al. 2011). Determining the age of these deposits can provide important information about the history of coastal processes in a region.

Anthropological concentrations of shells are generally termed shell middens and are common in coastal environments. Shell middens are best defined by Waselkov (1987) as a human created cultural deposit in which the main material constructing the deposit is shells and shell fragments. This loose definition can include deposits of shells discarded by humans in a haphazard manner (i.e., a trash pile) or shells used for a specific purpose, such as the construction of a building or monument. The age of a shell midden can be used to determine the age of artifacts of cultural significance found within the midden. Shell middens are formed from processes completely

*Email: hendricks.robert.r@gmail.com

different from coastal deposits, but differentiating them from natural shell accumulations can be difficult (Rosendahl et al. 2007). For further discussion on the cultural significance and identification of shell middens, readers are referred to Waselkov (1987) and Rosendahl et al. (2007).

While OSL has been used with success in the shallow marine and coastal environments (see Jacobs (2008) for a detailed review), the deposits that are targeted are generally composed of sand. Most studies that endeavor to determine the age of a shell-rich horizon use OSL on sand layers above or below the shell layers (Stone and Cupper 2003; Parker and Goudie 2007; Bateman et al. 2008). However, OSL on quartz sand grains within shell layers has been used with success (Lopez 2007; Thompson et al. 2007; Burdette et al. 2009; Pluckhahn et al. 2014). There has also been a published report of using IRSL to determine the age of feldspar grains from within a shell-rich deposit (Mauz 1999). The dating of sediments with abundant calcite cements commonly referred to “beach rock” (Frechen et al. 2001; Tatum et al. 2003; Frechen et al. 2004) is similar to the dating of shell-rich layers and shares the same challenges with regard to determination of the long-term dose rate.

This article will highlight as a case study in the use of OSL in shell-rich deposits in several anthropological shell middens at the Crystal River Site on the Crystal River in Dixie County, Florida USA. Based on artifactual content and radiocarbon dating, this site experienced human occupation during the Woodland Period from 1000 BC to 1000 AD and includes a number of burial and ceremonial mounds (Thompson and Pluckhahn 2010). The mounds at the Crystal River Site provide an opportunity to compare results of OSL and radiocarbon dating.

Advantages and Disadvantages of Using OSL Relative to Other Geochronologic Methods

The main advantage that OSL has over other methods commonly used to determine the age of shells and shell-rich horizons, such as ^{14}C , ($^{230}\text{Th}/^{234}\text{U}$), and amino acid racemization (AAR), is that it determines the age of a depositional process, not a biological event. This allows for the age of the shell deposit to be determined regardless of the age of the individual shells that compose the deposit. Studies of modern marine shell deposits (Flessa et al. 1993; Wehmiller et al. 1995; Carroll et al. 2003) have shown that the average age of the shells composing these deposits are far from modern. Flessa et al. (1993) discovered that the average shell in their modern study area was approximately 450 years old, with shells over 3.5 ka present. These results are not surprising when considering that these types of deposits represent time-averaged assemblages (Kowalewski 1996). This attribute can prove to be a significant barrier to determining the true age of the depositional process that brought all the shells together. These studies show that any depositional process occurring on a thousand year or smaller time scale might not be resolved by dating of the shells themselves due to the range of shell ages (Flessa et al. 1993).

Radiocarbon

Radiocarbon dating of marine shell requires a carbon reservoir correction in order to account for the age of the inorganic carbon taken up by the shell during growth (see section on [Cross-References](#)). These corrections can be quite large and require information about the conditions where the shell formed. The use of OSL eliminates the uncertainties associated with the estimation of the reservoir effects of a particular location. Studies such as Bateman et al. (2008) have used the combination of

OSL and ^{14}C to highlight the need for further investigation of the reservoir effects of local sites. Dating sand found within a shell deposit can provide independent age control to sites that have had extensive research into the areas local carbon reservoir. Stone and Cupper (2003) also exemplify the usefulness of using OSL when contamination of radiocarbon samples is suspected.

$^{230}\text{Th}/^{234}\text{U}$

The $^{230}\text{Th}/^{234}\text{U}$ dating method uses the ratio of parent (^{234}U)-to-daughter (^{230}Th) isotopes within the uranium decay chain to determine the age of a particular object (see [Cross-References](#)). Mollusks, particularly oyster, are a major component in many shell middens (Waselkov 1987). Unfortunately oysters often exhibit post-burial open-system behavior where parent and daughter isotopes are added or removed through diagenetic processes (Kaufman et al. 1971; Blackwell and Schwarcz 1995; McLaren and Rowe 1996; Edwards et al. 2003; Calsteren and Thomas 2006). This makes oysters difficult to date with U-series. OSL does not rely on isotopic ratios to determine the age of a deposit and can be used on shell deposits that may experience this open-system behavior. However, the open-system behavior can lead to problems with dose-rate determination, because uranium is mobilized through this process.

Amino Acid Racemization (AAR)

AAR dating uses the racemization, or change, of amino acid peptides that occur over time after the death of an organism to determine the time since death (see section on [Cross-References](#)). The rate of the racemization process is dependent on the temperature, pH, and species of the sample. Many of these factors have to be estimated when attempting to determine the age of a sample (Rutter and Blackwell 1995; Wehmiller and Miller 2000; Wehmiller 2012). Due to the many factors associated with the determination of an AAR shell age, this technique often lacks the high resolution needed in many Holocene and Pleistocene geologic and archaeological sites. OSL can provide the independent age confirmation in shell deposits in which one may wish to attempt to use AAR.

Heterogeneity and Uranium Uptake/Loss

OSL requires that the annual radioactive dose rate of the material be known to calculate the age of a sample. In sandy deposits, this is relatively straightforward as sediment is generally homogeneous in composition and radioactive dose within distances that affect the samples. In shell-rich deposits, the larger shells can lead to the formation of heterogeneous radioactive doses to the sample complicating the calculation of the annual dose rate. Furthermore the open-system behavior of oyster shells with respect to uranium can have a significant impact on dose rates through time, leading to larger errors in the age estimation of older shell-rich horizons (Zander et al. 2007; Burdette et al. 2009). While this open-system behavior has been studied (Prescott and Hutton 1995; Olley et al. 1996; Zander et al. 2007), more research specific to OSL dose rates in shell-rich deposits is needed.

Obtaining and Isolating Quartz

There are some specific problems with sample collection and preparation. Unlike sand deposits, the large shells or dense shell concentrations can make it difficult to collect a sample using a sample tube or core. To overcome this problem, a sample taken by hand at night maybe necessary. Samples of a shell-rich deposit may also need to contain more material than a bulk sample from a sand-rich environment so that enough quartz can be collected. After the sample is prepared, it generally yields only a very small amount of pure quartz. Quartz sand will adhere to shells, and a gentle agitation maybe required to separate quartz from the larger shells (brushing the sand off works well). The sieved fraction needs some special care because its high calcium carbonate fraction causes a vigorous reaction at the beginning of the acid dissolution step and may require several repeat dissolutions to isolate the non-carbonate fraction.

Case Study of Crystal River

Crystal River and Roberts Island are neighboring archaeological sites. Of the many mounds present, three mounds were studied. One composed of about 98 % whole oyster shells (Roberts Mound) and two constructed of sand with few shell fragments (Mounds A and H). Radiocarbon dates obtained from Roberts Mound as well as other artifacts at the site provide general age control and make the site an excellent opportunity to use OSL on a shell-rich deposit and compare it to the results of sand-rich deposits (Pluckhahn et al. [2014](#)).

Vertical push-core samples were taken from the sandy Mounds A and H, while a sample collected by hand at night was collected at Roberts Mound. A Harwell gamma spectrometer was used in vertical holes to determine the annual gamma dose rates in Roberts Mound to try to avoid any homogeneity in dose rate that might have been present. Less than about 2 % of the total materials in the mound were sediment, the remainder being air space and oyster shell. In Roberts Mound, the beta dose rate (reconstructed from uranium, thorium, and potassium concentrations) of the sediment and the beta dose rate contributed by the shells were calculated separately. The shell beta dose rate proved clearly more appropriate, as using the sediment itself to calculate this leads to major underestimates of the age based on radiocarbon dating. Moreover, the results of these calculations showed that the shells contributed less than 10 % of the total annual dose compared to the dose sourced from the sediment and cosmic radiation sources (Pluckhahn et al. [2014](#)). It was also found that the oyster shell beta plus gamma dose rate comprised only 50–60 micrograys per year, which was only about 20–25 % of the total dose rate to the quartz grains (the remainder coming from cosmic rays). To a large extent, this ameliorates any affects associated with changing dose rate in the shells due to uranium uptake or loss during open-system behavior at Roberts Mound. However, this is only the case for sites where shell makes up such a large proportion of the buried material.

Results of the OSL analysis of Roberts Mound correlate well with radiocarbon ages from the mound. At the Crystal River site, OSL ages of Mounds A and H showed some significant age inversions, but a minimum age model in other samples yielded agreement with radiocarbon ages. This latter result is best explained by incomplete bleaching of the sand during the construction of Mounds A and H (Pluckhahn et al. [2014](#)), which were ceremonial in nature.

Summary and Conclusions

OSL is not dependent upon dating biological processes, thus having obvious advantages in some cases over radiocarbon, $^{230}\text{Th}/^{234}\text{U}$, and AAR in the dating of shell-rich deposits. It can provide direct determination of a depositional event and enclosing of archaeological materials, eliminating some of the possibilities of age mixing and allowing for better resolution within Holocene deposits. The main challenges of using OSL within shell-rich horizons include open-system behavior affecting dose rates, and in sandy ceremonial mounds, there is a considerable possibility of incomplete zeroing as sand was poured onto the mound surface during construction.

Uranium–Lead Dating, Opal

Leonid Neymark*

US Geological Survey, Denver, CO, USA

Synonyms

U–Pb dating of opal; Uranium–lead ages of opaline silica

Definitions

Uranium–lead dating. A geochronological method that uses final decay products in the ^{238}U and ^{235}U radioactive decay chains to determine the length of time required to accumulate present amounts of stable daughter isotopes ^{206}Pb and ^{207}Pb , respectively.

Opaline silica (opal). A hydrated amorphous form of silica ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) that commonly contains between 6 % and 10 % water by weight. It precipitates from silica-saturated aqueous solutions at relatively low temperature on or near the surface of the Earth.

Mineralogy and U–Th–Pb Geochemistry of Opal

Due to its amorphous nature, opal is categorized as a mineraloid (Jones and Segnit 1971; Smith 1998), unlike other crystalline forms of silica (e.g., quartz, cristobalite, and tridymite) which are classified as minerals. Opal typically occurs near the Earth's surface where it is deposited in the voids from silica-saturated circulating waters at relatively low temperatures. It is most common in volcanic rocks where volcanic glass is a source of water-soluble silica. Opal also forms in hot-spring mounds and may be a major constituent in petrified wood and other fossil organic substances. As a secondary material, it can replace preexisting minerals such as calcite. Evidence for the opaline silica in young deposits on Mars has been reported (Milliken et al. 2008).

Amorphous opal (called opal-A) forms from maturing silica gel and contains nonstructural water ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$). Water contents can reach 10 % and tend to decrease with increasing crystallinity. Subsequent crystallographic ordering and transformations, such as opal-A $\rightarrow$ opal-CT (cristobalite–tridymite) $\rightarrow$ chalcedony (microcrystalline quartz), may be caused by changes in thermal conditions and aging of opal (Kano 1983; Thiry and Millot 1987; Herdianita et al. 2000), although chalcedony also may precipitate directly from solutions at relatively low temperatures ($<100^\circ\text{C}$) (Heaney 1993).

Hydrogenic (water-laid) opal precipitated from oxidizing, near-neutral pH groundwater scavenges U and becomes substantially enriched in U relative to Th and Pb, both of which are much less soluble than U^{+6} under these conditions (Langmuir 1978; Bourdon et al. 2003; Gaillardet et al. 2003). Gaillou et al. (2008) report U concentrations in opals from different continents ranging from

*Email: lneymark@usgs.gov

Fig. 1 Simplified ^{238}U and ^{235}U radioactive decay series (Modified from Bourdon et al. 2003)

<0.1 to 131 ppm. Larger U concentrations, up to thousands of ppm, have been reported for common opals from the USA (Ludwig et al. 1980; Neymark and Paces 2000; Neymark et al. 2000; Amelin and Back 2006; Paces et al. 2010). Amelin and Back (2006) observed that most common opal samples they analyzed are enriched in U relative to average upper crust, whereas all other measured elements are depleted. In contrast, precious opals are not enriched in uranium and their crust-normalized U abundances were similar to crust-normalized REE abundances in the same samples. In common opals, measured $^{238}\text{U}/^{204}\text{Pb}$ values range between about 41,000 and 8,700,000, whereas in precious opals these ratios were much lower (1.9–15.2). All of these observations indicate that common opal can be a promising U–Pb geochronometer, whereas precious opals probably are not suitable for U–Pb dating.

Because amorphous opal-A forms from maturing silica gel precipitated from water (Ludwig et al. 1980; Zielinski 1980), its U–Pb age would reflect the time when the redistribution and migration of dissolved ions terminated within the precipitating solid phase. This is probably very close to the time of the silica gel deposition, assuming closed-system behavior from that time until the present. However, subsequent crystallographic ordering and transformations (possibly due to thermal conditions and aging) may complicate the exact meaning of U–Pb ages of opal containing some crystalline silica.

Fig. 2 Concordia diagrams for the case of initial radioactive disequilibrium in U decay chains showing TIMS data for opal from fracture coatings in the vadose zone at Yucca Mountain, Nevada (Modified from Neymark et al. 2000). (a) Common-lead-corrected $^{206}\text{Pb}^*/^{238}\text{U}$ and $^{207}\text{Pb}^*/^{235}\text{U}$ ratios for opal samples from *outer* portions of the coatings. (b) Opal and chalcedony samples from deeper layers in the coatings. Data in (a) and (b) are plotted with a series of Concordia curves corresponding to different $^{234}\text{U}/^{238}\text{U}$ initial activity ratios (U_i). U–Pb isotope data are shown as 2σ error ellipses. Higher common-lead correction in some samples causes large uncertainties in $^{207}\text{Pb}^*/^{235}\text{U}$ ratios and results in near zero error correlation. The distribution of the data indicates a range of U_i values from ~2 to >10. Isochrons are shown as vertical *dotted lines* connecting points of equal age on the Concordia curves. These isochrons are labeled in thousands or millions of years (ka and Ma, respectively). (c) $^{234}\text{U}/^{238}\text{U}$ AR– $^{206}\text{Pb}^*/^{238}\text{U}$ and (d) $^{230}\text{Th}/^{238}\text{U}$ AR– $^{206}\text{Pb}^*/^{238}\text{U}$ Concordia diagrams for young opal samples showing U-series disequilibrium. U–Pb isotope data are shown as 2σ error ellipses if larger than symbol size. Families of evolution curves corresponding to different U_i values and isochrons connecting points of equal age are shown

The first U–Pb dating of uraniferous opals (from Spor Mountain, Utah; Ludwig et al. 1980) showed that such material is suitable for geochronologic purposes. Subsequent studies (Neymark et al. 2000, 2002; Amelin and Back 2006; Nemchin et al. 2006; Neymark and Paces 2013) have expanded the knowledge base and refined the techniques for interpretation of opal geochronology.

U–Pb Dating of Opal and Initial Radioactive Disequilibrium

Common-Pb-corrected $^{206}\text{Pb}^*/^{238}\text{U}$ and $^{207}\text{Pb}^*/^{235}\text{U}$ ratios yield two independent apparent ages for the same material based on the two different radioactive parent isotopes (Faure 1986).

Concordance of ages between these two systems is an important check for closed-system behavior with regard to gains or losses of uranium and its daughter nuclides. The conventional method of calculating U–Pb isotope ages assumes that all intermediate daughter isotopes in ^{238}U and ^{235}U decay chains (Fig. 1) were in secular equilibrium at the time of opal formation (i.e., radioactivity of all daughter isotopes was equal to that of the parent). This condition is not fully accomplished for most natural systems because of differences in geochemical behavior of parent and daughter elements (e.g., U, Th, Pa, Ac, and Ra). For example, ^{234}U (intermediate daughter isotope of ^{238}U , Fig. 1) enters solutions preferentially during water–rock interaction due to several decay-related mechanisms such as direct α -recoil of its short-lived parent ^{234}Th (Kigoshi 1971), leaching from damaged sites in crystalline lattice (Szilard–Chalmers effect), and increased aqueous mobility due to radiation-induced oxidation of ^{234}U to the +6 valent state (Gascoyne 1992). As a result, natural waters typically are ^{234}U -enriched with $^{234}\text{U}/^{238}\text{U}$ activity ratio (AR) > 1 (Porcelli 2008 and references therein). Hydrogenic opal inherits this ^{234}U enrichment, which causes its conventional $^{206}\text{Pb}^*/^{238}\text{U}$ ages to be biased to older values. This bias is partially compensated by the initial deficit of ^{230}Th (daughter isotope of ^{234}U , Fig. 1), which is not mobile in groundwater. For example, if an opal sample has a measured $^{206}\text{Pb}^*/^{238}\text{U}$ value of 0.0002, its conventional $^{206}\text{Pb}^*/^{238}\text{U}$ equilibrium age is 1.29 Ma, but in a case of no initial ^{230}Th , its true age will be 1.40 Ma, causing an age bias of –0.11 Ma. The age bias for the same sample is about –0.09 Ma if the initial $^{234}\text{U}/^{238}\text{U}$ AR = 1.6, but the effect of larger ^{234}U excess is much more significant and reaches +0.8 Ma for initial $^{234}\text{U}/^{238}\text{U}$ AR = 5.0. Similarly, conventional $^{207}\text{Pb}^*/^{235}\text{U}$ ages of opal may be biased to younger values due to initial deficit of ^{231}Pa (intermediate daughter isotope of ^{235}U , Fig. 1), which is also poorly soluble in groundwater. The maximum bias in opal $^{207}\text{Pb}^*/^{235}\text{U}$ age is –0.046 Ma in the case of zero initial ^{231}Pa .

In order to calculate U–Pb opal ages, it is necessary to use more general forms of age equations that take into account initial radioactive disequilibria of the uranium daughters (Bateman 1910; Ludwig 1977; Catchen 1984; Wendt and Carl 1985; Neymark et al. 2000) instead of conventional U–Pb age equations (Faure 1986).

Neymark et al. (2000) introduced two new Concordia plots ($^{234}\text{U}/^{238}\text{U}$ AR vs $^{206}\text{Pb}^*/^{238}\text{U}$ and $^{230}\text{Th}/^{238}\text{U}$ AR vs $^{206}\text{Pb}^*/^{238}\text{U}$) (Fig. 2c, d), which are applicable to young opals (<2 Ma) with measured ^{234}U and ^{230}Th disequilibrium. The combination of the U–Pb and U-series geochronometers provides new opportunities for dating young opals as long as the condition of severe initial radioactive disequilibrium is addressed. The use of the combined ^{238}U – ^{234}U – ^{230}Th – ^{206}Pb technique to date Quaternary opals significantly extends the age range beyond that of the $^{230}\text{Th}/\text{U}$ dating method from <500 ka to >1.5 Ma.

U–Pb Dating of Vadose Zone Hyalitic Opal by TIMS

The need to understand the history of water movement through the unsaturated (vadose) zone at Yucca Mountain, Nevada, considered as a possible repository for high-level nuclear waste, prompted substantial dating efforts of secondary opals in fractures and lithophysal cavities within Tertiary tuffs. This opal preserves a record of paleohydrologic conditions at this site; the U–Th–Pb isotopic systems within opal were studied using thermal ionization mass spectrometry (TIMS) in submillimeter-thick outermost layers (Neymark et al. 2000) and in deeper layers of opal and chalcedony (Neymark et al. 2002) from individual mm- to cm-thick calcite and silica coatings. These samples were collected at depths from ~0 to ~350 m below Earth's surface from the walls of an 8 km long and 7.6 m diameter tunnel, excavated beneath Yucca Mountain to the level of the

Fig. 3 Locations of opal (green) and chalcedony (brown) subsamples from a mineral coating (sample HD2019, Yucca Mountain, Nevada). TIMS $^{207}\text{Pb}^*/^{235}\text{U}$ ages with 2σ errors in Ma (Modified from Neymark et al. 2003). Opal glows bright green under the short-wavelength UV illumination due to its elevated uranium content

possible repository. The U–Pb ages of the youngest opal from the outermost surfaces of the coatings displayed strong reverse discordance ($^{206}\text{Pb}^*/^{238}\text{U}$ age $>$ $^{207}\text{Pb}^*/^{235}\text{U}$ age, Fig. 2a) because of excess radiogenic $^{206}\text{Pb}^*$ derived from the elevated initial ^{234}U . The data were best interpreted using Concordia diagrams defined by $^{206}\text{Pb}^*/^{238}\text{U}$, $^{234}\text{U}/^{238}\text{U}$ AR, and $^{230}\text{Th}/^{238}\text{U}$ AR (Fig. 2c, d). Ages and initial $^{234}\text{U}/^{238}\text{U}$ AR calculated using different Concordias are discordant, that is, observed $^{207}\text{Pb}^*/^{235}\text{U}$ ages of 170–1,772 ka were systematically older than $^{230}\text{Th}/\text{U}$ ages of 34.1–452 ka. In these cases, the age discordance was not interpreted as a result of initial disequilibrium or as mobility of uranium and its decay products under the open system conditions, but rather as a consequence of non-instantaneous growth of opal. Combined U–Pb and $^{230}\text{Th}/\text{U}$ ages support the model of slow mineral deposition (Neymark and Paces 2000) at the rates of millimeters per million years, resulting in layering on a scale too fine for mechanical sampling. In this case, U–Pb ages provided more accurate estimates of the average age for mixed multiage samples than $^{230}\text{Th}/\text{U}$ ages, because ages based on shorter-lived isotopes are nonlinearly biased by younger mineral additions (Neymark et al. 2000).

Uranium and Pb isotopes were also analyzed in deeper layers of opal and chalcedony from individual mm- to cm-thick calcite and silica coatings at Yucca Mountain (Neymark et al. 2002). These opal and chalcedony samples had high U (10–780 ppm) and low common Pb indicated by their large $^{206}\text{Pb}/^{204}\text{Pb}$ values, thus making them suitable for U–Pb age determinations. Similar to U–Pb ages of surface coatings, reverse discordance was also observed for opals from deeper layers within the coatings (Fig. 2b). This opal is sufficiently old to allow nearly all of its initial excess ^{234}U to decay, thus making it difficult to correct for potential bias in $^{206}\text{Pb}^*/^{238}\text{U}$ ages. However, because the $^{207}\text{Pb}^*/^{235}\text{U}$ ages, between 0.6 and 9.8 Ma, are much less affected by the deviation from initial secular equilibrium, they were interpreted as more reliable ages of most silica deposits. Some chalcedony subsamples showed normal age discordance ($^{206}\text{Pb}^*/^{238}\text{U}$ age $<$ $^{207}\text{Pb}^*/^{235}\text{U}$ age, Fig. 2b), so that these ages may represent minimum times of chalcedony formation. Typically, $^{207}\text{Pb}^*/^{235}\text{U}$ ages are consistent with the microstratigraphy of the coatings (Fig. 3), such that the ages increase with increasing depth of the samples. ^{234}U and ^{230}Th in most silica layers deeper in the coatings are in secular equilibrium with ^{238}U (Neymark et al. 2002, 2003), which is consistent with their old age and closed-system behavior during the past ~ 0.5 Ma.

Neymark and Amelin (2008) reported a range of Yucca Mountain opal/chalcedony $^{207}\text{Pb}^*/^{235}\text{U}$ ages from 132.9 ± 8.0 ka to 9.10 ± 0.21 Ma. The ages increased with microstratigraphic depth within coatings and defined slow long-term average growth rates of about 1.2–2 mm/Ma, in good agreement with previous results. These authors concluded that the presence of intermediate daughter isotopes did not appreciably impact the $^{207}\text{Pb}^*/^{235}\text{U}$ ages of opal/chalcedony, which were interpreted as mineral formation ages.

The $^{207}\text{Pb}^*/^{235}\text{U}$ ages of opal and chalcedony intercalated with low-U calcite containing two-phase fluid inclusions were used to constrain timing of fluids with elevated temperatures in the vadose zone at Yucca Mountain (Neymark et al. 2001; Wilson et al. 2003; Whelan et al. 2008). Most $^{207}\text{Pb}^*/^{235}\text{U}$ ages of opal/chalcedony from layers above the calcite that formed at temperatures >30 °C are older than 6–8 Ma. Whelan et al. (2008) interpreted combined opal/chalcedony U–Pb dating and calcite fluid inclusion data as evidence of slow cooling of ~ 13 Ma tuffs within the vadose zone. Wilson et al. (2003) concluded that the results of integrated U–Pb dating of opal/chalcedony and fluid inclusion microthermometry indicate that two-phase fluid inclusion assemblages that trapped fluids of >50 °C are older than ~ 6.3 Ma. Two-phase inclusions in paragenetically later calcite, which formed from fluids of 35–45 °C, are older than ~ 5.3 Ma, and there is no evidence for trapping of fluids with elevated temperatures during the past 5.3 Ma. These data indicate that fluids with elevated temperatures have not been present in the vadose zone at Yucca Mountain since 6–8 Ma.

U–Pb Dating of Opal by SIMS

Several studies (Paces et al. 2001, 2004, 2010) have shown that opal may be finely laminated with growth bands having variable U concentrations and ages. This heterogeneity reflects the time sequence of silica deposition in slow-growing opal and requires high spatial resolution of sampling to minimize the effects of analyzing mixed samples from multiple growth bands (Neymark and Paces 2000; Paces et al. 2001). These studies used TIMS analyses of U, Th, and Pb chemically separated from opal samples of a few to tens of milligrams. Neymark et al. (2000) noted that the relatively large samples used in TIMS-based studies may contain multiple growth zones, producing mixed ages. These ages showed a consistently discordant pattern between $^{230}\text{Th}/^{238}\text{U}$ ages, $^{234}\text{U}/^{238}\text{U}$ model ages, and $^{207}\text{Pb}^*/^{235}\text{U}$ ages and thus required high spatial resolution of sampling. This high sampling resolution can be achieved by in situ dating of opal using the secondary ion mass spectrometry (SIMS), which allows dating of 30- μm -diameter spots on polished opal cross sections.

In situ U–Pb analysis of opal by SIMS or by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) requires a reference opal that has been well characterized by TIMS. This opal must have limited variations in U concentration, low common-Pb abundance, and concordant U–Pb ages to be used as a matrix-matching standard. Amelin and Back (2006) reported structural, geochemical, and TIMS U–Th–Pb and U-series isotopic data for eight samples of precious and common opal, which they tested as potential standards for ion microprobe and LA-ICP-MS isotopic studies. Nemchin et al. (2006) reported the first U–Pb analyses of colorless uraniferous opal from Yucca Mountain, Nevada; Hosszu Hill, Hungary; and Guanajuato, Mexico, using sensitive high-resolution ion microprobe (SHRIMP II). These authors used one of the opals from Amelin and Back (2006) study (sample M21277 from Virgin Valley, Nevada) as a standard and demonstrated the potential of this technique for dating of opal with ages ranging from several tens of thousands years to millions of years. In addition to the high spatial resolution of SHRIMP

analysis, other advantages of the SIMS technique are the following: (1) the ability to analyze in situ all isotopes required to determine both U–Pb and U-series ages, (2) a relatively short analysis time which allows determining the history of opal growth during a single SHRIMP session, and (3) the relatively nondestructive analysis which enables subsequent imaging of the dated samples to aid in interpretation. Nemchin et al. (2013) also emphasized the role of in situ SIMS opal analysis in establishing growth rates of this slowly forming material.

U–Pb Dating of Authigenic and Detrital Opal

The use of the TIMS and SIMS U–Pb dating to establish the age of Neogene–Quaternary clastic sediments was tested on samples of authigenic (formed in situ) and detrital (derived from weathering of the source rocks) opal and chalcedony from boreholes at Midway Valley, Nevada (Neymark and Paces 2013). Dating of authigenic opal that occurs as rinds on rock clasts and in calcite/silica cements establishes minimum ages of alluvium deposition; dating of detrital opal or chalcedony gives the maximum age of sediment deposition.

Large U concentrations (tens to hundreds of ppm) and high U/Pb allowed calculation of $^{206}\text{Pb}^*/^{238}\text{U}$ ages that ranged from 1.64 to 6.16 Ma for authigenic opal and from 8.34 to 11.2 Ma for detrital opal/chalcedony. Samples with the most radiogenic Pb allowed calculation of $^{207}\text{Pb}^*/^{235}\text{U}$ ages, which were concordant with $^{206}\text{Pb}^*/^{238}\text{U}$ ages from the same samples. These ages resulted in the determination of constraints for the timing of the basin development, the rate of erosion of Yucca Mountain, and the last movement on buried faults (Neymark and Paces 2013).

Conclusions

Opal is a hydrogenic mineraloid typically precipitated from silica-saturated solutions near the Earth's surface. Common opal deposited from low-temperature oxidizing groundwater may contain high U concentrations with little or no initial ^{206}Pb and ^{207}Pb , making it a promising candidate for U–Pb dating method. Opal can retain U decay products for long periods of time (>1 Ma) even after some crystallographic ordering and transformation. Samples of slow-growing opal may contain multiage growth zones, thus requiring the use of high spatial resolution in situ analyses for dating. Initial radioactive disequilibrium (^{234}U excess and ^{230}Th deficit) can complicate interpretations of ^{238}U – ^{206}Pb dating results but can be taken into account by combining U-series and U–Pb methodologies for opal samples younger than ~2 Ma. The ^{235}U – ^{207}Pb decay scheme gives more accurate age estimates for older opal samples.

Definition

The radioactive decay constant (λ) is a characteristic of unstable radionuclides (see chart of the nuclides) that spontaneously decay at different rates to a more stable atomic configuration; the larger the decay constant, the more rapidly the parent radionuclide is depleted with time. The basic formulation of the radioactive decay equation is based on the principle that the number of decay events of any radioactive parent atom is proportional to the number of these atoms present at any given time (Rutherford and Soddy 1902). This basic principle has been transformed into the law of radioactive decay $N = N_0 e^{-\lambda t}$, which states that given an initial number N_0 of radioactive parent nuclei at start time $t = 0$, the number of radioactive nuclei remaining at time t is given by N . Related to the decay constant is the half-life $t_{1/2}$ of a radioactive nucleus: $t_{1/2} = \ln 2/\lambda$. The half-life is the time in which half the number of parent nuclides have decayed.

Introduction

The determination of decay constants and/or corresponding half-lives of radionuclides is a fundamental aspect of geochronologic methods. A wide range of scientific questions can be addressed with dating techniques. A variety of questions can be addressed using dating methods. These range from the age of archaeological materials and human fossils to the age of the oldest materials in our solar system and many geological processes on earth.

The process of radioactive decay proceeds through two main mechanisms: (1) α -decay, which is alpha particle emission (two protons plus two neutrons) from the nucleus, and (2) β -decay, when a nucleus emits an electron or positron. The accuracy and precision of the decay constant measurements are a determinant in the accuracy and precision of the age result. Progress in this area for long-lived radioactive nuclides in part depends on the difficulty in directly measuring the decay events and the range in mass and energy of the different particles emitted during decay. As better methods become available to determine the decay constants for the various methods, more accurate and precise values become available.

Approaches to Determining Decay Constants

There are essentially three different approaches used to determine the decay constant of long-lived radionuclides: (1) direct counting techniques, (2) age comparison of geological materials using multiple dating techniques, and (3) the in-growth method. The direct counting technique involves directly measuring the alpha, beta, or gamma activity, commonly using liquid scintillation counting

Table 1 Summary of ^{87}Rb decay constant determinations

Reference	Year	$T_{1/2}(10^{10} \text{ a})$	$\lambda (10^{-11} \text{ a}^{-1})$
Age comparisons			
Aldrich et al.	1956	5.0 ± 0.2	1.39 ± 0.06
Steiger and Jäger	1977	4.88 ± 0.03	1.420 ± 0.010
Minster et al.	1982	4.94 ± 0.03	1.402 ± 0.008
Shih et al.	1985	4.94 ± 0.04	1.402 ± 0.011
Amelin and Zaitsev	2002		1.396 ± 0.006
Nebel et al.	2011		1.393 ± 0.004
Absolute counting experiments			
Flynn and Glendenin	1959	4.70 ± 0.10	1.475 ± 0.031
Neumann and Huster	1976	4.88 ± 0.06	1.420 ± 0.030
Kossert	2003	4.967 ± 0.032	1.396 ± 0.009
Ingrowth experiments			
McMullen et al.	1966	4.72 ± 0.04	1.468 ± 0.012
Davis et al.	1977	4.89 ± 0.04	1.419 ± 0.012
Rotenberg et al.	2012	4.9624 ± 0.0065	1.3968 ± 0.0017

Modified after Begemann et al. (2001)

for beta emitters, and dividing by the total number of radiogenic atoms present (e.g., Neumann and Huster 1976; Kossert 2003). The age comparison approach involves selecting relatively simple geological materials and determining their age using multiple dating techniques where the decay constant for the parent isotope in one dating system (e.g., ^{238}U) is considered to be well established and accurate (e.g., Amelin and Zaitsev 2002). The in-growth method involves storing a quantity of purified radioactive parent in a closed container, and after a period of time (typically years to decades), the quantity of daughter isotope is determined using isotope dilution (e.g., Rotenberg et al. 2012).

Tabulations

The strengths and weaknesses of each approach to determinations of decay constants or half-lives are nicely summarized by Begemann et al. (2001), and the range of decay constant values obtained for ^{87}Rb using all three methods are summarized in Table 1. An important aspect of these decay constant determinations is that with improved detection systems and more robust in-growth experiments, there is convergence and general agreement between all three methods for the value of the ^{87}Rb decay constant.

Here, we report on the most recent determinations of the values relevant to geochronology (Table 2). The values are given as either the decay constant with uncertainty or the half-life with uncertainty. The published reported value is shown in bold; the other is calculated from it. Emphasis here was given to reporting not only the values but the research works that actually made the most recent determinations alongside those which have remained in current use for long periods of time. All of the values reported in the tables are revisions of earlier determinations with the exception of Libby 1952. We note that more than half of the values in the table have been reported since 2000. Table 2 is for reference and not meant as a tabulation of “recommended values” for use. Rather, we aim to provide the most up-to-date compilation of the values and let geochronologists themselves decide if the revised values are to become routinely used in practice.

Table 2 Radioactive decay constants and half-lives for selected radionuclides in current use in geochronology

Nuclide	Daughter	Decay constant (a^{-1})	Half-life (a)	Reference	Note
Cosmogenic					
^{10}Be	^{10}B	$(4.997 \pm 0.043) \times 10^{-07}$	$(1.387 \pm 0.012) \times 10^6$	Korschinek et al. 2010	
^{14}N	^{14}C	$(1.2448 \pm 0.0067) \times 10^{-04}$	5568 ± 30	Libby 1952	a
		$(1.2097 \pm 0.0084) \times 10^{-04}$	5730 ± 40	Godwin 1962	b

Volcanic Rocks (K–Ar and Ar–Ar)

Ian McDougall*

Research School of Earth Sciences, The Australian National University, Canberra, ACT, Australia

Keywords

K/Ar dating; $^{40}\text{Ar}/^{39}\text{Ar}$ dating; East Africa; Hadar; Hominins; Omo-Turkana Basin

The K/Ar dating scheme, using the conventional K/Ar method, and the closely related $^{40}\text{Ar}/^{39}\text{Ar}$ dating technique, especially the latter, yield numerical ages on igneous rocks that are commonly precise to 1 % or better in the range 0.1 Ma or younger to much older ages (Lee 2014). The younger limit is dependent on detecting radiogenic argon above an atmospheric argon component mainly from the sample itself. The basis for these techniques is described by McDougall (2014) and Lee (2014). The means by which fossils in sedimentary sequences are assigned numerical ages by interpolation between dated volcanically derived beds is illustrated by an example from the hominin-bearing sequence in the Turkana area of East Africa.

Historically, the K/Ar dating method has been of importance in providing age information related to a variety of studies over at least the last five decades, including the delineation and calibration of the geomagnetic polarity time scale, one of the essential foundations for the development of plate tectonic concepts (see McDougall 2013); the numerical calibration of the relative geological time scale, as well as calibration of the evolution of flora and fauna; and the determination of rates of geological processes and the age of individual geological events.

In the $^{40}\text{Ar}/^{39}\text{Ar}$ dating technique, it is the $^{40}\text{Ar}^*/^{39}\text{Ar}_\text{K}$ ratio that needs to be determined (see Lee 2014), and this is derived from the Ar isotopic ratios measured on the argon gas extracted from the sample after irradiation. The equation is listed in McDougall and Harrison (1999, p. 91). McDougall (2014) advocated that the more precise atmospheric argon $^{40}\text{Ar}/^{36}\text{Ar}$ ratio of 298.56 ± 0.31 , given by Lee et al. (2006), be used instead of the recommended Steiger and Jäger (1977) value, derived from Nier (1950), of 295.5, although it makes little practical difference to most calculated ages. It needs to be noted, however, that the latter only applies if all calibrations are done using this newer rather precise value.

The Omo-Turkana Basin Sequence

This stratigraphic sequence, up to 800 m thick, in subaerial exposure, is of significance mainly because of the large number of hominin fossils (>400) that have been recovered over the last five decades by the Leakeys (Leakey and Leakey 1978; Leakey et al. 1998; Feibel et al. 1989; Wood 1991), providing a remarkable picture of the complexity of evolution of hominins. Specimens assigned to *Australopithecus anamensis*, *A. aethiopicus*, *A. africanus*, *A. boisei*, *Kenyanthropus platyops*, *Homo habilis*, *H. rudolfensis*, *H. erectus*, and *H. sapiens* have been recorded (Wood 1991;

*Email: Ian.McDougall@anu.edu.au

McDougall et al. 2012, etc.). Many other vertebrate fossils have been collected and described from which much information on evolution of genera has been obtained (Harris 1983).

The Omo-Turkana Basin in northern Kenya and southern Ethiopia comprises the depositional environment around the present-day closed basin of Lake Turkana (Fig. 1). Much of the sedimentary material deposited in the basin was brought in by the Omo River, which drains part of the Ethiopian highlands. The basin extends at least 350 km N-S and up to 90 km E-W (Fig. 1) and lies within the East African Rift system where the NNE-SSW trending Ethiopian Rift intersects the N-S trending Kenya Rift. Initially it was thought that the various regions mapped comprised separate depocenters, which is reflected in the stratigraphic nomenclature.

The detrital sediments themselves are not particularly useful for correlation as there are major facies variations from fluvial to deltaic and lacustrine deposits over short distances. Tephra or tuffaceous sediments, usually named as tuffs, with their distinctive elemental signatures of the contained volcanic glass, however, have been the key to stratigraphical correlations from area to area. Chemical analysis of glass shards in these tuffs has shown that some are widespread (Brown et al. 2006), and it has become increasingly obvious that the sediments of the Omo-Turkana Basin are all part of a single depositional system. Some tuffs locally contain pumice clasts, which usually have glass of the same composition as the enclosing tuff, indicating derivation from the same volcanic eruption. The pumice clasts commonly have alkali feldspar (anorthoclase) phenocrysts, which are ideal for isotopic dating by the K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods. The tuffs have facilitated correlations throughout the basin, and some have been isotopically dated, from which a numerical time framework has been developed. Over the last several decades, more than 35 units in the Omo-Turkana Basin have been dated, with most now having been measured using single-crystal $^{40}\text{Ar}/^{39}\text{Ar}$ total fusion techniques (McDougall and Brown 2006, 2008; McDougall et al. 2012). Virtually all these ages are consistent with the stratigraphic order, indicating that the ages not only record the time of eruption but also that deposition occurred very shortly after eruption. The isotopic dating results already available mean that fossils can usually be assigned ages to better than 0.1 Ma, without further direct dating, provided that the fossils can be placed within the stratigraphic sequence of tuffs.

Alkali feldspar crystals were initially separated in 1978 from pumice clasts in a number of the tuffaceous beds in the Koobi Fora region and K/Ar ages were measured on multigrained samples (McDougall et al. 1980; McDougall 1985, 2014). Subsequently this was followed by $^{40}\text{Ar}/^{39}\text{Ar}$ step heats on selected multigrained samples (McDougall 1981, 1985) and then by multiple single-crystal $^{40}\text{Ar}/^{39}\text{Ar}$ total fusion analyses (McDougall and Brown 2006, 2008; McDougall et al. 2012), yielding essentially concordant results. The fluence monitor used in the earlier step-heating experiments was GA1550 biotite with K/Ar age of 97.9 Ma (McDougall and Roksandic 1974; Steiger and Jäger 1977), although with a revised K content, the K/Ar age is now given as 98.5 ± 0.5 Ma (McDougall and Wellman 2011). The step-heating experiments all yielded essentially flat age spectra, providing increased confidence that the derived ages are those of the igneous eruption and have not been subsequently disturbed (Lee 2014). The single-crystal $^{40}\text{Ar}/^{39}\text{Ar}$ ages are reported versus the Fish Canyon Tuff sanidine (FCs) fluence monitor age of 27.8 Ma, although subsequently we used 28.1 Ma for its age (Spell and McDougall 2003). Figure 2 shows the recent single-crystal results on the alkali feldspars from the volcanic-derived tuffs, and the concordancy of the results with the stratigraphy, younging upward (using the latter age for FCs), is striking.

The ages recorded at Kanapoi, southwest of Lake Turkana, are also on alkali feldspar. These ages were initially reported by Leakey et al. (1995, 1998) and were recalculated by McDougall and Brown (2008) using the slightly greater age of 28.1 Ma for the Fish Canyon Tuff sanidine (FCs) fluence monitor. The significance of these rather precise ages is that many fossil hominins assigned

Fig. 1 Distribution and thickness of Omo Group sedimentary sequences in the Omo-Turkana Basin from interpretation of seismic data and from measured stratigraphic thicknesses. Principal areas of outcrop of the Shungura, Nachukui, and Koobi Fora formations are shown with diagonal shading. Inset shows the location of the map in northeast Africa (Diagram produced by F. H. Brown and published in McDougall et al. (2012))

to *Australopithecus anamensis* were found in this stratigraphic section, mainly below the Kanapoi Tuff, so their age is very tightly controlled between about 4.2 and 4.1 Ma. However, Leakey et al. (1995, 1998) also included hominin fossils of this species from Allia Bay, on the east side of

Fig. 2 Composite stratigraphic sections of the main formations in the Omo-Turkana Basin, together with the results of $^{40}\text{Ar}/^{39}\text{Ar}$ dating of mainly alkali feldspar from pumice clasts within tuffs, where the quoted error is the standard deviation of the population (McDougall and Brown 2006, 2008; McDougall et al. 2012). The main tuffaceous beds are shown, often named, and correlations between the stratigraphic columns are indicated by linking lines (Diagram drawn up by F. H. Brown, slightly modified from that in McDougall et al. (2012)). To the left of the stratigraphic columns for the Koobi Fora and Shungura formations are the measured magnetic polarities, where gray shading represents normal polarity and unshaded indicates reversed polarity. Ages assigned to the polarity boundaries are from Gradstein et al. (2012). For the dating, the Fish Canyon Tuff sanidine fluence monitor was assigned a reference age of 28.1 Ma (Spell and McDougall 2003)

Lake Turkana, where they are shown to be just below the Moiti Tuff, which has been dated at 3.97 ± 0.03 Ma, thus extending the age range for *A. anamensis* significantly.

About 100 km to the north of Lake Turkana, the Kibish Formation was deposited between about 200 ka and nearly the present time (McDougall et al. 2005, 2008; Brown and Fuller 2008). Four members were defined in the Kibish Formation, each reflecting a very high stand of Lake Turkana at the time of deposition, with Members I to III showing evidence of having been deposited in deltaic environments, whereas the youngest member, Member IV, is thought to have been formed as a lake margin deposit, during the Holocene. Each of the members was deposited over very short intervals, with much of the time represented by the disconformities usually evident between members. From Member I several hominin fossils were recovered in the original expedition to the region. Leakey (1969) and Day (1969) described two of these crania as belonging to somewhat archaic *Homo sapiens*. The more recent expeditions to the region confirmed the provenance of these fossils and also were able to $^{40}\text{Ar}/^{39}\text{Ar}$ date alkali feldspar from the Nakaa'kire Tuff from just below the level of Omo II, one of the fossil hominins. The age of the tuff was determined to be 198 ± 14 ka or ± 2 ka, where the latter error quoted is that for the weighted mean age. It was argued by McDougall et al. (2005, 2008) that this age was very close to that of hominin Omo II, because of the deduced rapid deposition of each member and because there was a quite unexpected correlation with deposition of sapropel 7 in the Mediterranean Sea, some 3,000 km to the northwest. The link was that high lake levels required for deposition of the members of the Kibish Formation as delta deposits of the earlier Omo River, some 100 km north of the present Lake Turkana, was brought about by very high rainfall in the Ethiopian Highlands, the source of the Omo River and the Blue Nile, and this resulted in overflow of Lake Turkana across the divide into the White Nile. These very large flows of the Nile River system were implicated in the formation of the sapropels in the Mediterranean Sea (Rossignol-Strick et al. 1982). In Member III of the Kibish Formation occurs the Aliyo Tuff, from which small pumice clasts yielded alkali feldspar crystals that were also dated, yielding a mean age of 104 ± 7 ka (Fig. 2) or ± 1 ka if the error is that of the weighted mean age. This age is consistent with its stratigraphic position and also shows that the hominins Omo I and II are older than this. The age of Omo I and II is regarded as close to 195 ka, the oldest presently known occurrence of *Homo sapiens*.

Results from Afar, Ethiopia

Studies in the Afar region of Ethiopia have been of significance and most helpful in providing age constraints on the many hominin fossils recovered from these sequences that range in age from Miocene to Pleistocene. The sequences have produced a prolific vertebrate fauna, including fossils assigned to a number of hominins; these include *Ardipithecus ramidus* (White et al. 1994, 1995), *Australopithecus afarensis* (Johanson et al. 1978, 1982; Johanson and White 1979), and *Homo sapiens* (White et al. 2003), among others. The sedimentary rocks occur over a wide region, with geological and palaeontological studies concentrated in particular areas. Space does not permit a review of the results (see McDougall 2014), but many hominin species are in the range 5.6–3.1 Ma and younger, through many interbedded volcanically derived tuffs, etc., dated by the $^{40}\text{Ar}/^{39}\text{Ar}$ technique, with ages concordant with the stratigraphic order (Renne et al. 1999; Walter 1994). The *Homo sapiens* at Bouri has an age between about 154 and 160 ka (Clark et al. 2003).

Conclusions

In this contribution, a review of the place of K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating has been made in relation to youthful volcanic rocks and related products and how these results have provided well-constrained ages for a wide range of hominin fossils, especially those recovered from sites in East Africa. In the majority of cases, this has enabled workers to place hominin fossils in an independent time scale, unrelated to the perceived evolutionary stage exhibited by the fossils. It has been stressed that most numerical ages assigned to hominins and other vertebrates are from interpolation between dated igneous-derived samples rather than by directly dating the fossils themselves. Especially with continued development of the $^{40}\text{Ar}/^{39}\text{Ar}$ technique, the results generally have become well accepted by the geological and paleoanthropological community.
